NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher, nor any other party who has been involved in the preparation or publication of this work, warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions, or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

THE COLOR ATLAS OF PEDIATRICS

EDITORS

Richard P. Usatine, MD
Professor of Family and Community Medicine
Professor of Dermatology and Cutaneous Surgery
Assistant Director, Medical Humanities Education
University of Texas Health Science Center at San Antonio
Medical Director, Skin Clinic, University Health System
San Antonio, Texas

Camille Sabella, MD
Associate Professor of Pediatrics
Vice Chair for Education, Pediatric Institute
Center for Pediatric Infectious Diseases
Cleveland Clinic Children's
Cleveland, Ohio

Mindy Ann Smith, MD
Clinical Professor
Department of Family Medicine
Michigan State University
East Lansing, Michigan

E.J. Mayeaux, Jr., MD
Professor and Chairman, Department of Family
and Preventive Medicine
Professor of Obstetrics and Gynecology
University of South Carolina School of Medicine
Columbia, South Carolina

Heidi S. Chumley, MD
Executive Dean and Chief Academic Officer
American University of the Caribbean

Elumalai Appachi, MD, MRCP (UK)
Department of Pediatric Critical Care
Cleveland Clinic Children's
Cleveland, Ohio

This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

DEDICATION

To our patients who unselfishly agreed to let us display their diseases and afflictions to the world to enhance the study and practice of medicine. We are honored by this trust. We have learned much from our patients as they continue to help us teach the next generation of health care providers.

Sincerely,

Richard P. Usatine, MD

CONTENTS

Contributors
Preface
Acknowledgments

PART 1

LEARNING WITH IMAGES AND DIGITAL PHOTOGRAPHY

1 An Atlas to Enhance Patient Care, Learning, and Teaching

PART 2

THE ESSENCE OF PEDIATRICS

2 Doctor—Patient Relationship
3 Patient- and Family-Centered Care
4 The Birth of a Child
5 Pediatric Palliative Care
6 Social Justice
7 Global Health

PART 3

PHYSICAL AND SEXUAL ABUSE

8 Child Physical Abuse
9 Child Sexual Abuse

PART 4

OPHTHALMOLOGY

10 Hordeolum and Chalazion

11 Corneal Foreign Body and Corneal Abrasion
12 Conjunctivitis
13 Uveitis and Iritis
14 Neonatal Nasolacrimal Duct Obstruction
15 Strabismus and Pseudostrabismus
16 Retinoblastoma and the Differential Diagnosis of Leukocoria
17 Preseptal (Periorbital) Cellulitis
18 Orbital Cellulitis
19 Eye Trauma—Hyphema

PART 5

EAR, NOSE, AND THROAT

Section 1: Ear

20 Preauricular Tags
21 Otitis Externa
22 Otitis Media—Acute Otitis and Otitis Media with Effusion
23 Mastoiditis
24 Ear—Foreign Body
25 Nasal Polyps

Section 2: Nose and Sinus

26 Sinusitis
27 Complications of Sinusitis
28 Scarlet Fever and Strawberry Tongue

Section 3: Mouth and Throat

29 Upper Respiratory Infections Including Pharyngitis
30 Acute Upper Airway Obstruction
31 Chronic Upper Airway Obstruction— Laryngomalacia
32 Thyroglossal Duct Cyst and Other Head and Neck Masses

Section 4: Neck

33 Lymphadenopathy
34 Congenital Anomalies of the Head and Neck

PART 6

ORAL HEALTH

35 Geographic Tongue
36 Early Childhood Caries
37 Dental Complications: Hard Tissue (Teeth)
38 Dental Complications—Soft Tissue (Gingiva and Mucosa)
39 Herpes Simplex Virus Gingivostomatitis
40 Aphthous Ulcer

PART 7

THE HEART AND CIRCULATION

41 Clubbing and Cyanosis
42 Acyanotic Congenital Heart Disease
43 Cyanotic Congenital Heart Disease
44 Bacterial Endocarditis
45 Acute Rheumatic Fever
46 Common Dysrhythmias
47 Syndromes Associated with Heart Disease

PART 8

THE LUNGS

48 Bronchiolitis
49 Asthma and Pulmonary Function Testing
50 Community-Acquired Pneumonia
51 Cystic Fibrosis
52 Congenital Pulmonary Malformations

PART 9

THE GASTROINTESTINAL TRACT AND NUTRITIONAL DISORDERS

53 Failure to Thrive
54 Esophageal Disorders: Gastroesophageal Reflux Disease and Eosinophilic Esophagitis
55 Peptic Ulcer Disease
56 Foreign Body Ingestion
57 Pyloric Stenosis
58 Intussusception
59 Inflammatory Bowel Disease
60 Celiac Disease
61 Neonatal Cholestasis
62 Anal and Rectal Disorders
63 Nutritional Disorders in Children

PART 10

THE GENITORURINARY SYSTEM AND KIDNEYS

64 Urinary Sediment/Urinary Tract Infections
65 Hydronephrosis and Ureteropelvic Junction Obstruction
66 Polycystic Kidneys
67 Nephrotic Syndrome
68 Nephritic Syndromes
69 Hemolytic Uremic Syndrome
70 Pediatric Kidney Stones
71 Renovascular Hypertension

PART 11

NEWBORN

72 Neonatal Conjunctivitis
73 Abdominal Wall Defects

PART 12

ADOLESCENT PROBLEMS

74 Overview of Vaginitis
75 Mucosal Ulcerative Disorders in Female Adolescents
76 Bacterial Vaginosis
77 Candida Vulvovaginitis
78 Trichomonas Vaginitis
79 Chlamydia Cervicitis
80 Breast Masses in Adolescents
81 Complications of Tattoos and Piercings

PART 13

MUSCULOSKELETAL PROBLEMS

82 Nursemaid's Elbow
83 Clavicular Fracture
84 Forearm Fractures
85 Metatarsal Fracture
86 Club Feet
87 Developmental Dysplasia of the Hip
88 Legg-Calvé-Perthes
89 Slipped Capital Femoral Epiphysis (SCFE)
90 Osgood-Schlatter
91 Scoliosis

PART 14

DERMATOLOGY

Section 1: Early Childhood Dermatology

92 Normal Skin Changes of Infancy
93 Childhood Hemangiomas and Vascular Malformations
94 Pustular Diseases of Early Childhood
95 Diaper Rash and Perianal Dermatitis

Section 2: Acneiform Disorders

96 Acne Vulgaris

97 Rosacea
98 Hidradenitis Suppurativa

Section 3: Bacterial

99 Impetigo
100 Folliculitis
101 Pitted Keratolysis
102 Erythrasma
103 Cellulitis
104 Abscess
105 Staphylococcal Scalded Skin Syndrome
106 Necrotizing Fasciitis
107 Ecthyma Gangrenosum

Section 4: Viral

108 Varicella
109 Herpes Zoster
110 Zoster Ophthalmicus
111 Measles
112 Fifth Disease
113 Hand Foot Mouth Syndrome
114 Herpes Simplex
115 Molluscum Contagiosum
116 Common Warts
117 Flat Warts
118 Genital Warts
119 Plantar Warts

Section 5: Fungal

120 Fungal Overview
121 Candidiasis
122 Tinea Capitis
123 Tinea Corporis
124 Tinea Cruris

125 Tinea Pedis
126 Tinea Versicolor

Section 6: Infestations

127 Lice
128 Scabies
129 Cutaneous Larva Migrans

Section 7: Dermatitis/Allergic

130 Atopic Dermatitis
131 Contact Dermatitis
132 Eczema Herpeticum
133 Nummular Eczema
134 Urticaria and Angioedema

Section 8: Papulosquamous Conditions

135 Seborrheic Dermatitis
136 Psoriasis
137 Pityriasis Rosea
138 Lichen Planus
139 Lichen Nitidus and Lichen Striatus

Section 9: Benign Neoplasms

140 Juvenile Xanthogranuloma
141 Keloids
142 Pyogenic Granuloma

Section 10: Nevi and Melanoma

143 Benign Nevi
144 Congenital Nevi
145 Epidermal Nevi and Nevus Sebaceous
146 Dysplastic Nevus
147 Pediatric Melanoma

Section 11: Infiltrative Immunologic

148 Granuloma Annulare
149 Pyoderma Gangrenosum

150 Pediatric Sarcoidosis

Section 12: Hypersensitivity Syndromes and Drug Reactions

151 Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis
152 Erythema Nodosum
153 Vasculitis
154 Cutaneous Drug Reactions

Section 13: Bullous Disease

155 Chronic Bullous Disease of Childhood
156 Pemphigus
157 Other Bullous Diseases

Section 14: Hair and Nail Conditions

158 Alopecia Areata
159 Traction Alopecia and Trichotillomania
160 Normal Nail Variants
161 Pigmented Nail Disorders
162 Ingrown Toenail
163 Onychomycosis
164 Paronychia
165 Psoriatic Nails
166 Subungual Hematoma

Section 15: Pigmentary Conditions

167 Vitiligo and Hypopigmentation
168 Disorders of Hyperpigmentation

Section 16: Genetic Skin Disorders

169 Genodermatoses
170 Vascular and Lymphatic Malformations
171 Ichthyosis

PART 15

RHEUMATOLOGY

172 Juvenile Idiopathic Athritis
173 Lupus—Systemic and Cutaneous
174 Juvenile Dermatomyositis
175 Henoch Schonlein Purpura
176 Periodic Fever Syndromes
177 Kawasaki Disease
178 Scleroderma and Morphea

PART 16

INFECTIOUS DISEASES

179 Gastrointestinal Infections (Including Diarrhea)
180 Gonococcal Infections
181 Syphilis
182 Pediatric Human Immunodeficiency Virus (HIV) Infection
183 Lyme Disease
184 Epstein Barr Virus Infections (Infectious Mononucleosis)
185 Toxic Shock Syndromes
186 Pediatric Tuberculosis
187 Congenital and Perinatal Infections
188 Zoonoses

PART 17

ENDOCRINOLOGY

189 Diabetes Overview
190 Acanthosis Nigricans
191 Hypothyroidism
192 Hyperthyroidism
193 Hyperlipidemia and Xanthomas
194 Obesity
195 Cushing Syndrome

196 Addison’s Disease
197 Congenital Adrenal Hyperplasia
198 Rickets
199 Delayed Puberty
200 Precocious Puberty

PART 18

NEUROLOGY

201 Headache
202 Bell’s Palsy
203 Subdural Hematoma
204 Cerebral Vascular Accident
205 Tuberous Sclerosis
206 Neurofibromatosis
207 Sturge-Weber Syndrome
208 Duchenne Muscular Dystrophy

PART 19

HEMATOLOGY-ONCOLOGY

209 Iron Deficiency Anemia
210 Immune Thrombocytopenia Purpura
211 Sickle Cell Disease
212 Neuroblastoma
213 Wilms Tumor
214 Langerhans Cell Histiocytosis

PART 20

ALLERGY AND IMMUNOLOGY

215 Allergic rhinitis
216 DiGeorge syndrome
217 Primary Ciliary Dyskinesia

218 B-cell Immunodeficiencies

219 B and T Cell Immunodeficiencies—Severe Combined Immunodeficiency (SCID) and Other Well Defined Primary Immunodeficiencies

220 Chronic Granulomatous Disease

PART 21

GENETIC DISORDERS

221 Down Syndrome

222 Turner Syndrome

223 Marfan syndrome

224 Ehler Danlos syndrome

225 Osteogenesis Imperfecta

226 Noonan syndrome

227 PHACE Syndrome

228 Incontinentia Pigmenti

PART 22

SUBSTANCE ABUSE

229 Substance Abuse Disorder

APPENDIX

A Interpreting Evidence-Based Medicine (EBM)

B Topical and Intralesional Corticosteroids

PREFACE

Pediatricians see a wide variety of genetic and congenital disorders, infections, skin conditions, and many other problems that span the pediatric spectrum. It is clear that a comprehensive atlas that aids in diagnosis using visible signs and internal imaging will be of tremendous value. We have assembled more than 1,900 outstanding clinical images for this very purpose and are proud to present the first edition of a modern comprehensive atlas of pediatrics. Some photographs will amaze you and all will inform you about the various conditions that befall our patients.

It took a number of people many years to create the first edition of *The Color Atlas of Pediatrics*. For us, it has been a life long inspired by many great mentors, who taught us the importance of physical examination findings in caring for our patients. We have been fortunate to compile many photographs of our patients over the years, which we have used to teach medical students and residents. We now have the honor of sharing these images with the readers of this atlas. We are grateful to the many outstanding contributors to this textbook who have unselfishly shared with us their patient stories and images, and their vast knowledge of the disease processes, which has allowed us to compile this truly comprehensive pediatric atlas.

The Color Atlas of Pediatrics is written for pediatricians and all healthcare providers involved in providing care to children and adolescents. It can be invaluable to medical students, residents, nurse practitioners, physician assistants, family physicians and dermatologists.

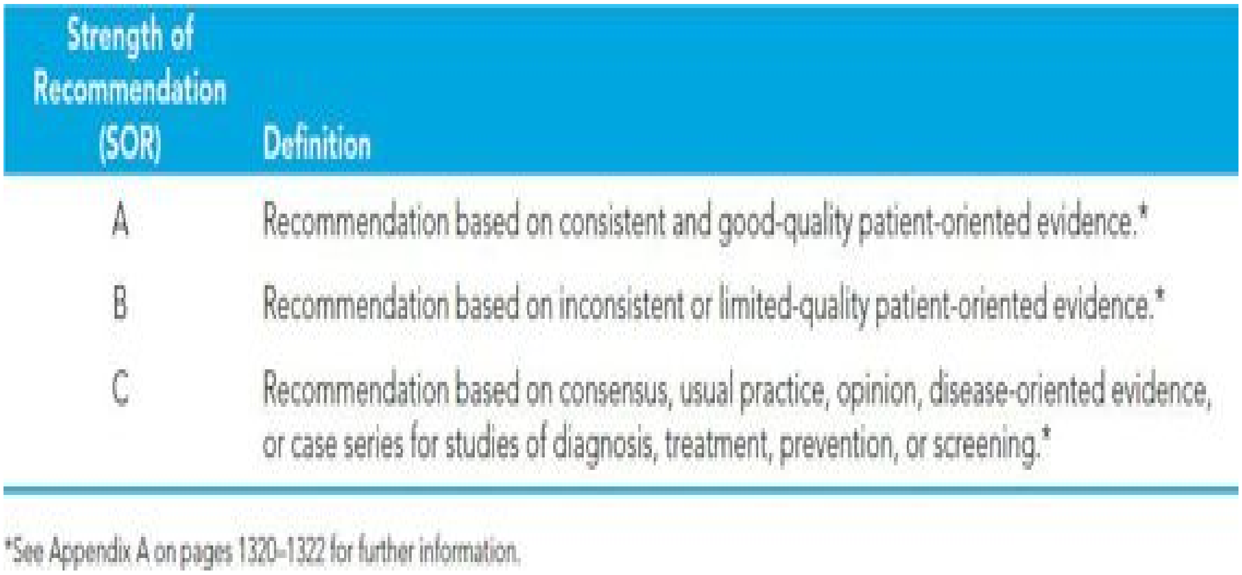
The Color Atlas of Pediatrics is also for anyone who loves to look at clinical photographs for learning, teaching, and practicing medicine. The first chapter begins with an introduction to learning with images and digital photography. The core of the book focuses on medical conditions organized by anatomic and physiologic systems. This book covers healthcare from birth to adulthood. There are special sections devoted to the essence of pediatrics, physical/sexual abuse, newborn and adolescent health, dermatology, and genetic disorders.

The collection of clinical images is supported by evidence-based information that will help the healthcare provider diagnose and manage a wide spectrum of common and not so common pediatric problems. The text is concisely presented with many easy to access bullets as a quick point-of-care reference. Each chapter begins with a patient story that ties the photographs to the real life stories of our patients. The photographic legends are also designed to connect the images to the people and their human conditions. Strength of recommendation ratings are cited throughout so that the science of medicine can be blended with the art of medicine for optimal patient care.

The first edition of *The Color Atlas of Pediatrics* is available electronically on iPad, iPhone, iPod touch, all Android devices, Kindle, and on the web through Access Pediatrics. These electronic versions will allow healthcare providers to access the images and the content rapidly and at the point-of-care.

Because knowledge continues to advance after any book is written, we recommend that you use the online resources presented in many of the chapters to keep up with the most current changes in medicine. Care deeply about your patients and enjoy your practice, as it is a privilege to be a healthcare provider and healer.

The Editors



Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1320–1322 for further information.

ACKNOWLEDGMENTS

This book could not have been completed without the contributions of many talented physicians, healthcare professionals, and photographers. We received photographs from people who live and work across the globe. Each photograph is labeled and acknowledges the photographer and contributor. There are some people who contributed so many photographs it is appropriate to acknowledge them upfront in the book. The dermatology division at University Of Texas Health Sciences Center San Antonio contributed much of their expertise in photography, writing, and reviewing the extensive dermatology section. During the last few years, I was fortunate to work closely with the dermatology faculty and residents and they contributed generously to our book. Dr. Eric Kraus, the program director, gave us many wonderful photographs, especially for the section on bullous diseases. He also gave us open access to the 35-mm slides collected by the Division of Dermatology. Drs. Jeff Meffert and John Browning also contributed photographs to many chapters. Dr. Jack Resneck, Sr., from Louisiana, scanned his slides from more than 40 years of practice and gave them to Dr. E.J. Mayeaux, Jr., for use. Dr. Resneck’s vast dermatologic experiences add to our atlas.

The UTHSCSA Head and Neck Department contributed many photographs for this book. We especially thank Dr. Frank Miller and Dr. Blake Simpson for their contributions. UTHSCSA pediatrics faculty contributed to our chapters on child abuse and otitis media. We are fortunate to have Dr. Nancy Kellogg contribute her photographs and expertise in caring for abused children to the book. Dr. Dan Stulberg, a family physician from New Mexico, with a passion for photography and dermatology, contributed many photographs throughout our book.

We thank our learners, many of whom coauthored chapters with us. UTHSCSA medical students and residents and fellows from Michigan State University’s Primary Care Faculty Development Fellowship program coauthored chapters and contributed photographs with great enthusiasm to the creation of this work. It was a pleasure to mentor these young writers and experience with them the rewards of authorship. Dr. Usatine is thankful for the contributions of his “Underserved Dermatology Fellows”. Working closely with such brilliant and caring doctors in our Skin Clinic and free outreach clinics allowed me to learn from them while doing my best to advance their academic and humanistic careers.

Of course, we would have no book without the talented writing and editing of my coeditors, Drs. Camille Sabella, Elumalai Appachi, Mindy A. Smith, E.J. Mayeaux, and Heidi Chumley. They each bring years of clinical and educational experience to the writing of the *Atlas*. Drs. Sabella, Appachi and Mayeaux contributed many of their own photographs. We also thank the chapter and photograph contributions of the many physicians at the Cleveland Clinic Children’s Hospital. It has been a real pleasure to work with this dedicated group of individuals. We thank them for their expertise, perseverance, and devotion to teaching. We also want to thank the late Dr. Robert Mercer, one of the founding fathers of pediatrics at the Cleveland Clinic, who was responsible for the Cleveland Clinic Children’s Hospital Photo Files, and whose photos are featured throughout this book. Dr. Mercer was a devoted clinician and educator, and we are indebted to him for his contributions to the field of pediatrics. We would like to also recognize Dr. Daniel Shapiro, who was responsible for collecting, safeguarding, and stressing the use of the photo files for educational purposes.

Most of all we need to thank our patients who generously gave their permission for their photographs to be taken and published in this book. While some photos are not recognizable, we have many photos of the full face that are very recognizable and were generously given to us by our patients with full written permission to be published as is. For photographs that were taken decades ago in which written consents were no longer available, we have used bars across the eyes to make the photos less recognizable—verbal consent was always obtained for these images.

I (Dr. Richard Usatine) thank my family for giving me the support to see this book through. It has taken much time from my family life and my family has supported me through the long nights and weekends it takes to write a book while continuing to practice and teach medicine. I am fortunate to have a loving wife, wonderful daughter, successful son, great son-in-law and one very cute grandson who add meaning to my life and allowed me to work hard on the creation of this *Color Atlas*. I personally want to thank Dr. Camille Sabella for his strong work ethic, warmth and good humor during the whole process. It is rare to find such superb collaborators in life. In every step of this journey, we worked together with mutual respect, kindness and consideration.

Dr. Camille Sabella would like to thank his wife Paula, and his three children, Carmen, Julia, and Annmarie, for their unwavering support, love, and encouragement. The sense of humor they provided also was instrumental in helping maintain a good balance throughout the process. He would like to personally thank Dr. Richard Usatine for sharing his knowledge, wisdom and experience, and for the selflessness he has shown in creating this *Color Atlas*. He would also like to thank his colleagues at the Cleveland Clinic Children's Hospital for their dedication to their patients and to the scholarly mission.

Dr. Mindy Smith adds, "I thank my husband, Gary, and daughter, Jenny, for their support and willingness to listen when I struggle with phrasing and wording in my writing and editing. I also thank several colleagues who have helped me to establish myself as an editor and supported my continued growth in this field—Drs. Barry Weiss, Mark Ebell, Richard Usatine, Suzanne Sorkin, and Leslie Shimp."

Dr. E.J. Mayeaux would like to thank his wife and family for understanding the many hours of work and computer time it takes to produce this work. He would like to dedicate this work to Mr. Bob (Papa Bob) Mitchell who can always find the funny angle to any situation and who gave him his partner and love of his life. I would also like to thank my new work family at the Department of Family and Preventive Medicine at the University of South Carolina School of Medicine in Columbia. We are going to do great things!

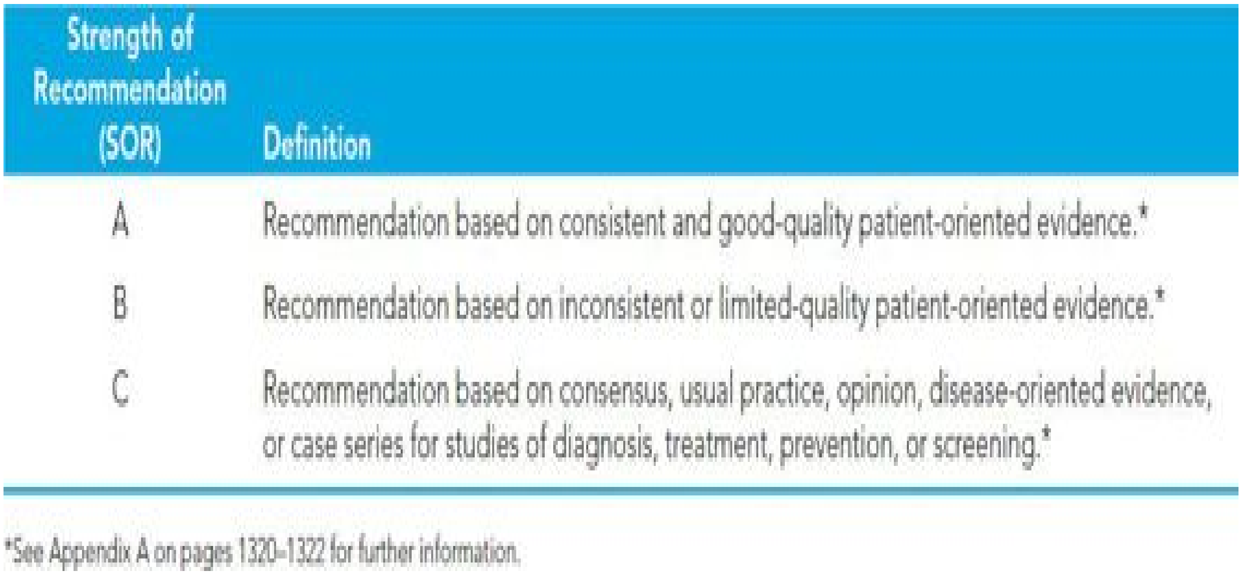
Dr. Heidi Chumley adds, "I want to thank my husband, John Delzell, who has brought love and peace to my often chaotic life, and my children, Cullen, Sierra, David, Selene, and Jack, who give me joy and provide the incentive to stay on task. Each one, in turn, has cheerfully pitched in to help a grumpy and tired mom who stayed up most of the night working on one of many chapters. I have been very blessed."

Dr Elumalai Appachi states that "I would like to thank all my teachers and patients who taught me the art of clinical pediatrics and how to show compassion for sick children. I want to take this opportunity to recognize my parents who always wanted me to be a physician and serve sick children. Finally I want to thank my family who has supported me to be sane and focused. Finally, I want to thank Camille Sabella who has given me opportunity to share what I learnt.”

Finally, we all thank James Shanahan, Alyssa Fried and Karen Edmonson from McGraw-Hill for believing in this project and never giving up as our book grew larger and more comprehensive over time.

PART 1

LEARNING WITH IMAGES AND DIGITAL PHOTOGRAPHY



Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1320–1322 for further information.

1 AN ATLAS TO ENHANCE PATIENT CARE, LEARNING, AND TEACHING

Richard P. Usatine, MD

> *People only see what they are prepared to see.*
>
> —Ralph Waldo Emerson

Whether you are viewing **Figure 1-1** in a book, in an aquarium, or in the sea, you immediately recognize the image as a fish. Those of you who are more schooled in the classification of fish might recognize that this is an angelfish with the tail resembling the head of the angel and the posterior fins representing the wings. If you are truly prepared to see this fish in all its splendor, you would see the blue circle above its eye as the crown of the queen angelfish.

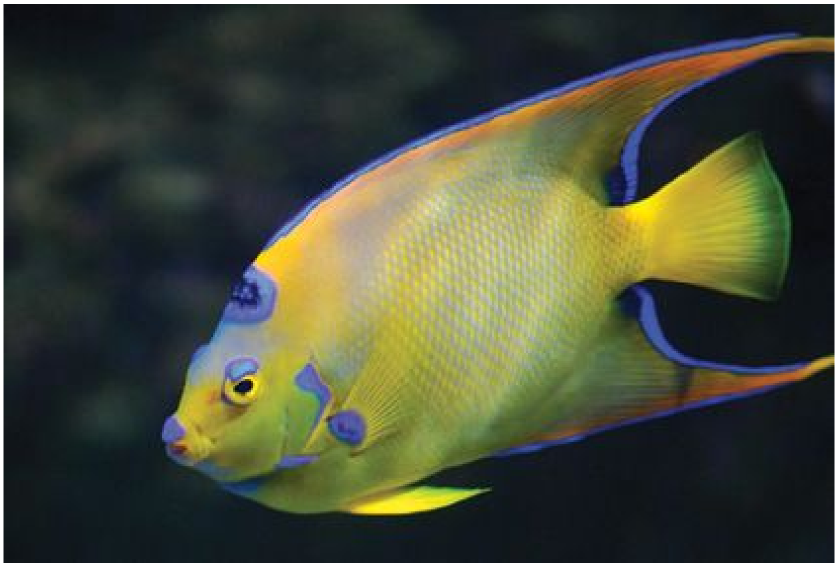


FIGURE 1-1 Queen angelfish (*Holacanthus ciliaris*). (*Used with permission from Sam Thekkethil. http://www.flickr.com/photos/natureloving.*)

Making a diagnosis in medicine often involves the kind of pattern recognition needed to identify a queen angelfish. This is much the same as recognizing a beautiful bird or the painting of a favorite artist. If you are prepared to look for the clues that lead to the identification (diagnosis), you will see what needs to be seen. How can we be best prepared to see these clues? There is nothing more valuable than seeing an image or a patient who has the condition in question at least once before you encounter it on your own. The memory of a powerful visual image can become hardwired into your brain for ready recall.

In medicine, it also helps to know where and how to look to find the clues you may need when the diagnosis cannot be made at a single glance. For example, a 3-year-old girl presents with bad seborrheic dermatitis of the scalp and hand dermatitis that is not responding to typical treatments with selenium based shampoos and topical steroids (**Figures 1-2** and **1-3**). The prepared clinician knows that not all scaly erythematous rashes on the scalp and hands are dermatitis and looks for clues of psoriasis such as nail changes (**Figure 1-4**) or scaling erythematous plaques around the elbows and knees (**Figure 1-5**). Knowing where to look and what to look for is how an experienced clinician makes the diagnosis of psoriasis.

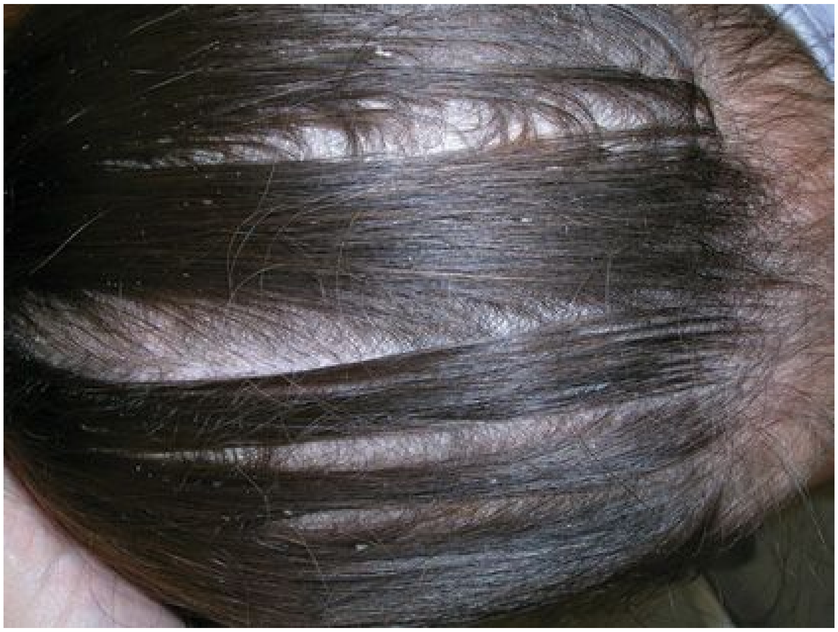

FIGURE 1-2 Scaling on the scalp of this 3-year-old girl was thought to be seborrheic dermatitis for one year. When the cradle cap did not go away with appropriate treatment another clinician looked for other clues of disease to determine that this was psoriasis. (*Used with permission from Richard P. Usatine, MD.*)

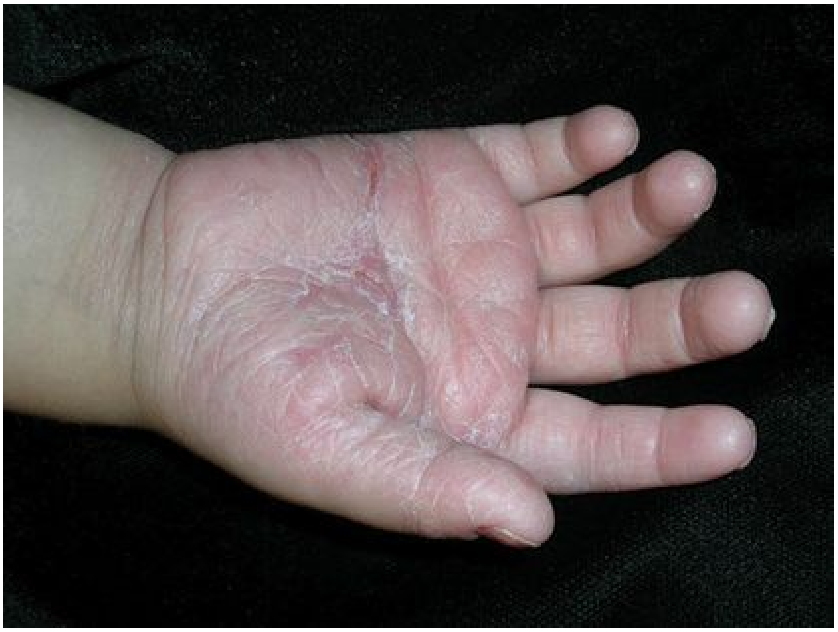

FIGURE 1-3 The same 3-year-old girl with scaling and cracking of the hands thought to be atopic dermatitis. It was not until another clinician looked carefully at the nails and knees that the correct diagnosis of psoriasis was made. Knowing where to look for the clues is critical to making the correct diagnosis. (*Used with permission from Richard P. Usatine, MD*.)

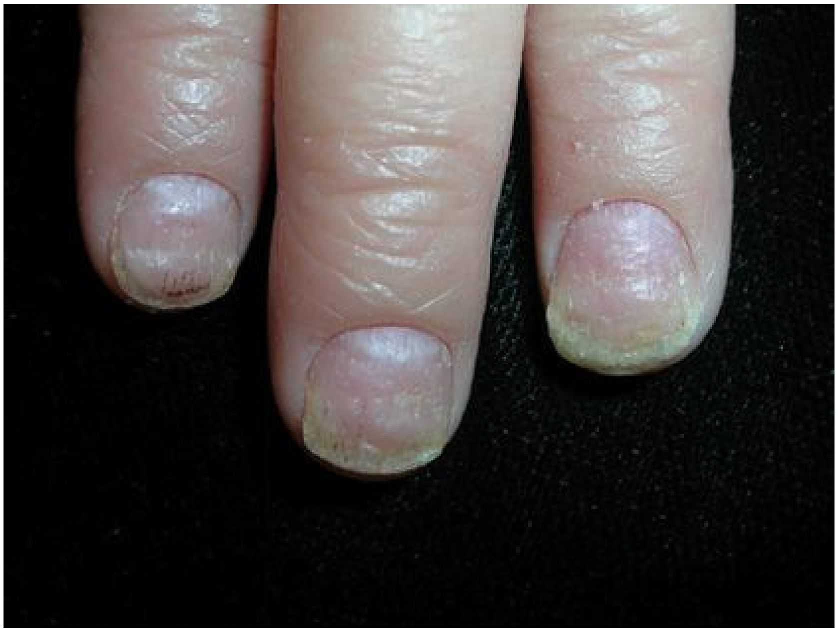

FIGURE 1-4 When the diagnosis of psoriasis is being considered, look at the nails for pitting or other nail changes such as splinter hemorrhages,

onycholysis, or oil spots. This is a good example of nail pitting and splinter hemorrhages in a 3-year-old girl with psoriasis. (*Used with permission from Richard P. Usatine, MD.*)

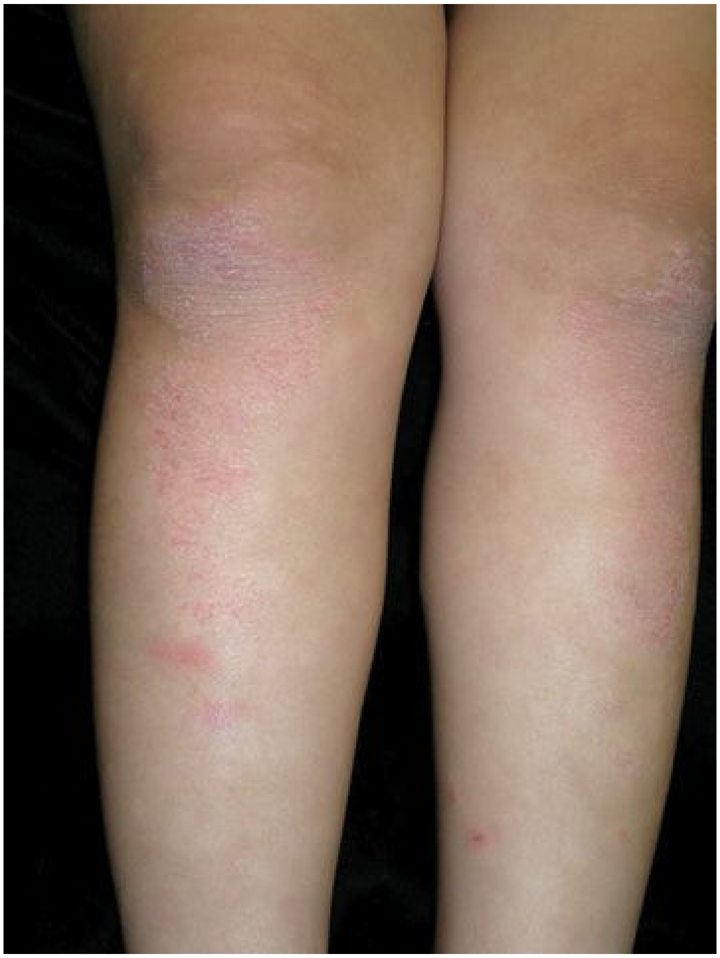

FIGURE 1-5 Subtle plaques over the knees and extensor surfaces of the lower legs in a 3-year-old girl with psoriasis. (*Used with permission from Richard P. Usatine, MD.*)

USING OUR SENSES

As physicians we collect clinical data through sight, sound, touch, and smell. Although physicians in the past used taste to collect data, such as tasting the sweet urine of a patient with diabetes, this sense is rarely, if ever, used in modern medicine. We listen to heart sounds, lung sounds, bruits, and percussion notes to collect information for diagnoses. We touch our patients to feel lumps, bumps, thrills, and masses. We occasionally use smell for diagnosis. Unfortunately, the smells of disease are rarely pleasant. Even the fruity odors of *Pseudomonas* are not like the sweet fruits of a farmers' market. Of course, we also use the patient's history, laboratory data, and more advanced imaging techniques to diagnose and manage patients' illnesses.

It was our belief in the value of visual imagery that led to the development of this first *Color Atlas of Pediatrics*. We are pleased to provide more than 2,000 images to you and doctors around the world as a large color textbook and also as an interactive electronic application for easy use on the iPhone, iPod touch, iPad, and all Android devices.

EXPANDING OUR INTERNAL IMAGE BANKS

The larger our saved image bank in our brain, the better clinicians and diagnosticians we can become. The expert clinician has a large image bank stored in memory to call on for rapid pattern recognition. Our image banks begin to develop in medical school when we view pictures in lectures, textbooks, and electronic media. We then begin to develop our own clinical image bank by our clinical experiences. Our references are printed color atlases and those color atlases are available on the Internet and electronically.

Studying and learning the patterns from any atlas can enhance your expertise by enlarging the image bank stored in your memory. An atlas takes the clinical experiences of clinicians over decades and gives it to you as a single reference. We offer you a modern comprehensive pediatric color atlas, which includes all areas of pediatrics from head to toe with special areas of focus on newborn and adolescent health, dermatology, and genetic disorders.

USING IMAGES TO MAKE A DIAGNOSIS

We all see visible clinical findings on patients that we do not recognize. When this happens, open this book and look for a close match. Use the Topic Index, Table of Contents, or Subject Index to direct you to the section with the highest yield photos. If you find a direct match, you may have found the diagnosis. Read the text and see if the history and physical examination match your patient. Perform or order tests to confirm the diagnosis, if needed.

If you cannot find the image in our book try the Internet and Google's search engine. Try a Google image search and follow the leads. Of course, this is easiest to do if you have a good differential diagnosis and want to confirm your impression. If you do not have a diagnosis in mind, you may try putting in descriptive words and look for an image that matches what you are seeing. If the Google image search does not work, try a Web search and look at the links for other clues.

Finally, there are dedicated atlases on the Internet for organ systems that can help you find the needed image. Most of these atlases have their own search engines, which can help direct you to the right diagnosis.

Table 1-1 lists some of the best resources currently available online.

USING IMAGES TO BUILD TRUST IN THE PATIENT–PHYSICIAN RELATIONSHIP

If you are seeing a patient with a mysterious illness that remains undiagnosed and you figure out the diagnosis, you can often bridge the issues of mistrust and anxiety by showing the patient and their family the picture of another person with the diagnosis. Use our atlas for that purpose and supplement it with the Internet. This is especially important for a patient who has gone undiagnosed or misdiagnosed for some time. “Seeing is believing” for many patients. Ask the patient or parents first if they would want to see some pictures of other persons with a similar condition; most will be very interested. The parents and the patient can see the similarities between their condition and the other images, and feel reassured that your diagnosis is correct. Write down the name of the diagnosis and use your patient education skills.

Do be careful when searching for images on the Web in front of patients. Sometimes what pops up is not “pretty” (or, for that matter, G or PG rated). I turn the screen away from the patient and their family before initiating the search and then censor what I will show them. I also explain that the images in a book or on the Internet may be the worst cases so that they may appear more severe than what your patient has. This can help blunt the anxiety of whether the child will go on to develop a worse case.

If you teach, model this behavior in front of your students. Show them how reference books and the Internet at the point of care can help with the care of patients.

TAKING YOUR OWN PHOTOGRAPHS

Images taken by you with your own camera of your own patients complete with their own stories are more likely to be retained and retrievable in your memory because they have a context and a story to go with them. We encourage our readers to use a digital camera (within a smartphone or a stand-alone camera) and consider taking your own photos. Of course, always ask permission before taking any photograph of a patient. Explain how the photographs can be used to teach other doctors and to create a record of the patient’s condition at this point in time. If the photograph will be identifiable, ask for written consent; for patients younger than age 18 years, always ask the parent to sign. Store the photos in a manner that avoids any Health Insurance Portability and Accountability Act (HIPAA) privacy violations, such as on a secure server or on your own computer with password protection and data encryption. These photographs can directly benefit the patient when, for example, following various chronic diseases or skin conditions for changes.

Digital photography is a wonderful method for practicing, teaching, and learning medicine. You can show patients pictures of conditions on parts of their bodies that they could not see without multiple mirrors and some unusual body contortions. You can also use the zoom view feature on the camera or smartphone to view or show a segment of the image in greater detail. Children generally love to have their photos taken and will be delighted to see themselves on the screen of your camera/phone. If the child is old enough to be self-conscious about the condition that is “not normal,” consider asking to take a picture of a healthy aspect of the child first. Most children will smile for a photograph of their face when they are feeling well and then be less puzzled or disturbed by a photograph of their foot or other involved area.

The advent of digital photography makes the recording of photographic images less expensive, easier to do, and easier to maintain. Digital photography also gives you immediate feedback and a sense of immediate gratification. No longer do you have to wait for a roll of film to be completed then processed before finding out the results of your photography. Not only does this give you instant gratification to see your image displayed instantaneously in the camera, but also alerts you to poor-quality photographs that can be retaken while the patient is still in the office. This speeds up the learning curve of the beginning photographer in a way that could not happen with film photography.

OUR GOALS

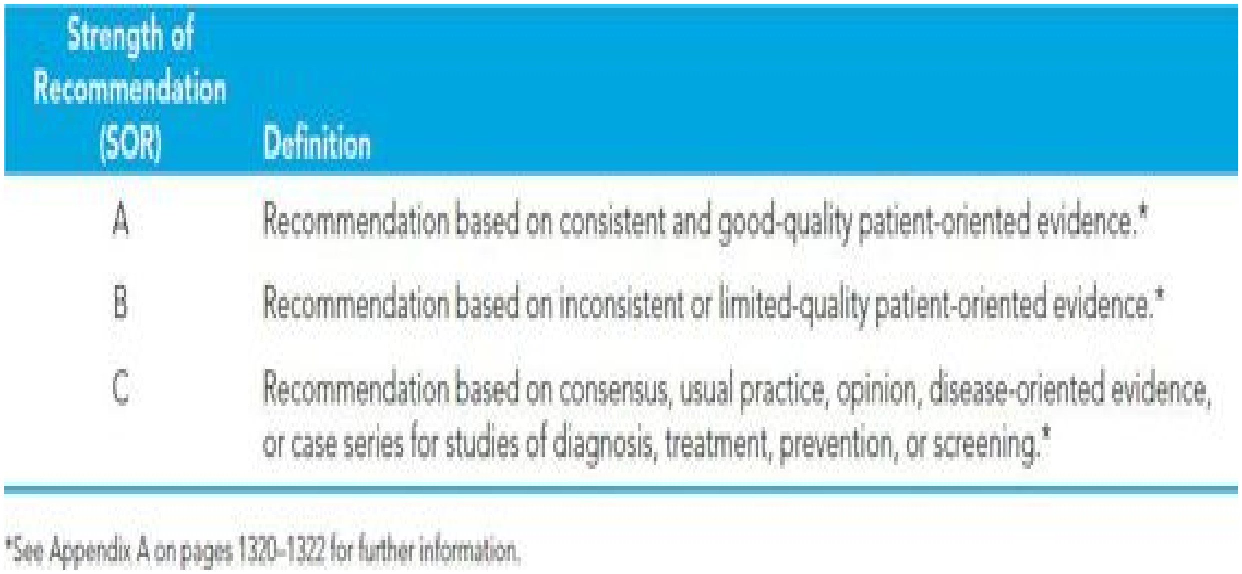
Many of the images in this atlas are from my collected works over the past 30 years of my practice in medicine. My patients have generously allowed me to photograph them so that their photographs would help the physicians and patients of the future. To these photos, we have added images that represent decades of experiences by other physicians and specialists. The Cleveland Clinic Children’s Hospital photo files have been a real treasure for the rare conditions not seen regularly by the practicing pediatrician. For those photos, I thank my co-author and co-editor Dr. Camille Sabella for all the work that went into cataloguing and providing these treasured images for this atlas.

It is the goal of this atlas to provide you with a wide range of images of common and uncommon conditions, and provide you with the knowledge you need to make the diagnosis and initiate treatment. We want to help you be the best diagnostician you can be. We may aspire to be a clinician like Sir

William Osler and have the detective acumen of Sherlock Holmes. The images collected for this atlas can help move you in that direction by making you prepared to see what you need to see.

PART 2

THE ESSENCE OF PEDIATRICS



Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1320–1322 for further information.

2 DOCTOR—PATIENT RELATIONSHIP

Camille Sabella, MD

PATIENT STORY

Patient and family stories, particularly if we listen attentively and non-judgmentally, provide us with a window into their lives and experiences. These stories help us to know our patients and families in powerful ways, and that knowledge about the patient, as someone special, provides the context, meaning, and clues about their symptoms and illnesses that can lead to healing. At our best, we serve as witness to their struggles and triumphs, supporter of their efforts to change and grow, and guide through the medical maze of diagnostic and therapeutic options. Sometimes, their stories become our own stories—those patients who we will never forget because their stories have changed our lives and the way we practice medicine (**Figures 2-1** and **2-2**).

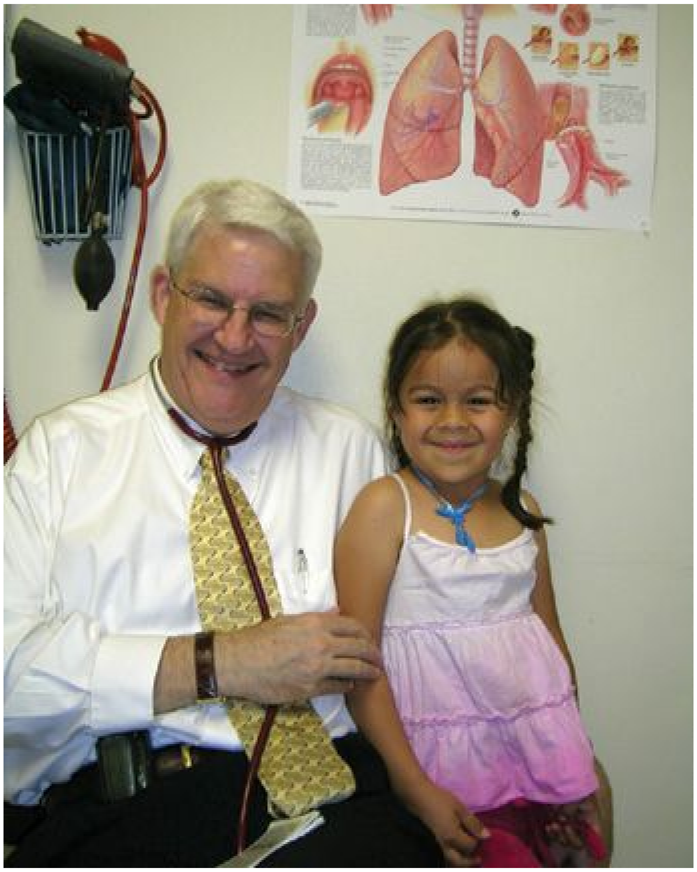


FIGURE 2-1 Dr. Jim Legler caring for a young girl in a free clinic within a transitional housing village for homeless families. He is a pediatrician who volunteers every week to care for the families working their way out of homelessness. He had been caring for Kimberly and her family for many months at the time this photograph was taken. Dr. Legler serves as a role model for students interested in primary care of the underserved. He is known for his kindness and compassion to all his patients.

FIGURE 2-2 Dr. Camille Sabella examines a child recovering from osteomyelitis of the femur. This child required 6 weeks of antimicrobial therapy, which was accomplished successfully. Because this is a common and “routine” infection for a pediatric infectious diseases physician, it is easy to forget the considerable psychosocial effect that this infection had on this boy and his mother. Close follow-up, careful listening, education regarding the expectations and prognosis, and engaging the child in his own care all are important for a successful outcome.

WHAT FAMILIES WANT FROM THEIR PEDIATRIC PROVIDERS

- In a study of families of pediatric patients under 13 years of age in a large outpatient clinic, three elements were shown to be essential for effective physician-parent-child communication from a parent perspective.[1] These included:
  - Informativeness—Parents place considerable importance on the quality and quantity of information provided by the physician regarding their child’s health.
  - Interpersonal sensitivity—Parents highly value physicians who were supportive and sensitive to the child’s and parent’s feelings and

concerns.
  - Partnership building—The extent to which the physician involves the parent and child in the care of the child.
- Yet, traditionally, there has been little emphasis placed on building interpersonal skills in pediatric practice and training. This led to an American Academy of Pediatrics (AAP) report in 2001, which stated that “there is a need to better learn how to elicit information, including a narrative interview approach, allowing the child, adolescent, and parents to tell their stories” and that “there is a need to communicate empathy.”[2]

BENEFITS OF EFFECTIVE COMMUNICATION

- The pediatric encounter is complex and unique because it:
  - Involves the physician-parent-child and other family members.
  - Is influenced by the developmental and cognitive stage of the child.
  - Needs to cover medical issues, emotional concerns, behavioral issues, anticipatory guidance, immunizations, and parent and child education.
- Dealing with these unique aspects in an effective manner requires that the physician be flexible in adjusting the history and physical exam to gain the most information and provide the most education efficiently.
- Communicating with patients and families is essential for quality care; effective physician-parent communication has been shown to be essential in securing:
  - An accurate diagnosis.
  - Parental satisfaction with care.
  - Implementation and adherence to treatment recommendations.
  - Improved patient knowledge.
  - Enhanced discussion of psychosocial issues leading to improved psychological and behavioral outcomes.

- Effective communication is essential for patient-centered and family-centered care, which is endorsed by the AAP as a cornerstone for care.

COMMUNICATION WITH THE CHILD PATIENT

- A unique aspect of pediatric care is the approach to the child patient.
- Communication with the child patient is important if we expect the child to be an active participant in their care because it shows respect for the child's abilities and capacities, enhances their skill in making future health decisions, and enables their input in situations where there is more than one method of diagnosis or treatment. This is especially relevant for older children and adolescents.
- Treating the child as a partner results in improved adherence to the treatment plan and resultant outcome.[3,4]
- Despite the importance of direct communication with children, this appears to be limited in outpatient medical visits. In an older study from the Netherlands, children's contributions were limited to 4 percent of the encounters, although pediatricians directed 1/4 of their statements to the child.[5] In addition, only a small portion of medical information (13%) was directed at children.
- To help physician-child communication, pediatricians and primary care providers caring for children need to develop strategies for engaging children in the outpatient setting.
- To encourage participation of children in the medical encounter, physicians can ask children social questions early in the visit, phrase questions as requiring a yes-no response, and direct their gaze at the child when asking questions.[5]
- Other suggested strategies may include:[6]
    - Speak with the child—Not at or to him/her.

  - Setting should be private—Especially with the adolescent patient where confidentiality is critical.
  - Begin with a nonthreatening topic.
  - Listen actively.
  - Pay attention to body language and tone of voice.
  - Use drawings, games, or other creative communication techniques.
  - Elicit fears and concerns by reference to self or a third party.

FAMILY-ORIENTED CARE

- Ten years ago, the American Academy of Pediatric appointed a Task Force on the Family, in part to assist pediatricians in promoting well-functioning families.[7] This type of care was referred to as “family-oriented care” or “family pediatrics” and was strongly endorsed as a way to provide pediatric care in a context that promotes successful families and good outcomes for children.
- Family-oriented care is also important in addressing psychosocial issues, which accounts for 65 percent of primary care visits and requires a holistic approach by the clinician. It has been shown that a majority of parents welcome or do not mind being asked about emotional and psychosocial stressors.[8] It is clear that disclosure of psychosocial issues are likely to occur when the pediatrician:
  - Shows interest and attention while listening.
  - Directly asks questions.
  - Shows interest in managing parenting and behavioral concerns.[9]
- Caring is also an essential feature of family oriented care. Caring, as connectedness with a patient, evolves from the relationship. Within the context of this relationship, the clinician makes the patient and family feel known, pays attention to the meaning that a symptom or illness has in the family’s life, expresses real feeling (separate from reflecting back the patient’s feelings), and practices devotion (e.g., a willingness at times to do something extra for the patient and family).[10] To provide caring to patients, clinicians must take care of themselves.

CONCLUSION

The physician-parent-child interaction is complex and unique, and requires the provider to address multiple aspects of care, including medical diagnosis, treatment plan, anticipatory guidance, family education, and attention to psychosocial aspects. Genuine caring, empathy, support, and respect for the patient and family provide the foundation for an effective and long lasting physician-family relationship.

3 PATIENT- AND FAMILY-CENTERED CARE

Michelle Marks, DO, FAAP, FHM
Rita Pappas, MD, FAAP, FHM

PATIENT STORY

A 15-month-old boy is admitted with fever, rash, and conjunctivitis. Kawasaki disease is suspected and he is transferred to the inner city academic hospital from the community hospital. The mother of the boy is very concerned about the child and the diagnosis. Family Centered Rounds occur in the morning (**Figures 3-1** to **3-4**). During rounds, the health care team is introduced and a plan of care is initiated with input from the mother.

FIGURE 3-1 Patient-and Family-Centered Care. The pediatric team is preparing to enter the room by pre-rounding prior to entering the room.

FIGURE 3-2 The pediatric team includes nursing, residents, medical students, and attending staff. It is vital to patients and families to include all involved in the care of the child and family.

FIGURE 3-3 In the patient room, all participants need to be engaged and participate in the discussion.

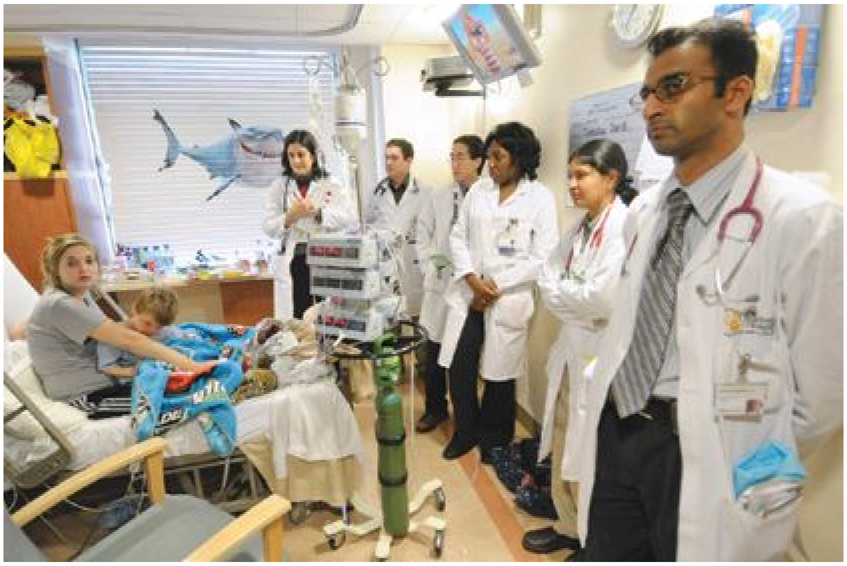

FIGURE 3-4 The pediatric team conducting rounds in the patient’s room. The parents should be offered the choice to round inside of the patient room or outside of the patient room.

SYNONYMS

Family centered care; Family centered rounds.

DEFINITION

An innovative approach to the planning, delivery, and evaluation of health care that is grounded in a mutually beneficial partnership among patients, families, and providers, all of whom recognizes the importance of the family in the patient’s life.[1,2]

It is an approach to health care that shapes policies, programs, facility design, and staff day-to-day interactions. It leads to better health outcomes, wiser allocation of resources, and greater patient and family satisfaction.

It should be noted that the term “Patient- and Family-Centered Care” has replaced “Family-Centered Care” to more explicitly capture the importance of engaging the family and the patient in a developmentally supportive manner, as essential members of the health care team.

CORE PRINCIPLES OF PATIENT AND FAMILY-CENTERED CARE[1,2]

1. Listening to and respecting each child and his or her family, and honoring various types of backgrounds and family experiences. Patient and family knowledge, values, beliefs, and cultural backgrounds are incorporated into the planning and delivery of care.
2. Ensuring flexibility in the practice of the team so that services can be tailored to the needs, beliefs, and cultural values of each child and family, thus facilitating choice for the child and family about approaches to care.
3. Sharing complete, honest, and unbiased information with patients and their families on an ongoing basis, and in ways they find useful and affirming. Patients and families should receive timely, complete, and accurate information in order to effectively participate in care and decision-making. Health information for children and families should be available in the appropriate health literacy. In hospitals, conducting physician rounds in the patients’ rooms with nursing staff and family present will enhance the exchange of information and encourage the involvement of the family in decision-making.
4. Providing and/or ensuring formal and informal support (e.g., peer-to-peer support) for the child and family during each phase of the child’s life. Patients and families are encouraged and supported in participating in care and decision-making at the level they choose.
5. Collaborating with patients and families at all levels of health care: in the delivery of care to the individual child; in professional education, policy making, program development, implementation, and evaluation; and in health care facility design. In the area of medical research,

patients and families should have voices at all levels in all facets of research.

HISTORY/INTRODUCTION

- Patient- and family-centered care emerged as an important concept in health care during the second half of the 20th century. Much of the early work focused on hospitals; for example, as research emerged about the effects of separating hospitalized children from their families, many institutions adopted policies that welcomed family members to be with their child around the clock and also encouraged their presence during medical procedures.
- The Maternal and Child Health Bureau of the Health Resources and Service Administration played an active role in furthering the involvement of families and the support of family issues and service needs.
- Federal legislation of the late 1980s and 1990s, much of it targeted at children with special needs, provided additional validation of the importance of family-centered principles.
- Family-centered care has long been a characteristic of an effective medical home. Founded in 1992, Family Voices comprises advocates for family-centered, community-based services for children with special health care needs.
- Building on work started in the previous decade, the Institute for Family-Centered Care (now the Institute for Patient- and Family-Centered Care) was also founded in 1992 to foster the development of partnerships among patients, families, and health care professionals, and to provide leadership for advancing the practice of family centered care in all settings.
- Patient- and family-centered care is supported by a growing body of research and by prestigious organizations, such as the Institute of Medicine (IOM), which in its 2001 report, “Crossing the Quality Chasm:

A New Health System for the 21st Century," emphasized the need to ensure the involvement of patients in their own health care decisions, to better inform patients of treatment options, and to improve patients' and families' access to information.[3]

- In 2006, the Institute for Family-Centered Care and the Institute for Health care Improvement (IHI) brought together leadership organizations and patient and family advisors to advance the practice of patient- and family-centered care and ensure that there are sustained, effective partnerships with patients and families in all aspects of the health care system.[2,4,5]
- The American Academy of Pediatrics (AAP) has incorporated many of the principles of patient- and family centered care into several policy statements and manuals.[1,6] In 2006, the AAP Board of Directors approved a Parent Advisory Group pilot program under the section on Home Care. Members of the Parent Advisory Group all share a special interest in patient- and family-centered care, have personal experience with children with special health care needs, and serve as advisors and leaders for patient- and family-centered pediatric care within their own communities and at the national level.
- Founded in 1991, the IHI is an independent organization to improve health care throughout the world. Among its core values is patient and family centeredness. The National Institute for Children's Health care Quality (NICHQ) was launched as an IHI program in 1999. The NICHQ is dedicated to improving the quality of health care provided to children. One component of its 4-part improvement agenda is promoting evidence-based patient and family-centered care for children with chronic conditions.[7]
- There now have been several studies published in the literature, which demonstrate the benefits of patient and family-centered care.
- In the hospital environment, patient and family-centered care is associated with a decreased length of stay, reduced medical errors, and improved staff satisfaction.[8,9]
- There is also a significant link between patient and family satisfaction as well as hospital safety and communication, which is a fundamental part

of this type of care.[8–10]

- Overall, this model of care can improve patient and family outcomes, improve the patient's and family's experience, increase patient and family satisfaction, build on child and family strengths, increase professional satisfaction, decrease health care costs, and lead to more effective use of health care resources.

RECOMMENDATIONS FOR IMPLEMENTATION[1]

1. As leaders of the child's medical home, pediatric providers should ensure that true collaborative relationships with patients and families as defined in the core concepts of patient- and family-centered care are incorporated into all aspects of their professional practice. The patient and family are integral members of the health care team. They should participate in the development of the health care plan and have ownership of it.
2. Pediatric providers should unequivocally convey respect for families' unique insights into the understanding of their child's behavior and needs, should actively seek out their observations, and should appropriately incorporate family preferences into the care plan.
3. In hospitals, conducting attending physician rounds (i.e., patient presentations and discussions) in the patients' rooms with nursing staff and the family present should be standard practice.
4. Parents or guardians should be offered the option to be present with their child during medical procedures and offered support before, during, and after the procedure.
5. Families should be strongly encouraged to be present during hospitalization of their child, and pediatric providers should advocate for improved employer recognition of the importance of family presence during a child's illness.

6. Pediatric providers should share information with and promote the active participation of all children, including children with disabilities, if capable, in the management and direction of their own health care. The adolescent’s and young adult’s capacity for independent decision-making and right to privacy should be respected.
7. In collaboration with patients, families, and other health care professionals, pediatric providers should modify systems of care, processes of care, and patient flow as needed to improve the patient’s and family’s experience of care.
8. Pediatric providers should share medical information with children and families in ways that are useful and affirming. This information should be complete, honest, and unbiased.
9. Pediatric providers should encourage and facilitate peer-to-peer support and networking, particularly with children and families of similar cultural and linguistic backgrounds or with the same type of medical condition.
10. Pediatric providers should collaborate with patients and families and other health care providers to ensure a transition to good-quality, developmentally appropriate, patient- and family-centered adult health care services.
11. In developing job descriptions, hiring staff, and designing performance appraisal processes, pediatric providers should make explicit the expectation of collaboration with patients and families and other patient- and family-centered behaviors.
12. Pediatric providers should create a variety of ways for children and families to serve as advisors for and leaders of office, clinic, hospital, institutional, and community organizations involved with pediatric health care.
13. The design of health care facilities should promote the philosophy of patient- and family-centered care, such as including single room care, family sleeping areas, and availability of kitchen and laundry areas and other areas supportive of families. Providers should advocate for children and families to participate in design planning of health care facilities.

14. Education and training in patient and family-centered care should be provided to all trainees, students, and residents as well as staff members.
15. Patients and families should have a voice in shaping the research agenda, and they should be invited to collaborate in pediatric research programs. This should include determining how children and families participate in research and deciding how research findings will be shared with children and families.
16. Providers should advocate for and participate in research on outcomes and implementation of patient- and family-centered care in all venues of care.
17. Incorporating the patient- and family-centered care concepts into patient encounters requires additional face-to-face and coordination time by pediatricians. This time has value and is an investment in improved care, leading to better outcomes and prevention of unnecessary costs in the future. Payment for time spent with the family should be appropriate and paid without undue administrative complexities.

4 THE BIRTH OF A CHILD

Sabine Iben, MD

PATIENT STORY

Mary and Joe are expecting their first baby. The pregnancy has been without complications; routine prenatal screens and ultrasounds have been negative including the screen for Mary's Group B Streptococcal (GBS) status, the Quad screen for fetal anomalies and cystic fibrosis carrier status. Mary is happy to report strong fetal movements. One week before her due date Mary experiences strong contractions. She is admitted in active labor, membranes rupture spontaneously within 2 hours after arrival in the hospital. Labor progresses uneventfully, pain relief is provided by epidural anesthesia. Ten hours later a vigorous baby girl is born. The only intervention provided for resuscitation is drying followed by skin-to-skin placement on mother's chest for bonding. Initial physiologic cyanosis is resolved by 5 minutes of life (**Figure 4-1**). APGAR scores of 8 at 1 min and 9 at 5 min are assigned. Her weight shows that she is appropriate for gestational age. Erythromycin eye ointment is applied to both eyes for prophylaxis of ophthalmia neonatorum, an injection of Vitamin K intramuscularly is given for prophylaxis of hemorrhagic disease of the newborn. Mary chooses to breastfeed that is initiated shortly after delivery with the aid of a lactation consultant. Over the next couple of days, the newborn is breastfeeding about 10 times a day, voiding several times a day and has passed her first meconium stool by 14 hours of life. On day of life # 2 she has lost 6 percent of her birthweight and appears mildly jaundiced. A bilirubin level shows a value within the physiologic range. She is discharged at about 50 hours of life with her mother and a follow-up visit with her pediatrician is arranged for 2 days after discharge.

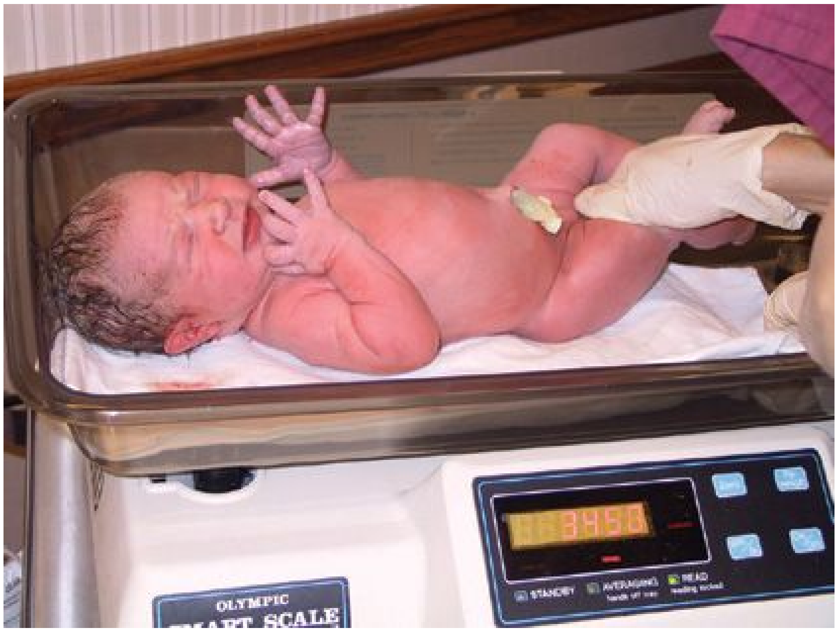

FIGURE 4-1 Acrocyanosis of hands and feet in a newborn is physiologic and not a sign of hypoxia. (*Used with permission from Dr. Sabine Iben*.)

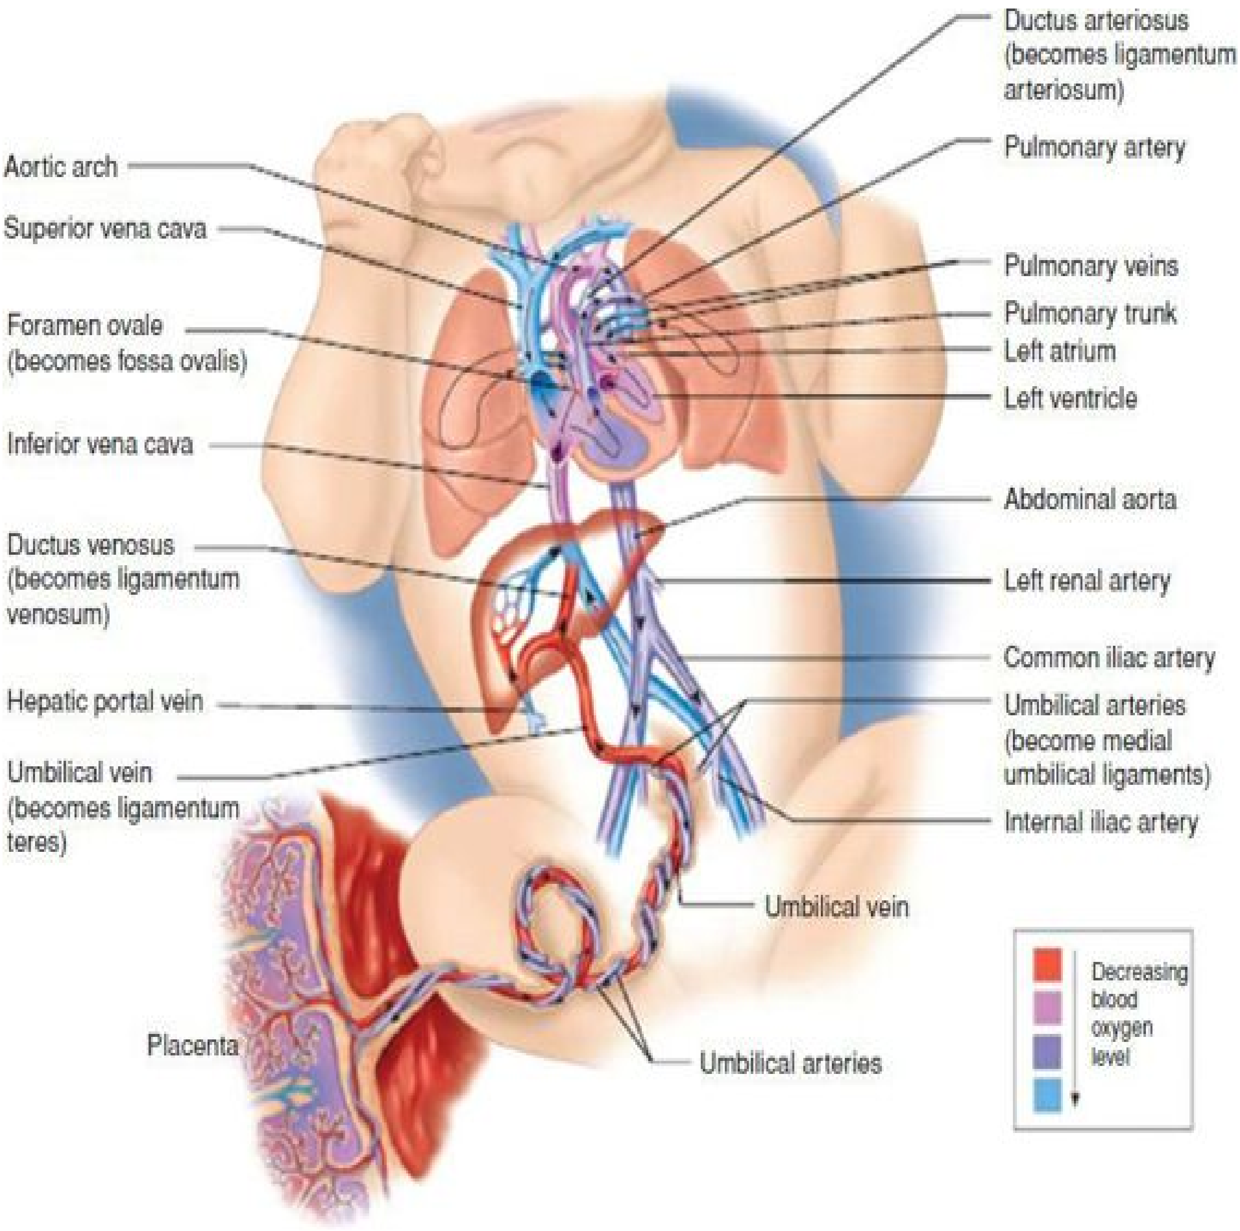
EPIDEMIOLOGY

- According to the Center for Disease Control,[1] in the US in 2011 there were:
  - a total of 3,953,593 births recorded.
  - 32.8 percent of infants delivered by Cesarean Section.
  - 11.72 percent of infants preterm.
  - 8.1 percent of low birthweight (<2500g).
- The neonatal mortality rate in 2011 was 4.04 neonatal deaths/1,000 live births/year, resulting in ca. 24,000 deaths per year.[2]
- The leading causes of neonatal deaths are preterm related (ca. 35%) and due to congenital malformations, most commonly heart defects.[3]
- Overall, 3 percent of all infants in the US are born with a major structural or genetic birth defect.[4]

- Ten percent of newborns require some degree of assistance in the delivery room; less than 1 percent require extensive resuscitation measures.[5]

ETIOLOGY AND PATHOPHYSIOLOGY

- A baby’s due date (Estimated date of Confinement [EDC]) is calculated at 40 weeks after the Last Menstrual Period (LMP).
- A baby born at <37 weeks gestational age (GA) is considered preterm; borderline of viability is considered 22 to 23 weeks GA.
- Irrespectively of gestational age, a baby weighing less than 2500 g is considered low birthweight; less than 1500 g very low birthweight; and less than 750 g extremely low birthweight.
- Transition from intrauterine to extrauterine life.
  - Intrauterine fetal circulation (**Figure 4-2**):



Aortic arch
Superior vena cava
Foramen ovale (becomes fossa ovalis)
Inferior vena cava
Ductus venosus (becomes ligamentum venosum)
Hepatic portal vein
Umbilical vein (becomes ligamentum teres)
Placenta
Ductus arteriosus (becomes ligamentum arteriosum)
Pulmonary artery
Pulmonary veins
Pulmonary trunk
Left atrium
Left ventricle
Abdominal aorta
Left renal artery
Common iliac artery
Umbilical arteries (become medial umbilical ligaments)
Internal iliac artery
Umbilical vein
Umbilical arteries
Decreasing blood oxygen level

FIGURE 4-2 Illustration of the fetal circulation. Blood is oxygenated in the placenta, bypassing the lungs through physiologic shunts (Ductus arteriosus, Foramen ovale). (*Used with permission from Hole's* Human Anatomy and Physiology, *12e*, *McGraw-Hill*.)

- Gas exchange occurs through the placenta, which represents the path of lowest resistance in fetal circulation.

        - Non-ventilated high-resistance lungs are bypassed by the foramen ovale and the patent ductus arteriosus and receive only minimal perfusion.
    - Uncomplicated transition is characterized by:
        - Increase in systemic pressure promoted by clamping of the cord and removal of the low resistance placenta.
        - Surfactant secretion which decreases the surface tension in the alveoli.
        - Loss of fetal lung fluid.
        - Establishment of a Functional Residual capacity (FRC) facilitated by the first breaths.
        - Functional closure of physiologic shunts (Foramen ovale and Ductus arteriosus).
        - These changes result in a decrease in pulmonary vascular resistance and increase in pulmonary artery blood flow.
    - Failure of appropriate transitioning into the newborn circulation may result in Persistent Pulmonary Hypertension of the Newborn (PPHN) characterized by hypoxemia due to persistently high pulmonary vascular resistance and decreased pulmonary blood flow.

RISK FACTORS

Common prenatal factors that may result in a need for neonatal intervention at delivery or further intensive care include:

- Fetal malformations/chromosomal anomalies.
- A variety of hereditary familial disorders.
- Multiple gestation (**Figure 4-3**).

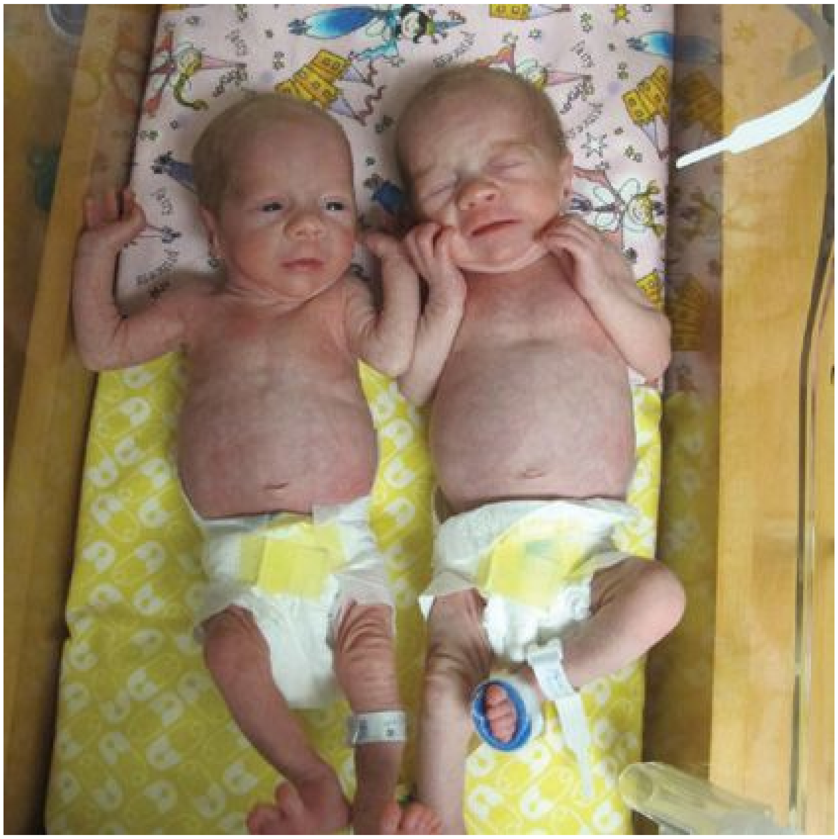


FIGURE 4-3 Monoamniotic, dichorionic twin girls with a 10 percent growth discrepancy, born premature at 31 weeks. (*Used with permission from Dr. Sabine Iben*.)

- Placental insufficiency due to maternal hypertension/preeclampsia, abnormal cord insertion, placental infarcts, chronic abruption (**Figure 4-4**).

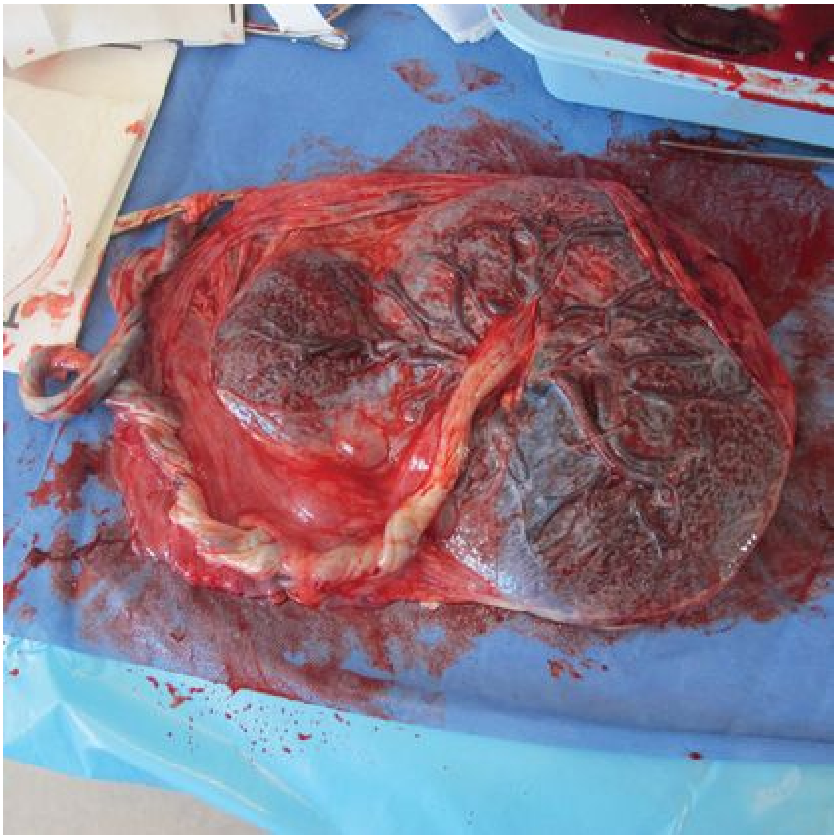

FIGURE 4-4 Bilobate placenta, rarely of clinical significance. Placental anomalies or abnormal cord insertions can be associated with poor fetal outcome. (*Used with permission from Dr. Sabine Iben*.)

- Exposure to certain maternal medications or illicit drugs.
- Poor maternal nutrition.
- Maternal obesity/diabetes.
- Poor prenatal care.
- Inappropriate fetal growth (intrauterine growth retardation or macrosomia).
- Known blood group incompatibility.
- Untreated maternal sexually transmitted diseases.
- Abnormal fetal monitoring (fetal decelerations, poor reactivity, tachycardia).

- Abnormal color of amniotic fluid (e.g., meconium as indicator of fetal distress).
- Maternal fever.
- Maternal colonization with pathogens—GBS, *Escherichia coli*.
- Prolonged rupture of membranes.
- Preterm labor.
- Abnormal fetal lie.
- Cesarean delivery.

DIAGNOSIS

Assessment of the newborn in the delivery room (**Figures 4-5** to **4-8**) include:

FIGURE 4-5 Resuscitation table set up for newborn resuscitation: heat source is turned on, several blankets prepared for drying the newborn, suction devices (bulb and wall suction), bag/mask, oxygen source and intubation equipment all available and checked. (*Used with permission from Dr. Sabine Iben*.)

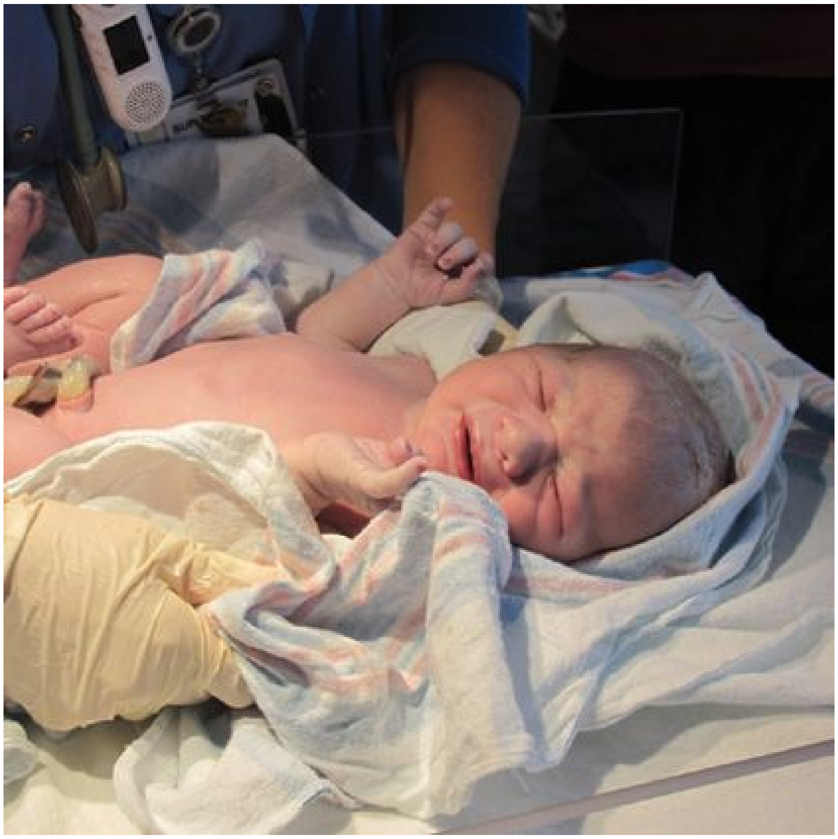

FIGURE 4-6 Vigorous newborn at 1 minute of age, no resuscitation needed other than drying. (*Used with permission from Dr. Sabine Iben*.)

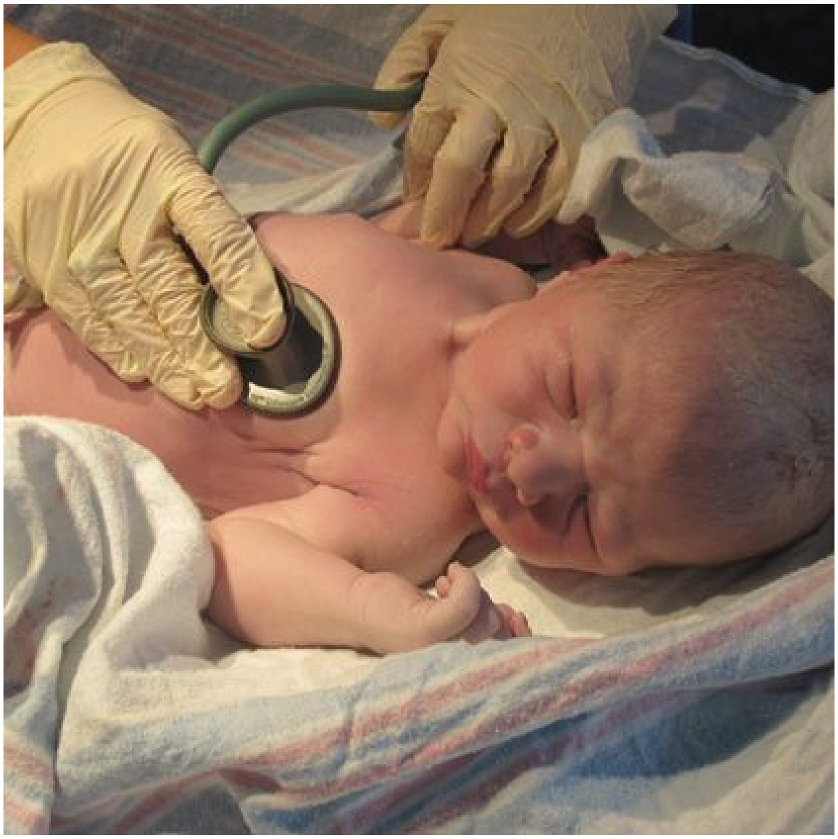

FIGURE 4-7 An initial physical examination is part of the newborn assessment. (*Used with permission from Dr. Sabine Iben*.)

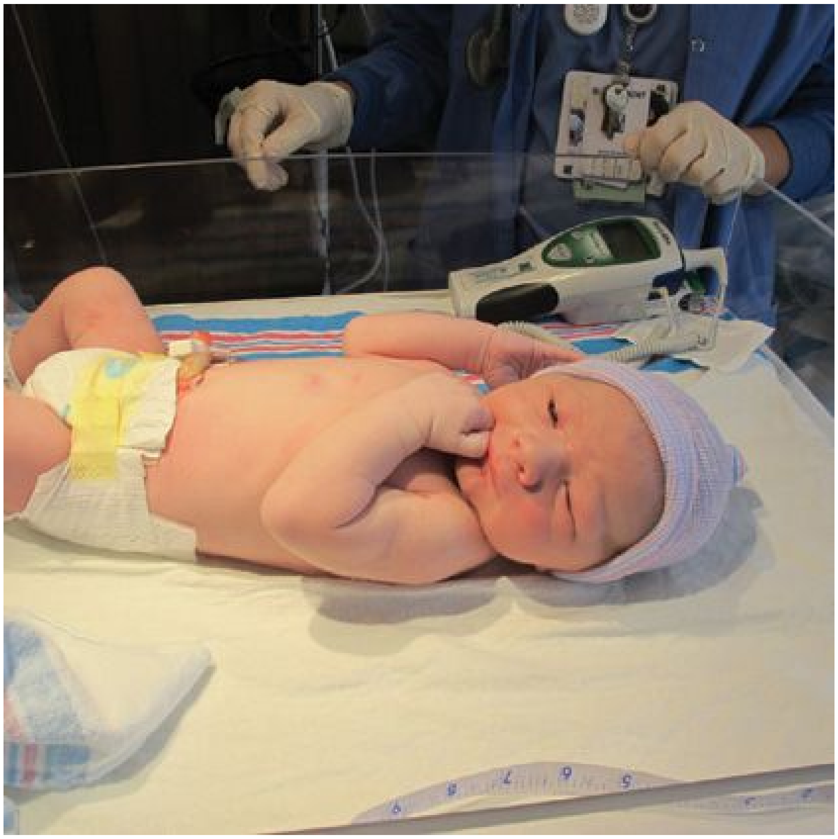

FIGURE 4-8 A hat helps to minimize heat loss. The baby is in no distress and ready to spend time with mom. (*Used with permission from Dr. Sabine Iben*.)

- Detailed maternal history.
- Determination of the gestational age by history.
- Identification of risk factors for conditions that require additional monitoring or intervention.
- Assignment of APGAR scores by the team attending the delivery:
  - At 1 minute reflecting the assessment at birth.
  - At 5 minutes reflecting the response to resuscitation.
  - At 10 minutes if score at 5 minutes is less than 7.[6]
- A cursory physical examination. Findings of a normal transition may include peripheral cyanosis and mild tachypnea.

Initial assessment in the newborn nursery include:

- Length, head circumference, and weight measurements.
- Vital signs including temperature, heart rate (HR), and respiratory rate.
- Categorization into SGA (small for gestational age, weight <10th percentile), AGA (appropriate for gestational age, weight 10–90th percentile), and LGA (large for gestational age, weight >90th percentile).
- Complete physical examination.
- Review of maternal medical history, prenatal screens, and prenatal imaging.
- Screen for hypoglycemia as indicated:
  - Infants with risk factors only, asymptomatic: 30 minutes after the first feed. Risk factors include LGA or SGA, infant of diabetic mother (IDM), and prematurity. Symptomatic infants need to be screened earlier.
  - Target glucose concentration is ≥45 mg/dl; babies should be followed before feedings for 12 (IDM) to 24 hours of life (preterm, SGA)[7]. SOR C
- Ballard exam[8] if gestational age is unknown or uncertain. Of note, gestational age is most accurately determined by early ultrasound or LMP. The estimated gestational age by Ballard exam may be inaccurate by as much as 2 weeks.
- Screening complete blood count with differential, blood culture as recommended by the CDC algorithm for prevention of early GBS sepsis[9] or if risk factors for sepsis are present.[10]
- Assess for risk factors for jaundice, which includes the verification of maternal blood type. Most facilities routinely obtain the infants blood type on cord blood, either universally or selectively if maternal blood type is O, Rh negative, or direct antibody positive.

MANAGEMENT

In the delivery room:

- Newborn resuscitation according to NRP guidelines.[11] SOR Ⓒ
- Vitamin K 0.5 to 1mg intramuscularly for prophylaxis of hemorrhagic disease of the newborn.[12] SOR Ⓐ
    - Incidence is 0.25 to 1.7 percent without prophylaxis.
    - Oral Vitamin K may not prevent late-onset hemorrhagic disease of the newborn.
- Eye prophylaxis with erythromycin 0.5 percent ointment for prevention of gonococcal ophthalmia neonatorum.[13] SOR Ⓐ
- Identification band on baby, mother, and second adult (father or other support person designated by mother).
- Application of security device/sensor if available.
- Determination of appropriate further care (newborn nursery, transitional care, neonatal intensive care unit).

In the newborn nursery:

- Recording of birth parameters on growth charts.
- Bath/sponge bath with mild, non-medicated soap after temperature is stable.
- Encourage breastfeeding and educate mothers about benefits.
- Assess for contraindications for breastfeeding (active herpes simplex virus lesions on the breast, maternal human immunodeficiency virus [HIV] infection, treatment with antimetabolites, chemotherapeutic or radioactive agents, some metabolic disorders in the infant). If in doubt, consult with lactation consultant or neonatologist:
    - Estimation of intake and output by recording duration of breastfeeding, amount of formula, number of wet diapers, and meconium.
    - Eecording of vital signs.
    - Maintain temperature.
    - Daily weight.
    - Appropriate positioning (supine on flat surface).
    - Regular assessment for signs and symptoms of withdrawal using a narcotic abstinence scoring system if exposed to opiates prenatally.[14]

  - Exam by physician at least by 24 hours of age, within 24 hours before discharge.

- Circumcision care
  - Cleaning of surgical site and application of petroleum jelly with each diaper change for 4 to 7 days after circumcision.[15]
  - Foreskin should not be forcibly retracted in uncircumcised penis. Adhesions are physiologic.

- Cord care
  - Cord should be kept clean and dry.
  - Antiseptic agents (alcohol, triple dye, chlorhexidine) not indicated in developed countries. SOR A

- Assess maternal hepatitis B surface antigen (HepBsAg) status and follow recommendations per CDC[16]; early immunization is effective in preventing acquisition of Hepatitis B. SOR A
  - If maternal screen is positive the infant will require Hepatitis B vaccine AND Hepatitis B immunoglobulin (HBIG) within first 12 hours of life.
  - If Hep B status cannot be determined within first 12 hours of life the baby will need Hepatitis B vaccine within that timeframe as well as immunoglobulin within 7 days of life if the maternal screen returns positive or remains unknown.
  - If Hepatitis B status is unknown and the baby's birthweight is less than 2000g, both the vaccine and immunoglobulin should be given within first 12 hours of life.

Some problems can be managed in the newborn nursery while many require monitoring and treatment in the neonatal intensive care unit.

- Dehydration as indicated by excessive weight loss and/or poor urine output:
  - If bottle-feeding, observe feeding technique. Consider change in nipple or feed more frequently.
  - Lactation consultation for breastfeeding moms.
  - Consider transient supplements with formula.
  - Bottle versus tube extension to the breast, finger feeding, or cup feeding.

- Jaundice

- Assess need for phototherapy (**Figure 4-9**) using American Academy of Pediatrics recommended phototherapy levels and guidelines.[17,18]

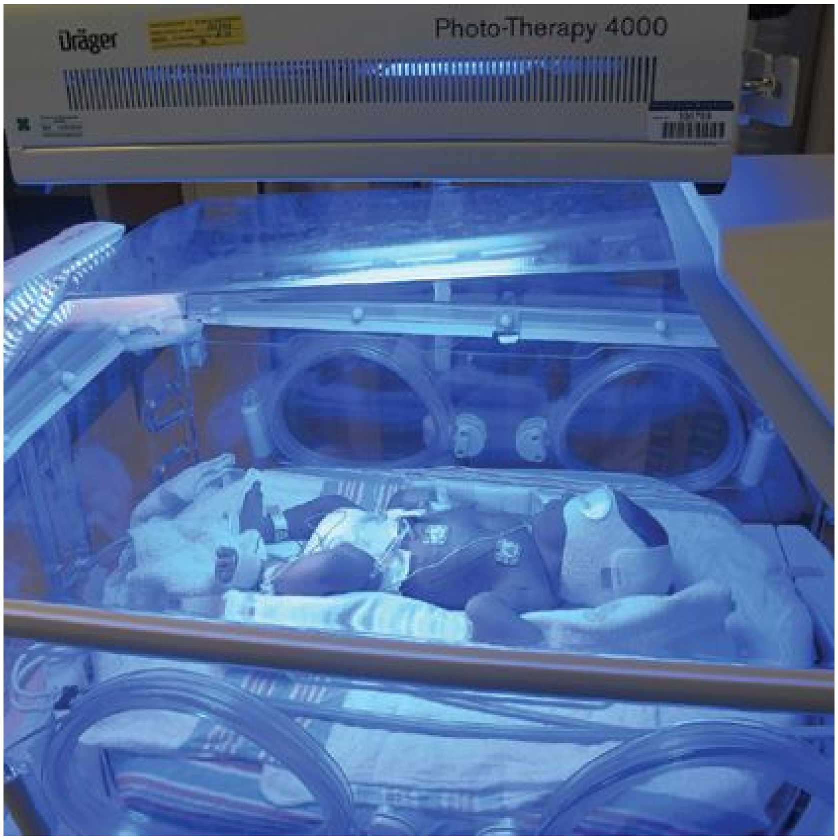

FIGURE 4-9 Maximized phototherapy in a newborn with ABO-incompatibility and hemolytic jaundice. Several banks of phototherapy may be used including a biliblanket. The baby is in an Isolette to prevent heat loss while clothing is removed to maximize exposed body surface area. (*Used with permission from Dr. Sabine Iben*.)

  - May be provided in the newborn nursery as long as there is no excessive rise and/or impending need for exchange transfusion.
  - Assure optimal skin exposure while closely monitored for hypothermia.
  - Devices include phototherapy banks and biliblankets that may provide continuous phototherapy while breastfeeding and enable maximal skin surface exposure.
  - Efficacy of phototherapy lights can be measured with a commercially available radiometer.

        - Depending on the rate of rise Serum Bilirubin should be checked every 6 to 24 hours.
        - Transcutaneous measurements cannot be used during and up to 48 hours after receiving phototherapy.
        - Eyes have to be covered with eye patches. SOR Ⓒ
        - Infant can be removed for a limited time for feeding and bonding after decrease in bilirubin is documented.
        - Dehydration should be avoided, supplementation of breastfeeding infants can be considered.

- Hypothermia
    - Investigate causes.
    - Add additional blankets.
    - Optimize environmental temperature.

- Hypoglycemia
    - Encourage oral (po) feeds, feed every 2 to 3 hours
    - Consider supplements.
    - Consider IV fluids.
    - Regular monitoring BEFORE feeds.
    - Work-up for causes of persistent hypoglycemia with endocrinology input.

- Failure to pass meconium by 48 hours.
    - Avoid rectal stimulation/suppositories.
    - Obtain plain abdominal radiograph.
    - Detailed exam to make sure anus is patent.
    - Specialty consultation (neonatology, pediatric surgery) for suspected bowel obstruction.

- Emesis
    - Assess volume/frequency.
    - Physical exam.
    - Consider radiographic studies (abdominal x-ray).
    - Bilious vs. non-bilious.
    - Bilious emesis ALWAYS requires work-up including abdominal x-ray, Upper GI, subspecialty consultation; this finding could be the only

symptom of a volvulus and may present a surgical emergency because of the risk of bowel necrosis.

- Neonatal withdrawal
  - Elevated narcotic abstinence scores on an assessment scale.[14]
  - Encourage breastfeeding.
  - Initiate comfort measures (swaddling, holding, minimal stimulation, or dark room).
  - May require pharmacologic treatment.

Discharge criteria:

- Most states and US Congress enacted legislation that ensures hospital stay for up to 48 hours for a vaginal delivery and up to 96 hours after Cesarean delivery.
- The following criteria should be met:[19]
  - Physiologic stability.
  - Family competence to provide newborn care at home.
  - Assessment of family, environmental and social risk factors with actions taken if needed.
  - Completed teaching about care of the newborn.
  - Access to the health care system and resources, follow-up appointments have been made.
  - No excessive weight loss.
  - No significant jaundice.
  - Feeding appropriately.

PREVENTION AND SCREENING

- Hearing screen.
  - The incidence of hearing loss is approximately 1 to 3/1000 newborns (20 to 40/1000 in the NICU population).
  - Benefits of early detection and intervention include higher receptive and expressive language skills.

  - Hearing screens at discharge by otoacustic emissions (OAE) or automated auditory brainstem response (ABR) are mandatory in most states[20] following the recommendations of the Joint Committee of Infant Hearing by the American Academy of Audiology.[21]
- Screening for critical congenital heart disease by pulse oximetry.
  - Recommended by Health and Human Services since September 2011 and endorsed by the AAP.[22]
  - Goal is to identify infants with critical congenital heart disease before infant becomes symptomatic, cardiac work-up is pursued after positive screen.[23]
- Newborn metabolic state screen.
  - Obtained between 24 to 48 hours of life by heelstick.
  - Included disorders vary by state.[24,25]
- Car safety seat testing for premature infants at less than 37 weeks gestational age.
  - Preterm infants are more prone to hypoxic events in a semi-upright position.
  - Car safety seat monitoring involves infant being placed in infant car seat and monitored by pulse oximetry for a set amount of time, a minimum of 90 to 120 minutes or longer if expected to spend longer periods in a car.[26]
- Initiation of Hepatitis B vaccination per CDC childhood immunization schedule.[27]
- Vitamin D supplements for breastfeeding babies (400 IU/day) to start in the first few days of life.[28]
- Male circumcision before discharge if parental preference.
  - Circumcision rates in the US vary widely by region; overall, 55 percent of newborn males are currently being circumcised.[29]
  - The American Academy of Pediatrics currently justifies a medical indication for circumcision based on preventive health benefits including a decreased incidence of urinary tract infection in first year of life, heterosexual acquisition of HIV and other sexually transmitted

diseases, and for penile cancer in circumcised males, outweighing the risks of the procedure.[30]

- Screening for developmental dysplasia of the hip by physical exam.[31] Risk factors include female gender, breech birth, or positive family history.

PROGNOSIS

- Readmission rates have been shown to be higher with earlier discharges.[32]
- Readmissions most frequently related to jaundice, dehydration, and feeding difficulties.[33]

FOLLOW-UP

Follow-up with the primary care provider within 2 to 3 days or earlier if there are specific concerns. The follow-up visit should include:

- Tracking the infant’s weight.
  - Weight loss beyond 3 days of age, >7 percent of birthweight or failure to regain birthweight by 10 days of age warrants evaluation of feeding technique/breastfeeding adequacy.
- Assessment of jaundice.
- Answering parental questions and concerns.

PATIENT EDUCATION

Routine discharge teaching should include education about:

- Appropriate urination and stooling pattern.

- Transition from meconium to yellow around 3 to 4 days of age.
- Umbilical cord, skin, and genital care.
- Temperature assessment and measurement with a thermometer.
- Signs of illness and common newborn problems.
- Infant safety and SIDS education:[34]
    - Use of an appropriate car safety seat.
    - Supine positioning (“Back to sleep”) for sleeping with supervised tummy time while awake.
    - Firm sleeping surface.
    - “Bare crib,” no loose blankets, or soft objects.
    - No positioning devices in cribs.
    - Avoid smoke exposure, alcohol and illicit drug use before and after birth.
    - Breastfeeding.
    - Avoid overheating.
    - Room sharing, but no bed sharing.
    - Pacifier use during sleep.
    - Safe handling—never shaking.
- Hand hygiene as a way to reduce infection.
- Instructions to follow in the event of a complication or emergency.

5 PEDIATRIC PALLIATIVE CARE

Brooke Johnston, MD
Denise Powers-Fabian, MSSA, LISW-S
Nancy Carst, MSW
Sarah Friebert, MD

PATIENT STORY

At 7 months of age, Blake (**Figure 5-1**) was diagnosed with a rare, progressive malignancy. His initial admission was prompted by swelling of his left lower extremity, and imaging studies revealed an extrarenal rhabdoid tumor. His family experienced a rapid indoctrination into the world of childhood cancer. Blake had a central line placed and chemotherapy begun; his parents faced the accompanying challenges of work absence, needs of their other child, the responsibilities of communicating complicated information to supportive communities, and the fear of losing their infant son. Six weeks later, Blake was admitted for emesis and the detection of brain metastases lent new gravity to his prognosis. A ventriculoperitoneal shunt was placed and bone marrow studies performed. The Palliative Care service met Blake, his parents, and 4 year-old sister shortly thereafter. Blake's family sought support in managing anticipatory grief, supporting and preparing his sister, decision-making discussions, end-of-life planning, as well as in planning for life after his death. The Palliative Care service also provided symptom control consultation for Blake's disease-related pain and agitation. Music and art therapies were helpful for diversion and expression of difficult emotions, particularly for Blake's sister. Blake received palliative chemotherapy which was temporarily quite efficacious and resulted in marked clinical improvement. He would play, smile, engage those around him, and grant his family an unexpected gift of treasured time. Between admissions for chemotherapy, his family was supported by local hospice, as well as the on-call oncology and palliative care staff. Upon admission for a fourth round of high-dose chemotherapy it became evident that the hydration therapy necessary for chemotherapy administration would worsen Blake’s already tenuous respiratory status. His parents, who had clearly expressed that they desired only therapies that would be beneficial for Blake, wished to discontinue chemotherapy. Supportive measures, including opioid treatment for pain and dyspnea, and benzodiazepine infusion for anxiety and dyspnea, were titrated to address clinical symptoms. Team members supported the family through this decision-making process, and offered discussions regarding common occurrences at the end of life. His parents elected to have Blake’s end of life in the hospital setting as they felt most comfortable with the resources there. He died peacefully in the company of his family. The Palliative Care team continues to provide bereavement support.

FIGURE 5-1 Blake was diagnosed with an extra-renal rhabdoid tumor. Blake appears healthy in his home at an early stage of his disease. His parents elected to have Blake's end of life in the hospital setting as they felt most comfortable with the resources there. He died peacefully in the company of his family. The Palliative Care team remains involved. (*Used with permission from Blake's family*.)

INTRODUCTION

Pediatric palliative care (PPC) is comprehensive, interdisciplinary, compassionate, inclusive, adaptive and effective. Ideally, it begins at the time a child or adolescent is diagnosed with a life-threatening illness (including prenatally) whether or not the etiology is completely understood. It comprises a community of professionals trained in medical, spiritual and psychosocial arenas. PPC provides support during the unpredictable course of an illness, attends to needs at the time of death, and supports grieving persons for the years leading up to and following the death of a child.

EPIDEMIOLOGY

- According to National Summary of Vital Statistics data, there were 2,437,163 deaths in the US during the year 2009.[1] Of these deaths, 48,033 were among persons under the age of 19 years.
- It is difficult to compare statistics involving pediatric deaths, as the ages of inclusion often vary. Some studies include children and adolescents up to 19 years of age, while others include participants up to 24 years of age.[2]
- Overall, deaths among children are decreasing in number in the US and worldwide.[3,4]
- Over half of all pediatric deaths occur in the first year of life.[3]
- Antepartum losses (not included in the above statistics) occur at a rate of more than one million per year. In 2008, the most recent year for which data is available, 1,118,000 pregnancies ended in pregnancy loss. Over one million pregnancies in the same year were electively terminated.[5]
- The US infant mortality rate (IMR), or total number of deaths of all children under the age of one year divided by the number of live births, was 6.39 in 2009.[1] Preliminary 2010 data predict a decrease of IMR to 6.14.[6]

  - IMR, while decreasing in the US, continues to be markedly higher among black and Hispanic populations. IMR among whites was 5.30 for the same year, while non-whites had a rate of 10.02. The highest IMR was among black families, at a rate of 12.64.[6]
  - The US has higher IMRs than Hong Kong (1.7), Ireland (3.3), Netherlands (3.8), the United Kingdom (4.7), or Croatia (5.3).[3]
- Causes of death in the US pediatric population vary with age group.
  - Congenital malformations and chromosomal abnormalities are the most frequent cause of death among infants.
  - Among children greater than one year of age, the most common cause of death is unintentional injury.
  - Malignant neoplasm is a common cause of pediatric death, particularly for children under 14 years of age, and represents the most common cause of disease-related death.
  - Homicide and suicide are the second and third leading causes of death in adolescents aged 15 to 19 years, respectively.
- Internationally, the WHO reports that:
  - Twelve million children under the age of 5 years died in 1990. In 2011, deaths in this age group declined to fewer than 7 million, a decrease of 41 percent.[7]
  - Half of these deaths occurred in India, Nigeria, Pakistan, China, and the Democratic Republic of the Congo.
  - Rates of death of children under 5 years of age have steadily decreased since 1990, by about 2.5 percent per year. The decline is associated with increasing disparity, as American and Western Pacific countries have much greater decline than African and Southeast Asian countries.
  - Worldwide, leading causes of death decreasing order are undernutrition, pneumonia, preterm birth complications, diarrhea, and malaria.[7]
  - Most recent WHO information regarding adolescent mortality is from 2004. In that year, 2.6 million persons aged 10 to 24 died worldwide, with common causes including maternal conditions (15%), traffic accidents (14% in males and 5% in females), violence (12% males), and suicide (6%).[4]
  - A 2012 report on international adolescent health observed maternal mortality as a significant contributor to adolescent mortality.

Remarkable variation in mortality rates from causes such as suicide, traffic injury and violence—even among high-income nations—was also noted.[8]

- Location of death has been shown to be important to parents of children dying with cancer Parents who have the opportunity to choose are more prepared for and comfortable with their child’s end of life.[9]
- Of children who die in the US, most die in the hospital. While the precise number of children who die at home in the US is not known, studies of children with complex chronic diseases (CCCs) have shown the number of home deaths to be increasing in that population.[10] A Canadian study of children receiving PPC, in an area offering pediatric hospice facility services, showed an even distribution of number of deaths among hospital, pediatric hospice facility and home.[11]
- In a study of Florida children who died between 2003 and 2006, 65 percent died at home. Among hospice enrollees included in the study, 55 percent died at home; 15 percent of children not enrolled in hospice died at home.[12]
- The same study showed minority populations enrolling in hospice at reduced rates when compared to whites. Authors proposed distrust, cultural insensitivity, or lack of staff diversity as causes.[12] In addition, home deaths among black and Hispanic children with chronic illness were found to be significantly fewer than those among white children.[10]
- Persons under the age of 24 accounted for 0.4 percent of the 963,000 hospice admissions in 2009.[2] A Michigan survey of pediatric providers with experience in end-of-life care cited medical and non-medical support, preparation for death, care coordination and dignified death as benefits of hospice care. Detractors were a sense of intrusion, loss of hope, and distrust.[13]
- A 2007 survey of a small number of hospice agencies showed that 78 percent of hospice agencies care for children. Over 30 percent have pediatric programs and more than 20 percent have specialized staff members who care exclusively for children.[2] An upcoming survey conducted by the Center to Advance Palliative Care (CAPC) will detail more specifically PPC services that are available in hospitals.

- It is estimated that 100,000 parents suffer the death of a child each year. Such grief has been shown to be more intense and of longer duration than that experienced when mourning the loss of a parent or spouse. Approximately 19 percent of people in the US have been affected by the loss of a child in their nuclear or extended family.[14]

ETIOLOGY AND PATHOPHYSIOLOGY

- As mentioned previously, etiologies of pediatric death vary with age group.
- Prematurity and low birth weight (LBW).
    - Following a 16-year trend of increasing frequency, the rate of preterm birth (<37 weeks gestation) in the US declined from 2007 to 2009.[1]
    - LBW incidence has not declined, likely as a result of an increase in multiple compared to singleton births, early obstetric intervention, advanced maternal age and increased utilization of treatments for infertility.[1]
- Chromosomal abnormalities and congenital malformations.
    - According to the March of Dimes, the most common serious birth defects are congenital heart defects, neural tube defects such as anencephaly and encephalocele, and hemoglobin disorders such as sickle cell disease and thalassemia. The US experienced a 46 percent decline in birth defect-related mortality between the years of 1980 and 2001. Such declines have been observed in other nations with similar income levels; 95 percent of the 3.3 million annual deaths due to birth defects occur in middle or low-income nations.[15]
    - Most deaths due to congenital heart disease occur in the first year of life or after the age of 18 years.[16] Congenital heart malformations resulted in a death rate among infants of 38.8 annually.[1] Between the years 1999 and 2006 there was a decrease in infant mortality due to congenital heart disease attributed to improved surgical and catheter-based interventions.[16]

  - Mortality due to sickle cell disease has decreased a result of identification with newborn screening and the routine administration of pneumococcal vaccine and penicillin prophylaxis.[17]
  - Neural tube defects resulted in a death rate of 5.9/100,000 live births in 2009. The rate decreased after 1998, when guidelines mandating fortification of foods with folic acid were instituted.[18]
- Unintentional injury.
  - Among persons between the ages of 1 and 19 years, the death rate due to unintentional injury declined 29 percent between the years 2000 and 2009.[19]
  - Infant deaths from unintentional injury increased, primarily as a result of the increase in incidence of deaths due to suffocation. In 2009, 907 infants died as a result of suffocation.[19]
  - SIDS, or Sudden Infant Death Syndrome, is the most common cause of sudden unexpected infant death (SUID). SIDS occurs in a child under one year of age and investigation including autopsy does not reveal an etiology.[20] Over 2000 children died from SIDS in 2009, a decrease of more than 50 percent since 1990.[20] It is believed that safe sleeping recommendations such as supine positioning have resulted in this decrease, as well as identification of tobacco smoke exposure, bed sharing, overheating, prematurity and LBW, soft sleeping surfaces, and loose bedding as risk factors.[21] In addition, accurate diagnosis of other causes such as suffocation, have caused a decline in the incidence of SIDS.[22]
  - Poisonings among 15- to 19-year-olds nearly doubled between 2000 and 2009, associated with an increase in prescription drug misuse and deaths associated with prescription drugs.[19]
  - Increased seat belt and child safety seat usage, decreases in alcohol impaired driving, improved vehicle and road design and licensing requirements are credited with a 41 percent decline in traffic-related deaths since 2000. Despite this, traffic-related deaths remain the most frequent cause of death due to unintentional injury for persons aged 5 to 19 years.[19]
  - Males and American Indian/Alaskan Natives are more likely to die from unintentional injuries and great variation in death rates exists between

    states.[19]
  - Deaths due to unintentional injuries occur more often in the US than in countries of similar economic status.[19]
- Assault
  - In 2010, the Department of Health and Human Services reported 1,537 childhood deaths as a result of maltreatment such as neglect, physical, or sexual abuse. The majority of children who died as a result of maltreatment suffered multiple types of abuse. Almost 80 percent of deaths occurred in children under the age of 4 years, with 40 percent of these in children under one year of age. Over 12 percent of families had been previously referred to Child Protective Services. Parents are most commonly the perpetrators.[23]
  - Deaths from homicide in 10 to 24 year-olds occurred at a rate of 14.1 per 100,000 in 1990. In 2009 the rate for 15-24 year-olds was 11.3 per 100,000. Males are more likely than females to commit or become a victim of homicide. Over 80 percent of homicides involve a firearm and deaths due to homicide are most common among non-Hispanic black adolescents.[24]
- Suicide
  - Suicide occurred at a rate of 10.1 per 100,000 15 to 24 year-olds in 2009.[1] More suicides are attempted by women than men, and 7 percent of high school students had attempted suicide in 2007. On the other hand, more suicide completions occur in men (24). Approximately 4,600 adolescents and young adults die of self-inflicted harm each year.[25]
  - Risk factors for suicide include a history of substance abuse, suicide of a family member, child maltreatment, physical or mental illness, isolation, and access to means of committing an act of self-harm.
  - Protective factors include support from family and care providers, problem-solving skills, and cultural or religious beliefs that preclude suicide.[26]
- Malignant neoplasms
  - Surveillance, Epidemiology, and End Results (SEER) data from 1975 to 2006 show the incidence of childhood cancer to be increasing, most

  prominently in acute lymphoblastic leukemia (ALL). Brain tumor incidence has stabilized since increasing in the 1980s.[27]
  - Prognosis is more favorable with malignancies such as ALL, NHL, Wilm’s tumor, non-CNS germ cell tumors, and Hodgkin’s lymphoma than for solid tumors such as Ewing sarcoma, rhabdomyosarcoma, or osteosarcoma.[27]
  - Overall, the survival rates for childhood cancers have been increasing for the last forty years. Of children diagnosed with a pediatric malignancy, 80 percent will survive for at least five years from the time of diagnosis.[28] This represents a 50 percent decline in death rates from childhood malignancy between 1975 and 2006.[27] These advances are attributed to the increased use of combination and multimodal therapies, enhanced knowledge regarding molecular underpinnings of malignancy, and the customization of treatment regimens including advances in imaging and neurosurgical techniques.[29]
  - With increased survival comes the reality of a new population of persons living with long-term effects of cancer treatment. Cancer survivors have an increased risk of death from cancer-related illness for as long as 30 years after diagnosis and an increased risk of death from illnesses not related to their primary oncologic diagnosis.[28]
  - Infants typically have poorer outcomes due to inadequate therapy response, increased treatment-related morbidity, and therapy limitations due to known adverse effects.[29]
  - Despite advances, most cancer deaths are due to leukemias, followed by malignancies of the central nervous system. Total deaths from childhood cancers in 2006 numbered 2,035.[27]
  - Decreased survival rates can result from unfavorable genetic features and cancer subtypes, delayed detection and decreased likelihood of receiving therapy in accordance with a pediatric treatment regimen.[29]
  - Multiple studies have described ethnic disparity in cancer survival. Proposed explanations include differences in access, genetic predisposition to unfavorable subtypes, tendency toward poor therapy response, co-morbidities, and inadequate monitoring.[29,30]

- Complex Chronic Conditions (CCCs)

  - Some studies have distinguished characteristics of deaths among children with chronic illness from those of children without health issues. The death rate among children with CCCs, such as cancer, metabolic disorders and neuromuscular disorders, is double that of age-matched peers without disease. At the same time, the number of children with CCCs appears to be increasing, largely as a result of improved technology and supportive care.[10]

DIAGNOSIS

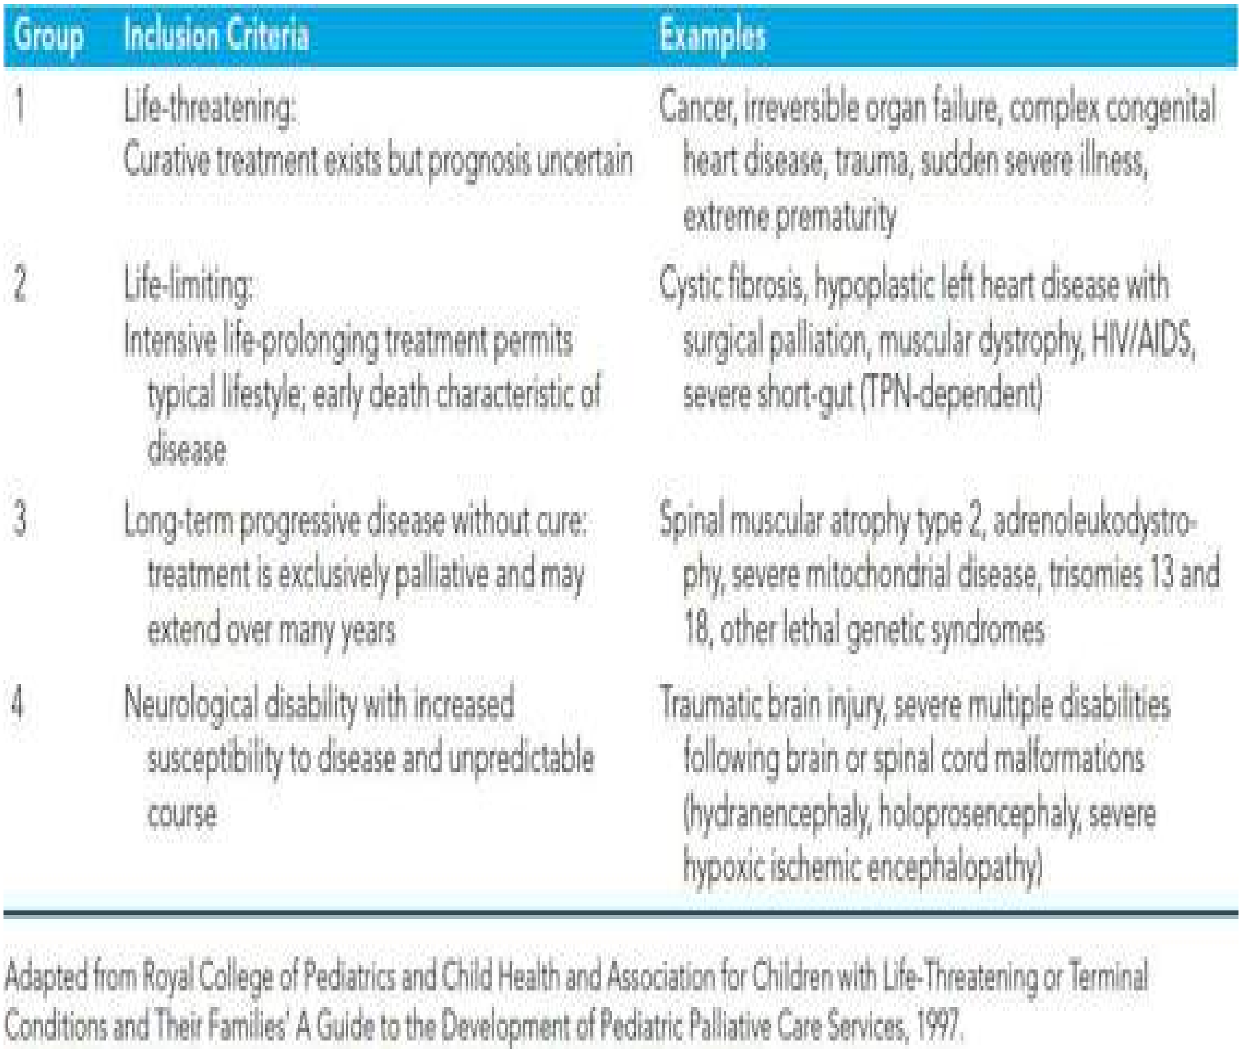
- Factors predictive of pediatric death have not yet been determined. Scoring tools such as PRISM, Pediatric Risk of Mortality Score, have accurately predicted death in some populations.[31] The tool accounts for factors such as mechanical ventilation, parenteral nutrition, vasoactive medication dependence, presence of hospital-acquired infection, and duration of hospitalization.
- A recent study of new admissions to six US palliative care programs included children with genetic/congenital (40.8%), neuromuscular (39.2%), oncologic (19.8%), respiratory 12.8%), and gastrointestinal (10.7) diagnoses[32] (**Figure 5-2**).

A

FIGURE 5-2 Brothers who died from complications of Becker's Muscular Dystrophy. The older brother Bobby (**A**) died first. The younger brother Rayshawn (**B**) having observed the decline and death of Bobby needed special support measures. (*Used with permission from Bobby and Rayshawn's family*.)

- Criteria developed in the United Kingdom by the Association for Children with Life-threatening or Terminal Conditions and their Families characterize children with life-limiting conditions into four groups by prognosis and treatment availability. See **Table 5-1** for descriptions of the categories created and clinical examples of each. Such categorization illustrates that patients and families will likely utilize palliative care services in different ways over the trajectory of their diseases and grieving processes and that each family has needs unique to the experience.[33]

TABLE 5-1 Categorization of life-limiting Illnesses in Children



Group	Inclusion Criteria	Examples
1	Life-threatening: Curative treatment exists but prognosis uncertain	Cancer, irreversible organ failure, complex congenital heart disease, trauma, sudden severe illness, extreme prematurity
2	Life-limiting: Intensive life-prolonging treatment permits typical lifestyle; early death characteristic of disease	Cystic fibrosis, hypoplastic left heart disease with surgical palliation, muscular dystrophy, HIV/AIDS, severe short-gut (TPN-dependent)
3	Long-term progressive disease without cure: treatment is exclusively palliative and may extend over many years	Spinal muscular atrophy type 2, adrenoleukodystrophy, severe mitochondrial disease, trisomies 13 and 18, other lethal genetic syndromes
4	Neurological disability with increased susceptibility to disease and unpredictable course	Traumatic brain injury, severe multiple disabilities following brain or spinal cord malformations (hydranencephaly, holoprosencephaly, severe hypoxic ischemic encephalopathy)

Adapted from Royal College of Pediatrics and Child Health and Association for Children with Life-Threatening or Terminal Conditions and Their Families' A Guide to the Development of Pediatric Palliative Care Services, 1997.

- CAPC has developed assessment tools to identify adult or pediatric patients and families who would benefit from palliative care services.[34,35]
- As illness trajectory is uncertain, particularly in pediatrics, it is essential that families are introduced to PPC at the time of diagnosis. Furthermore, early establishment of a relationship gives parents and patients access to resources for symptom management, financial and practical concerns, bereavement, decision-making and spiritual support. These services should be offered alongside curative efforts.
- Unfortunately, many children do not receive PPC until curative efforts are ceased, or until they are very near death.[36] Barriers such as uncertain prognosis, language barriers and time constraints, as well as inability of a

family to accept illness as incurable have been identified. Limited staff resources, insufficient knowledge of palliative care and absence of staff members trained in palliative care have also been identified as barriers.[37] However, it has been proposed that situations of diagnostic and prognostic uncertainty benefit greatly from early palliative care support, precisely because the disease trajectory is unknown. In addition, many illnesses are of unknown etiology and additional knowledge does not change treatment course.[38]

CLINICAL FEATURES

- Certain symptoms are common in PPC and at end of life. Estimates of prevalence vary among studies, but most frequently reported are pain, fatigue, dyspnea, anorexia and depression, nausea and vomiting, diarrhea, and constipation.[39,40] Many children also suffer from anxiety, agitation, sleep disturbances, pruritus, cough, seizures, and decubitus ulcers.[41]
- Needs of caregivers for children near the end of life are numerous. They are faced with social isolation, financial burdens, responsibilities for complicated medical care, obligations to other children and communities, as well as physical and psychological challenges that accompany their predicament.[42]

MANAGEMENT

- The following distinguish palliative care services for children from those of adults:
  - Wide range of ages and varied diagnoses, including patients with prenatal diagnoses as well as adults suffering from childhood illnesses.[2]
  - Unpredictable trajectory of illness—Due to the small numbers of children with terminal illnesses, relative to adults, it is difficult to establish standardized expectations.[2] Most children survive for more

    than a year after being referred to pediatric palliative medicine services.[32] In contrast, hospice studies have observed decreasing lengths of service, with almost 50 percent of patients dying or being discharged within 2 weeks of service initiation.[43]
    - Challenging symptom management—Many medications are not tested in pediatric populations, and their use in children is off-label. In addition, symptom assessment can be challenging because of limits in communication ability, either age-appropriate or due to disease or treatment.
    - Ethical concerns—In contrast to competent adults, a child relies upon parents or a community to make decisions in his or her best interest.[2] Children and adolescents have varying abilities to participate in decision-making regarding their care though many children desire to be active in such discussions.[44]
    - Personnel and resource needs—Children require size-appropriate equipment and personnel trained in their care. In addition, children are dependent upon others for medical as well as non-medical needs.[2] Interdisciplinary support of the child and family requires a diverse staff capable of providing spiritual, psychosocial, bereavement, medical, and decision-making support.
    - Other distinctions include a relative paucity of literature to guide assessment and management, increased use of in-home care and decreased use of long-term care facilities, loss of anticipated life of normalcy, increased use of life-sustaining technology that requires discontinuation prior to death, and varied models of care delivery.[45]

- Communication Facilitation and Decision-Making Support
    - At the time of diagnosis, establishment of a supportive therapeutic relationship involving honest, open, and respectful communication commences. Initial meetings may involve:
    - Introduction of palliative care services and staff members as well as patient and family members.
    - Opportunities for patient and/or family to share the story of their illness experience and other information about the persons involved, if desired by patient and family.
    - Information exchange. After assessing information needs, provide:
        - Name of the child’s illness and its etiology, if known.

        - Prognosis and illness trajectory.
        - Benefits and burdens associated with treatment options.
        - Symptoms and complications along with available interventions.
        - Sources of support for predicted changes in family life (38).
    - It is preferable to discuss these matters in a series of conversations, the first of which could include diagnosis and general prognosis information, as well as other information as desired by patient and family.[38]
    - Periods of silence may serve as opportunities for processing of information as well as invitations for patients and family members to express emotion, information need or other concerns.
    - It is helpful for meetings to conclude with a discussion of next steps and a plan for future communication. Thorough documentation ensures that all providers understand the plan of care and associated family priorities.
    - Clarification and reevaluation of goals of care (i.e., longevity of life, freedom from mechanical ventilation, school participation, opportunity to take a trip or experience a specific life event) may enhance the decision-making process.
    - For some parents, hope for cure is a means of coping.[46] Understanding this motivation may allow providers to identify with parents who comprehend the unlikelihood of cure but who are unwilling to discontinue curative therapies.
    - Updated advance directives reflect preferences in regard to medical treatment. Decisions may include the allowance of natural death, the discontinuation of medically-provided nutrition and hydration, continuation of antibiotic therapy to treat infection, or the refusal of chest compressions and medications for cardiac resuscitation. Preferences should be documented and shared with other medical providers, schools, and local emergency medical services.
    - Parent-child relationships continue within the context of a child’s illness. A child’s preferences may be affected by a desire to please her parents.[47] In contrast, a desire to establish control and independence may predispose an adolescent to make choices that do not mimic those of his parents.
- Psychosocial

- Families with an ill child continue to deal with demands of daily life, though now with increased financial and emotional stressors and decreased time and resources.[46] The extent to which a serious illness strains the constructs of a family system cannot be overestimated. Families encounter previously unimagined challenges to marital, sibling and parent-child relationships as well as to those with extended family and other communities. Medical expenses and missed work can result in significant financial hardship. The demands of caring for an ill child can result in decreased attention to other family members by the primary caregiver, as well as insufficient opportunity to care for him or herself.
- Support may include assistance with living expenses and transportation needs; child care, school absence and processing needs of siblings and parents as well as anticipatory grief work; work absence/Family Medical Leave Act processing; and assistance navigating the extensive web of available resources.
  - Child life specialists utilize play to facilitate communication of medical information to a patient, as well as to address anxiety of patients and siblings.[41]
  - Expressive Therapies involve writing, artwork, music, dance, spoken word, film and any medium that is meaningful to patients and families. They permit processing of difficult circumstances by individuals of differing abilities and interests. As an example, **Figure 5-3** shows prayer flags made by Brandon, a teenage patient with Spinal Muscular Atrophy. Such modalities are particularly helpful for children and patients who have communication limitations, as well caregivers facing limited time to process the coming loss.[48]

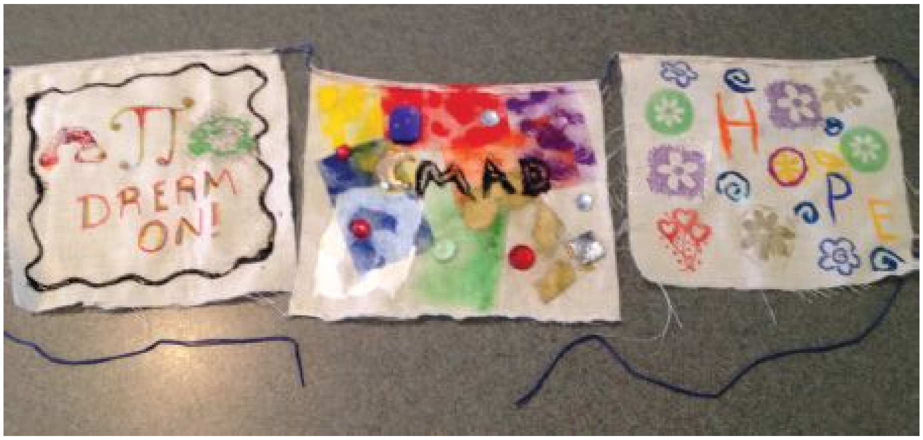


FIGURE 5-3 Prayer flags as expressive therapy for a child coping with the threat of death from an incurable disease.

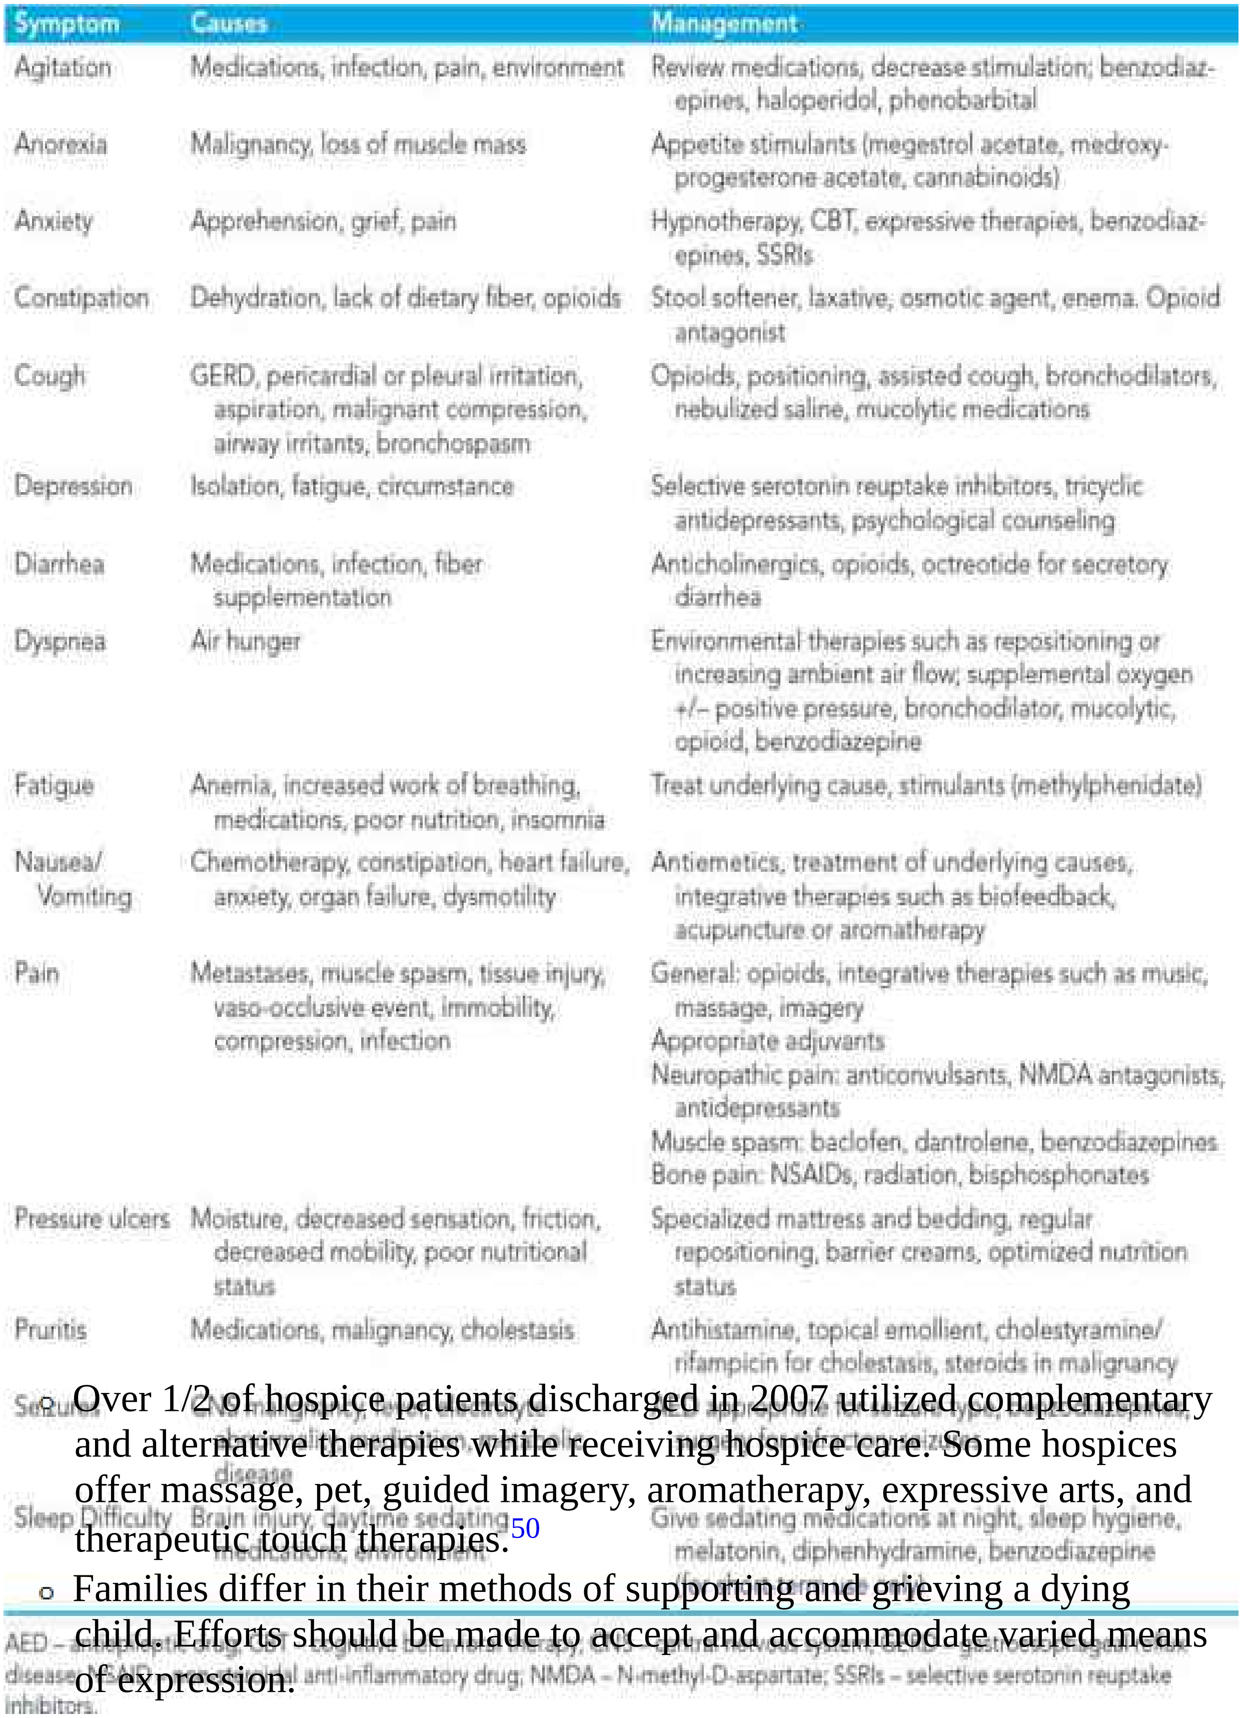
- Bereavement
    - Grief work begins at the time of diagnosis, as families mourn the loss of the life they had envisioned for themselves and their children. Bereavement specialists may establish relationships with families and begin the lifelong process of grieving. These staff members may also assist with funeral planning, sibling support, memory-making, and preparing families for what is to come. Anticipatory grief work is particularly important in families where serious illness and death has been encountered previously; for Rayshawn (**Figure 5-2B**), who knew what his future held from watching his older brother Bobby (**Figure 5-2A**) die of muscular dystrophy, nonpharmacologic outlets for his anxiety, depression and grief/loss were particularly important interventions from the palliative care team.
    - Memory-making may include tangible reminders such as plaster molds or ink prints of hands or feet, photographs of special events or family members with the child, songs, poems or writings, or videos, voice recordings and letters that allow patients to preserve special messages. See the photograph of Camden (**Figure 5-4**), who died shortly after birth, due to prenatally-diagnosed renal agenesis.

FIGURE 5-4 Camden died shortly after birth, due to prenatally-diagnosed renal agenesis. The family had this special photograph taken to provide a lasting memory of their child. (*Photo by Brent Watkins, Sylvart Studios*.)

  - Complicated grief may involve inability to engage in life activities, depression, isolation, compromised self-esteem, or even suicidal ideation.[48]

- Spiritual care
  - Staff members trained to listen and respond to spiritual concerns of patients and families may provide needed support, learn about culture-specific needs at the time of death, and provide space for discussion of difficult questions raised by such challenging circumstances.[49] In addition, some families desire baptisms, blessings or other rituals at or in preparation for the end of life or simply the presence of a spiritual care provider.
- Medical care during the dying phase involves preparation, support, and effective symptom management, and documentation of events.
  - Adequate personnel, medications and supplies will ensure timely care and enhance symptom management. For a list of common symptoms at the end of life as well as options for management, see **Table 5-2**.

TABLE 5-2 Common Symptoms in Pediatric End of Life



Symptom	Causes	Management
Agitation	Medications, infection, pain, environment	Review medications, decrease stimulation; benzodiazepines, haloperidol, phenobarbital
Anorexia	Malignancy, loss of muscle mass	Appetite stimulants (megestrol acetate, medroxyprogesterone acetate, cannabinoids)
Anxiety	Apprehension, grief, pain	Hypnotherapy, CBT, expressive therapies, benzodiazepines, SSRIs
Constipation	Dehydration, lack of dietary fiber, opioids	Stool softener, laxative, osmotic agent, enema. Opioid antagonist
Cough	GERD, pericardial or pleural irritation, aspiration, malignant compression, airway irritants, bronchospasm	Opioids, positioning, assisted cough, bronchodilators, nebulized saline, mucolytic medications
Depression	Isolation, fatigue, circumstance	Selective serotonin reuptake inhibitors, tricyclic antidepressants, psychological counseling
Diarrhea	Medications, infection, fiber supplementation	Anticholinergics, opioids, octreotide for secretory diarrhea
Dyspnea	Air hunger	Environmental therapies such as repositioning or increasing ambient air flow; supplemental oxygen +/– positive pressure, bronchodilator, mucolytic, opioid, benzodiazepine
Fatigue	Anemia, increased work of breathing, medications, poor nutrition, insomnia	Treat underlying cause, stimulants (methylphenidate)
Nausea/ Vomiting	Chemotherapy, constipation, heart failure, anxiety, organ failure, dysmotility	Antiemetics, treatment of underlying causes, integrative therapies such as biofeedback, acupuncture or aromatherapy
Pain	Metastases, muscle spasm, tissue injury, vaso-occlusive event, immobility, compression, infection	General: opioids, integrative therapies such as music, massage, imagery Appropriate adjuvants Neuropathic pain: anticonvulsants, NMDA antagonists, antidepressants Muscle spasm: baclofen, dantrolene, benzodiazepines Bone pain: NSAIDs, radiation, bisphosphonates
Pressure ulcers	Moisture, decreased sensation, friction, decreased mobility, poor nutritional status	Specialized mattress and bedding, regular repositioning, barrier creams, optimized nutrition status
Pruritis	Medications, malignancy, cholestasis	Antihistamine, topical emollient, cholestyramine/ rifampicin for cholestasis, steroids in malignancy
Seizures	CNS malignancy, fever, electrolyte abnormalities, medication, metabolic disease	AED appropriate for seizure type, benzodiazepines, surgery for refractory seizures
Sleep Difficulty	Brain injury, daytime sedating medications, environment	Give sedating medications at night, sleep hygiene, melatonin, diphenhydramine, benzodiazepine (for short-term use only)

AED – antiepileptic drug; CBT – cognitive behavioral therapy; CNS – central nervous system; GERD – gastroesophageal reflux disease; NSAID – nonsteroidal anti-inflammatory drug; NMDA – N-methyl-D-aspartate; SSRIs – selective serotonin reuptake inhibitors.

- Over 1/2 of hospice patients discharged in 2007 utilized complementary and alternative therapies while receiving hospice care. Some hospices offer massage, pet, guided imagery, aromatherapy, expressive arts, and therapeutic touch therapies.[50]
- Families differ in their methods of supporting and grieving a dying child. Efforts should be made to accept and accommodate varied means of expression.

  - In some cases, allowance of a natural death involves discontinuation of life-sustaining therapies that are no longer beneficial. Benefits and burdens of mechanical ventilation, medically-provided hydration and nutrition, chemotherapy regimens, dialysis, and other interventions should be discussed with patients and families.
  - Also considered is the desired location for death. Planned discontinuation of no-longer beneficial life-sustaining therapy may occur in a private area of a hospital, allowing families time during and after death to be with their loved one. With the help of an area hospice or other service provider, the process can occur in the home as well. Whatever the setting, it is essential to anticipate symptoms likely to accompany the change in support and ensure access to appropriate treatments.

- Pronouncement of death entails confirmation of patient identity and a physical exam to confirm lack of response to respectful tactile stimulation, absent pulse, respiratory effort, or pupillary response.
- Documentation requirements vary by state. In general, a death certificate must be completed by a physician and include cause of death and time of death recorded. A note recording end-of-life events is also crucial.
- Autopsy regulations also vary according to location. However, in situations of unexpected death, suspected harm, or unknown cause of death, an autopsy will likely be required. Regardless of regulations, families should be offered an autopsy; autopsies can answer families' questions regarding cause of death and indicate if testing of family members is indicated.[51]

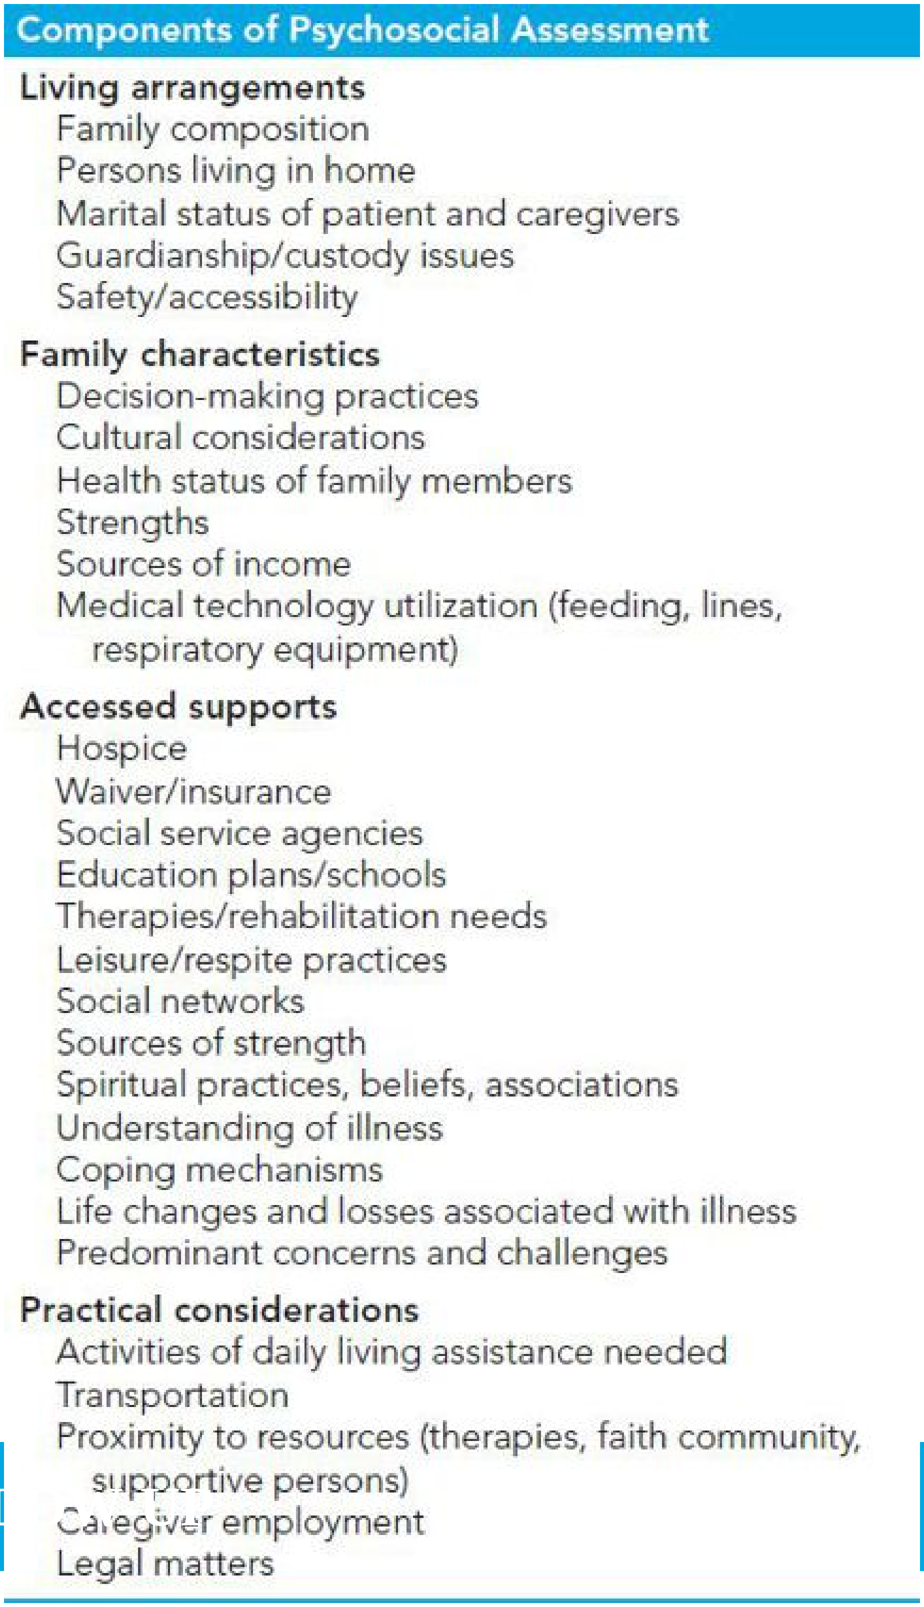
PATIENT AND FAMILY EDUCATION AND SUPPORT

- Communicating with children about death—be they a patient, sibling, or friend of a dying child—involves assessing what they already understand and what they wish to know.[51] Expressive arts, role-playing and play-based therapies can be helpful. It is of note that withholding information may produce more anxiety in children, who are apt to create their own explanations for what they observe.

- Persons caring for children at the end of life are susceptible to guilt and exhaustion. The stressful circumstance can exacerbate existing struggles such as marital or financial strain. Caregivers may be responsible for other children or family members. Respite services provided by facilities or community members may relieve some of this strain. Caregivers may also be helped by supportive providers who identify home health, transportation, financial, and spiritual resources that meet existing and future needs.[52]
- Numerous challenges face siblings of an ill child, including divided parental attention, travel for hospitalization(s), guilt, fear of “catching” the illness, embarrassment, social isolation and lifestyle change, and observing sibling suffering.[52] Helpful interventions can be designed to fit a sibling’s developmental level and needs. Conversations to discuss information at the sibling’s level of understanding are helpful, some with parents and some with trusted team members such as bereavement coordinators, child life specialists, or medical care providers, including the child’s primary care physician. Maintenance of these relationships after the death is helpful as siblings re-experience their grief through stages of development. Siblings may also benefit from support groups, appropriate engagement in research and decision-making, memory-making, or simply the option to participate in activities that were important prior to life changes due to illness.[52]
- The network of available resources for families with dying children is extensive and complicated. Financial difficulties can result from medical expenses and the need to cease working to care for an ill child. Families dealing with illness also need services related to respite care, home nursing, housing that can accommodate medical equipment, child care for siblings, and transportation. Some things that a child wishes to accomplish before his or her death are facilitated by wish organizations or local charities.[52] In short, families who have had adequate resources for their life before illness often find these same resources insufficient for their “new normal.” Contact information for organizations and information sources are listed in the resources sections later in this chapter.

- Advance directives discussion tools such as “My Wishes” booklets facilitate communication about a child’s preferences regarding treatment plans, comfort measures, how a child would like to be treated by those around him or her and what the child would like to communicate to caregivers and loved ones.[53]
- Families may benefit from descriptions of what the child will look like, what symptoms he/she may experience (color change, noisy breathing, gasping) and how family members may support him/her during the dying phase. Soliciting specific concerns will allow them to be addressed adequately.
- Organ donation is an option that may benefit families of eligible donors. Deaths of patients desiring to donate heart valves and cornea tissue may occur at home; if donation of solid organs is desired the death must occur in the hospital.[54]
- Primary medical doctors (PMDs) can be a resource for families of children with serious illness. Small studies suggest that PMDs play a diminished role, likely due to assumption of care by hospital-based physicians and lack of training in end-of-life care for primary medical doctors. However, funeral attendance and attention to grieving siblings were noted as significant by some parents.
- Hospice services offer extensive support and assistance with medical and psychosocial needs. With the passage and upholding of the Patient Protection and Affordable Care Act, children receiving Medicaid are eligible for the hospice benefit even if receiving curative therapies. This is substantially different from the restrictions upon adults receiving hospice care, who exclusively receive supportive care.
- A list of considerations for psychosocial assessment for a family of a child with life-threatening illness is found in **Table 5-3**.

TABLE 5-3 Components of Psychosocial Assessment for Families of a Child with Life-Threatening Illness



Components of Psychosocial Assessment

Living arrangements
- Family composition
- Persons living in home
- Marital status of patient and caregivers
- Guardianship/custody issues
- Safety/accessibility

Family characteristics
- Decision-making practices
- Cultural considerations
- Health status of family members
- Strengths
- Sources of income
- Medical technology utilization (feeding, lines, respiratory equipment)

Accessed supports
- Hospice
- Waiver/insurance
- Social service agencies
- Education plans/schools
- Therapies/rehabilitation needs
- Leisure/respite practices
- Social networks
- Sources of strength
- Spiritual practices, beliefs, associations
- Understanding of illness
- Coping mechanisms
- Life changes and losses associated with illness
- Predominant concerns and challenges

Practical considerations
- Activities of daily living assistance needed
- Transportation
- Proximity to resources (therapies, faith community, supportive persons)
- Caregiver employment
- Legal matters

FOL

- Ensure private space for caregivers to spend final moments with their child, as this is a valuable part of the grieving process. They may appreciate the opportunity to bathe, dress, or simply hold their child.[48,55]

- After the death of a child, families experience a drastic change in relationship to providers who were involved.[48] It may be appropriate for a member of the staff to contact the family a few days after the death. Some sources recommend phone calls or visits at predicted intervals such as 3 months, 6 months, 1 year, and beyond as families desire.[42] Continued support may take the form of funeral attendance, phone calls, letters commemorating a birthday or day of death, or hosting an annual memorial service for grieving families.
- Subsequent meetings may include autopsy review, discussions regarding the death of a child and the care received, opportunities to share a child's story with new staff members or learners, or conversations with subspecialty providers involved in a child's care.

CONCLUSION

Children with life-threatening conditions and their families are likely to encounter physical, psychosocial, spiritual, emotional, and practical challenges. Interdisciplinary PPC services offer support for families facing such challenges and are integral whether illness ends in cure or death and bereavement. PPC involvement beginning at the time of diagnosis provides an extra layer of support for children and families throughout their difficult journeys.

6 SOCIAL JUSTICE

Mindy A. Smith, MD, MS
Richard P. Usatine, MD

> *Of all the forms of inequality, injustice in health care is the most shocking and inhumane.*
>
> —Martin Luther King, Jr.

> *The first question which the priest and the Levite asked was: "If I stop to help this man, what will happen to me?" But? … the Good Samaritan reversed the question: "If I do not stop to help this man, what will happen to him?"*
>
> —Martin Luther King, Jr.

PATIENT STORIES

At only 5.5 pounds (10 pounds less than the fifth percentile for weight on the World Health Organization's growth chart), an 8-month-old boy suffered from severe malnutrition. In the summer of 2003, amidst the height of Liberia's civil war, his aunt brought him to the Médecins Sans Frontières/Doctors Without Borders hospital for treatment. Because of the war, his family had been forced to flee from their home, leaving behind their usual methods of getting food. Dr. Andrew Schechtman was there to help the day the child was brought to the clinic in Liberia (**Figure 6-1**). Despite the best available treatment for the malnutrition and concurrent pneumonia, the boy died on his third hospital day.

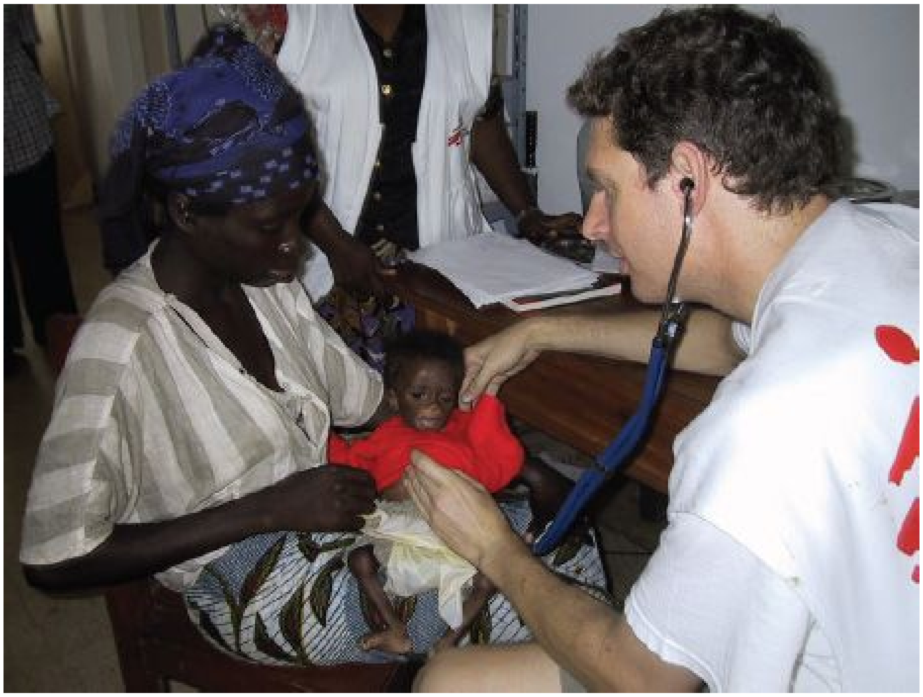

FIGURE 6-1 Dr. Andrew Schechtman was there to help the day a severely malnourished child was brought to the clinic in war-torn Liberia. Despite the best available treatment that could be provided in the Doctors Without Borders hospital, the child died of complications of malnutrition and pneumonia—a casualty of war and poverty. (*Used with permission from Andrew Schechtman, MD*.)

OUR STORIES AS CARING CLINICIANS

Those of us who become pediatricians or other health care providers do so for many reasons. One reason is because of a desire to help someone else. Along the way, we sometimes lose ourselves in the day-to-day struggles, disappointments, obligations, fatigue, and the profound helplessness that descends upon us after a particularly bad day. But we are still here, and if we listen with our hearts we are still capable of great and small things.

We are privileged in so many ways and we must recognize our power over ourselves and over the communities that we serve. It is easy to become overwhelmed by the problems that we face as clinicians and as fellow human beings. Our health care system is in shambles, our natural world is being poisoned, our nations are continually at war, and yet, as this chapter highlights, there is so much that we can do—we can listen, we can observe, we can witness, we can bring aid, we can touch, we can love, and we can lead.

The text that follows highlights just a few examples of the ways in which our colleagues are challenging themselves to find creative solutions to the many problems faced by those who are underserved, displaced, or suffering.

DOCTORS WITHOUT BORDERS (ANDREW SCHECHTMAN, MD)

EPIDEMIOLOGY

The United Nations (UN) High Commissioner for Refugees reported that in 2011 there were 10.9 million refugees (those displaced across an international border) and 27.5 million internally displaced persons (IDPs, those displaced within their own country).[1] At the end of 2010, the UN refugee agency was caring for an estimated 14.7 million of these IDPs. During times of a complex humanitarian emergency (defined as a humanitarian crisis in a country, region, or society where there is a breakdown of authority resulting from internal or external conflict and which requires an international response that goes beyond the mandate or capacity of any single agency and/or the ongoing UN country program), the following usually occur:[2]

- Civilian casualties.
- Populations besieged or displaced.
- Serious political or conflict-related impediments to delivery of assistance.
- Inability of people to pursue normal social, political, or economic activities.
- High security risks for relief workers.

ETIOLOGY

People can be displaced from their homes by manmade (war or persecution) or natural disasters (tsunami, earthquake, or hurricane). War is responsible for most of the displacement. Some of the source countries accounting for the most refugees are Afghanistan, Sudan, Somalia, the Palestinian territories, and Iraq.

- Communicable diseases usually cause the most illness and deaths in humanitarian emergencies in less-developed countries. Children younger than 5 years of age are the most vulnerable.[2] Other priority areas include provision of adequate safe water, food, shelter, and protection from violence.
- In addition to the usual causes of illness and death in emergency-affected populations in less-developed countries (measles, malaria, pneumonia, and diarrhea), crowded settlements may be prone to outbreaks of cholera, meningitis, and other diseases, which can be rapidly spread. Such outbreaks may be explosive and cause many deaths in a relatively short period of time.

PROBLEM IDENTIFIED

In times of stability, writes Dr. Andrew Schechtman, many of the poorest people in the world succeed in their struggle to meet basic needs for shelter, food, and water. When displaced from their homes by manmade or natural disaster, communities and extended families are disrupted, access to food and water are lost, and marginal circumstances become desperate. Displaced people are often dependent on the support of the international aid community to meet their basic needs.

BEING PART OF THE SOLUTION

When infrastructure collapses as a result of manmade or natural disasters, access to health care can be limited or nonexistent. Serving as a volunteer physician with Médecins Sans Frontières (Doctors Without Borders) allowed Dr. Schechtman to provide medical care to people in desperate circumstances who had nowhere else to turn for assistance. Bearing witness to tragedies such as the case described in **Figure 6-1** gave him another means to help, that is, the authority to speak out on behalf of victims like this child, focus public attention on the situation, and encourage political pressure to bring the fighting to an end.

GLOBAL HEALTH: PERU HEALTH OUTREACH PROJECT (SANGEETA KRISHNA, MD)

EPIDEMIOLOGY

Global health can be defined as the health of populations, which transcends national and international borders. As such, global health involves the perspectives of economics, epidemiology, medicine, public health, and many of the social sciences for measuring, understanding, and providing care to improve health and achieve equity in health for all people. The health issues faced on a global scale are staggering. Worldwide, one billion people lack access to health care systems.[3] Non-communicable diseases such as cardiovascular disease, cancer, chronic lung disease, and diabetes cause about 36 million deaths per year, and communicable diseases including AIDS/HIV, tuberculosis, malaria, and measles cause about 6.7 million deaths annually. Over 7.5 million children under the age of 5 years die from malnutrition and mostly preventable diseases each year.[3]

Global health experiences can complement and enhance physician training in many ways. For the student, these experiences can bring new interpersonal and technical skills, teach cultural competency, and enhance their knowledge base about health issues faced by their host country and management of many of these health problems. Students express great interest in these experiences. In a survey of medical students at Sanford School of Medicine, University of South Dakota, almost 95 percent of students indicated they were either very interested or somewhat interested in serving internationally during medical school or later during their career.[4] Following these experiences, students report having greater clinical skills, being more culturally competent, and are more likely to choose a primary care specialty and/or a public service career.[5,6]

ETIOLOGY

Peru, as the host country, is a nation of 29,988,000 people. The gross national income per capita is $9,440, making it one of the poorest nations in the region. Peru's total per capita expenditure on health also falls far below its neighbors, by nearly tenfold, and the health workforce of 9.2 physicians per 10,000 population and 12.7 nurses and midwives per 10,000 population is inadequate to meet the nation's health care needs. Based on the World Health Organization database, more people die of communicable disease in Peru than the regional average (37% versus 20%, 2008 data) and the probability of dying under age 5 years, although greatly improved since 1990 is 18/1000 live births, similar to the regional average. Communicable diseases such as infectious diarrhea, tuberculosis, hepatitis, dengue fever, and typhoid fever are widely seen, and malaria, bartonellosis, leishmaniasis, and yellow fever are endemic in specific areas of the country. All are potentially preventable through vaccinations and preventive health measures.

As global citizens, we can't ignore these health issues, particularly those of us in wealthier nations living in relative affluence. The brave among us actively work for change. While many schools offer global health experiences, the challenge to educators in the academic institution, medical care providers in the host country, and policy makers is to create regulatory frameworks and curricula that are current and relevant.[8] This requires a level of understanding of globalization on medical education, and the underlying ethical, cultural, and health issues to prepare students for the planned experience and to practice competently in a globalized world. The following should be considered in creating global health electives for medical students or residents:

- Balancing the provision of a fulfilling educational experience with honoring the integrity of medically underserved populations.[9]
- Offering training that is appropriate for the educational level of the learner, and different types of training for the types of physicians preparing to work in the global health community—the “globalized doctor,” “humanitarian doctor,” and the “policy doctor.”[10]
- Taking the time to observe and study the structure and function of the health care delivery system in the host country.
- Considering the safety of the health team, travel and lodging, and adequately preparing them prior to going to the host country on the nature of the host country culture, health care system, and assignment site.[11]
- Securing financial support.
- Preparing participating faculty members, who may have limited experience, to enable them to support and guide students during their global experience.

PROBLEM IDENTIFIED

Dr. Krishna’s involvement in “global health” began when, as a medical student in India, she witnessed a cholera epidemic in the neighboring country of Bangladesh. Overnight there was an influx of sick, dehydrated refugees at the doorsteps of the hospital where she was training. Intravenous lines were inserted before histories were taken. As the epidemic spread into the local communities, the vaccine fell into short supply and populations at risk received only one dose instead of the 2 recommended doses of Cholera vaccine. This left her with many unanswered questions regarding the efficacy of a single vaccine dose, the ethics of “good enough,” and how to dive into such issues when the opportunity arose. Now on staff at the Cleveland Clinic, Dr. Krishna had the opportunity to participate in and subsequently direct the Peru Health Outreach Project (PHOP), a formal elective for medical students at her institution.

BEING PART OF THE SOLUTION

The PHOP was started in 2007 by four medical students at the Lerner College of Medicine (Cleveland Clinic) and Case Western Reserve University School of Medicine. The mission of this student-led staff-mentored project is to collaborate with health care professionals in Peru to provide ethical and sustainable medical care to the underserved in the Sacred Valley of Peru. Since inception, it has continued to grow exponentially due to student interest and participation. Students participate in clinics; vision screening; well child checks (**Figures 6-2** and **6-3**); diabetes screening; counseling regarding hygiene including dental, lifestyle modifications, healthy diet; prophylaxis for Vitamin A deficiency (**Figure 6-4**); and research. In collaboration with physicians in Peru, the students also organize and hold a 2-day educational symposium for local health care workers. Speakers have included staff members and students with topics ranging from CPR to recognition of high-risk pregnancies and common respiratory illnesses in children.

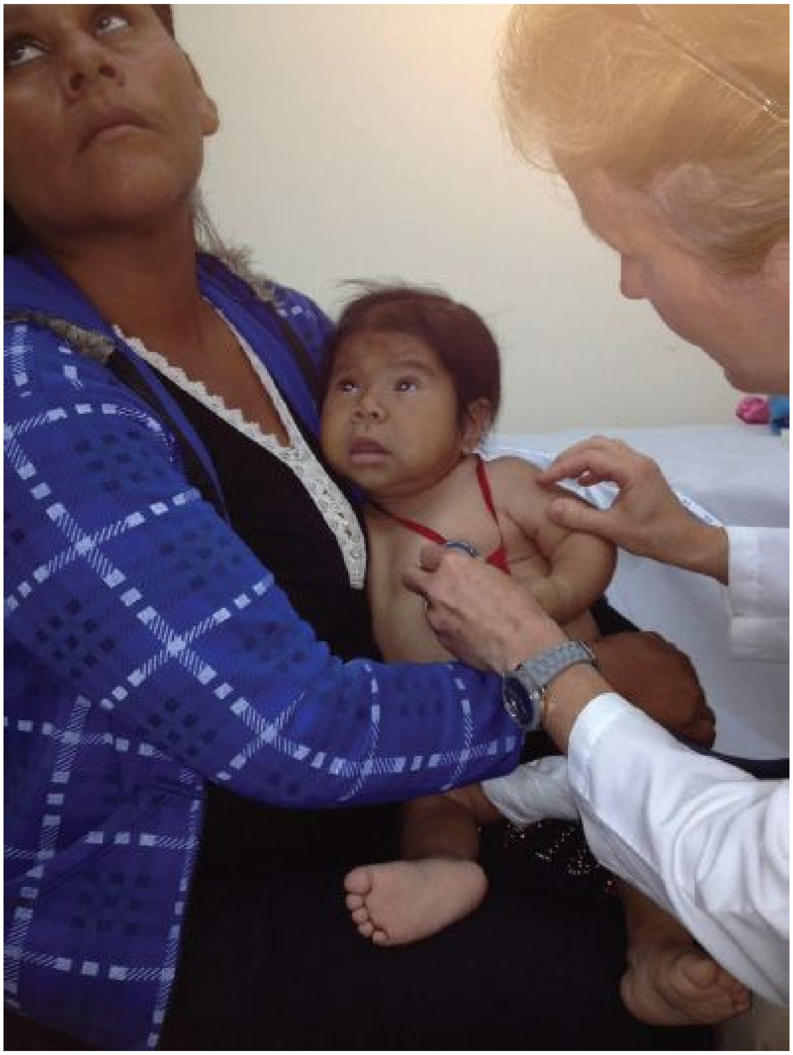

FIGURE 6-2 A 3-year-old girl with no prior medical care arrived at the free clinic in Chincha, Peru. She was unable to sit up without support, or say a few words. Her exam was significant for global developmental delay, hypotonia and an umbilical hernia. An elevated TSH, which was obtained at a subsidized price by the clinic, confirmed our suspicion of congenital hypothyroidism. She was referred to an endocrinologist in a tertiary care hospital in the capital city of Lima and started on thyroid hormone supplement. (*Used with permission from Sangeeta Krishna, MD*.)

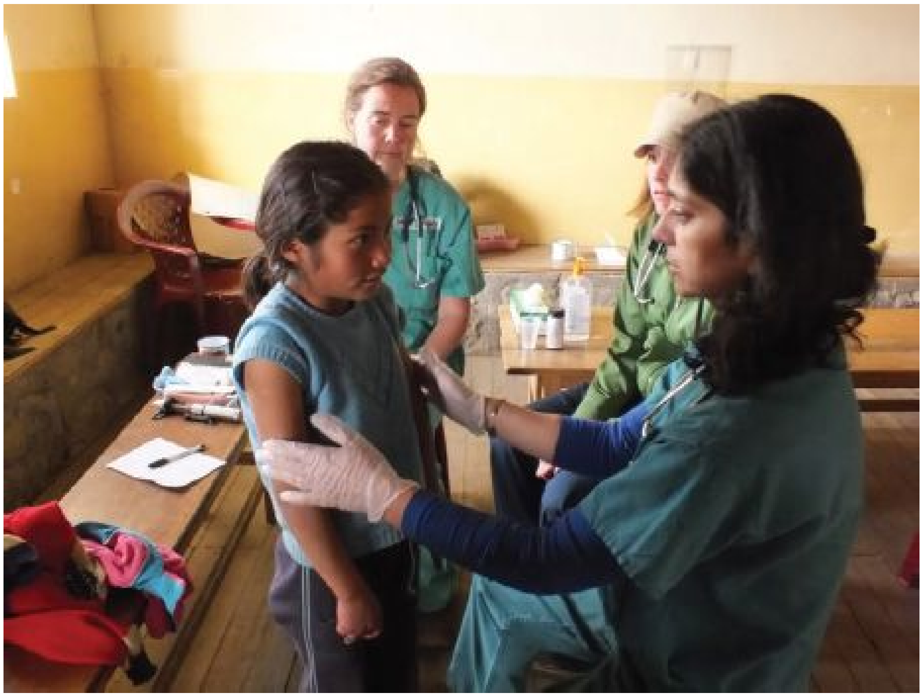

FIGURE 6-3 Dr. Sangeeta Krishna is examining an 11-year-old girl from a remote community of 200 people in Andean Peru where a health care worker was available only once a year. She had been involved in an accident that left her left arm partially paralyzed. She lacked access to medical care for years. She was taught strengthening exercises with the help of a physical therapist. (*Used with permission from Sangeeta Krishna, MD*.)

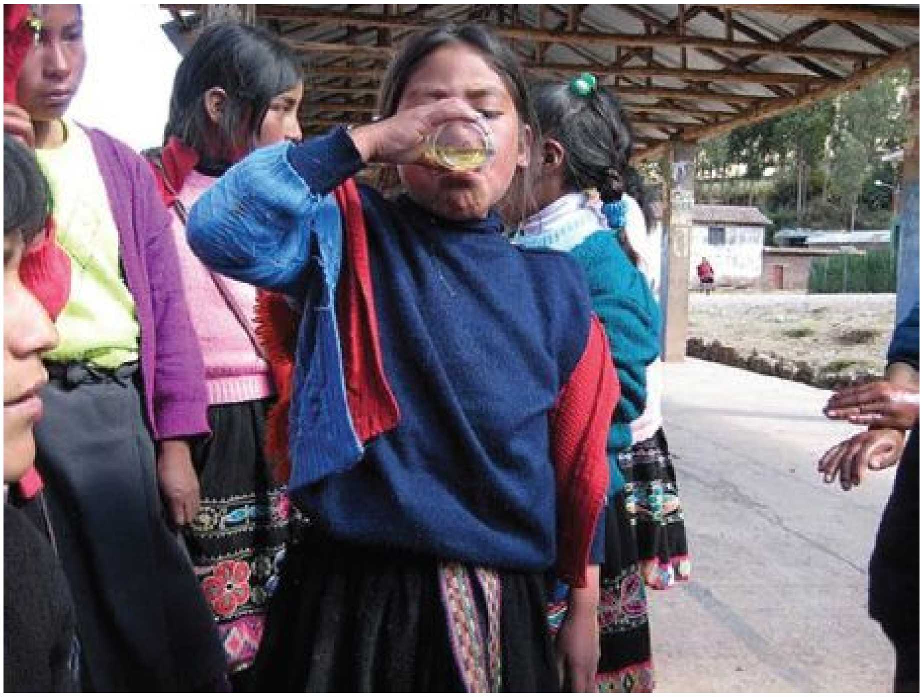

FIGURE 6-4 Vitamin A prophylaxis being provided for the schoolchildren of this remote Peruvian village. Vitamin A deficiency is common in developing countries and can result in blindness along with an increased risk of infection and death. (*Used with permission from Sangeeta Krishna, MD*.)

Students continue to provide very positive feedback from this elective. As one student wrote, “I learned a great deal about cross-cultural communication and humility. In terms of global health, I’ve learned that there’s a lot that needs fixing out in the world, particularly in the Sacred Valley of Peru, and that we need to search for a sustainable mechanism to help that involves and empowers the local residents to take charge of their own health and that of their neighbors. In terms of leadership, I’ve learned a lot about working with a team of people from all different backgrounds toward a common goal. I’ve learned that it can be extremely challenging at times but that the best way to come to a compromise is to encourage and use effective communication. Overall, I would say the Peru Trip has been one of the greatest learning experiences for me during my first two years of medical school, teaching me lessons I will take with me through the rest of my career and life. It has been truly life-changing.”—Andrea Grosz, Case Western Reserve University School of Medicine, class of 2014.

The Project leadership has also established a seminar series at the Cleveland Clinic for the benefit of current and future participants addressing topics such as ethics in clinical practice and research, cultural sensitivity, and exploring the standards of care in international rural outreach clinics. Speakers include experienced residents, Fellows, invited faculty from the local institutions, and Case Western Reserve University.

Dr. Krishna warns that these experiences just might change your life! Involvement in this work can be humbling, meaningful, and fulfilling. There are unexpected ethical dilemmas along the way, with no right or wrong answers necessarily. We strive not to set standards and expectations that cannot be sustained by us or the host community when we leave. Understanding the local health system, making appropriate contacts in the community and getting the support of local health authorities are vital to success. Staying aware of ethnocentricity, of the “mzungu” effect, studying the culture, and understanding local factors affecting health and illness are not an option, they are a necessity (mzungu is an African word for a white person). Empowering the community is the ultimate goal. Research if undertaken, should be such that it is acceptable to the community, respectful, and the results should be fed back to “close the loop” and hopefully drive local health care policy decision. Intervention based on the research builds community trust. Above all, we should strive to do no harm.

INTERNATIONAL HUMANITARIAN EFFORTS: ETHIOPIA (RICK HODES, MD)

EPIDEMIOLOGY

Chronic food deficits affect about 792 million people in the world, including 20 percent of the population in developing countries. Malnutrition greatly increases the risk of disease and early death, particularly in young children where protein-energy malnutrition plays a major role in half of all deaths of children under age 5 years annually in developing countries.[12] Worldwide, malnutrition affects one in three people and is especially common among the poor and those with inadequate access to health education, clean water, and good sanitation. About 26 percent of children with protein-energy malnutrition live in Africa. Severe forms of malnutrition include marasmus, iodine deficiency, which can result in cretinism and irreversible brain damage, and vitamin A deficiency, which can result in blindness and increased risk of infection and death.[12]

Worldwide, 2.4 billion people will remain without improved sanitation in 2015 and in 2011, 768 million people relied on unimproved drinking-water sources. In most of Africa, sanitation coverage is less than 50 percent.[13] Ethiopia and its neighbor Somalia are among the few remaining countries in Africa with <50 percent of the population using improved sources of drinking water.[13] Piped drinking water supplies, associated with the best health outcomes, are present for only 1 to 10 percent of Ethiopia's population.

ETIOLOGY

Ethiopia has a population of over 91 million people. The gross national income per capita is $1100, making it one of the poorest nations in the world. The probability of dying under age 5 years is 68/1000 live births, in part due to the low percentage of women attending antenatal care and only 10 percent of births being attended by skilled health personnel.14 The health workforce is nearly nonexistent with 0.3 physicians per 10,000 population and 2.5 nurses and midwives per 10,000 population. Health problems in Ethiopia include maternal mortality, malaria, tuberculosis and HIV/AIDS compounded by malnutrition and lack of access to clean water and sanitation.

PROBLEM IDENTIFIED

Rick Hodes is a physician who has lived and worked in Ethiopia for over 20 years. As an Orthodox Jew, he always aspired to serve others and even as a child, his favorite books were about doctors who went to remote places to help people. He first went to Ethiopia in 1984 to do famine relief work. His experience of working at a mission in Ethiopia run by Mother Theresa changed his life. He returned to Ethiopia on a Fulbright Fellowship and in 1990 was hired by the American Jewish Joint Distribution Committee as the medical adviser for the country. His original position was to care for 25,000 potential immigrants to Israel but he is continually drawn back to Ethiopia to provide care to patients. When asked once if he would prefer to work in the US rather than Africa with its poverty and lack of resources, Hodes said, “It would be less frustrating—but it would also be less inspiring.”

BEING PART OF THE SOLUTION

As senior consultant at a Catholic mission, Dr. Hodes helps patients with heart disease (rheumatic and congenital) (**Figure 6-5**), spinal disease (TB and scoliosis) (**Figures 6-6** and **6-7**), infectious disease (**Figure 6-8**) and cancer. He has worked with refugees in Rwanda, Zaire, Tanzania, Somalia, and Albania in addition to Ethiopia. Dr. Hodes is part of a team at the American Jewish Joint Distribution Committee (JDC), a Jewish humanitarian assistance organization founded in 1914 that provides needed services in more than 70 countries. Among his JDC duties has been providing medical care for thousands of Ethiopian Jews preparing to immigrate to Israel. In addition to its assistance to the Ethiopian Jewish community, the JDC has served tens of thousands of Ethiopians, Jews and non-Jews, through clinics, immunization, nutrition programs, family planning, and community health (**Figure 6-9**).

FIGURE 6-5 Dr. Hodes examining a young Ethiopian girl with heart disease secondary to rheumatic fever. (*Used with permission from Mark Tuschman*.)

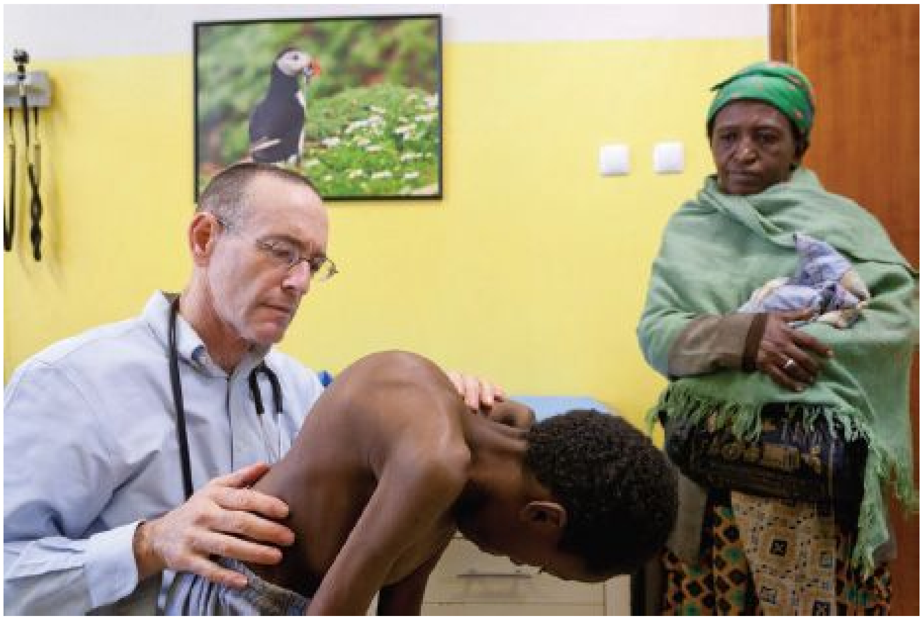

FIGURE 6-6 Dr. Hodes examining an Ethiopian boy with severe kyphoscoliosis secondary to TB of the spine. (*Used with permission from Richard Lord*.)

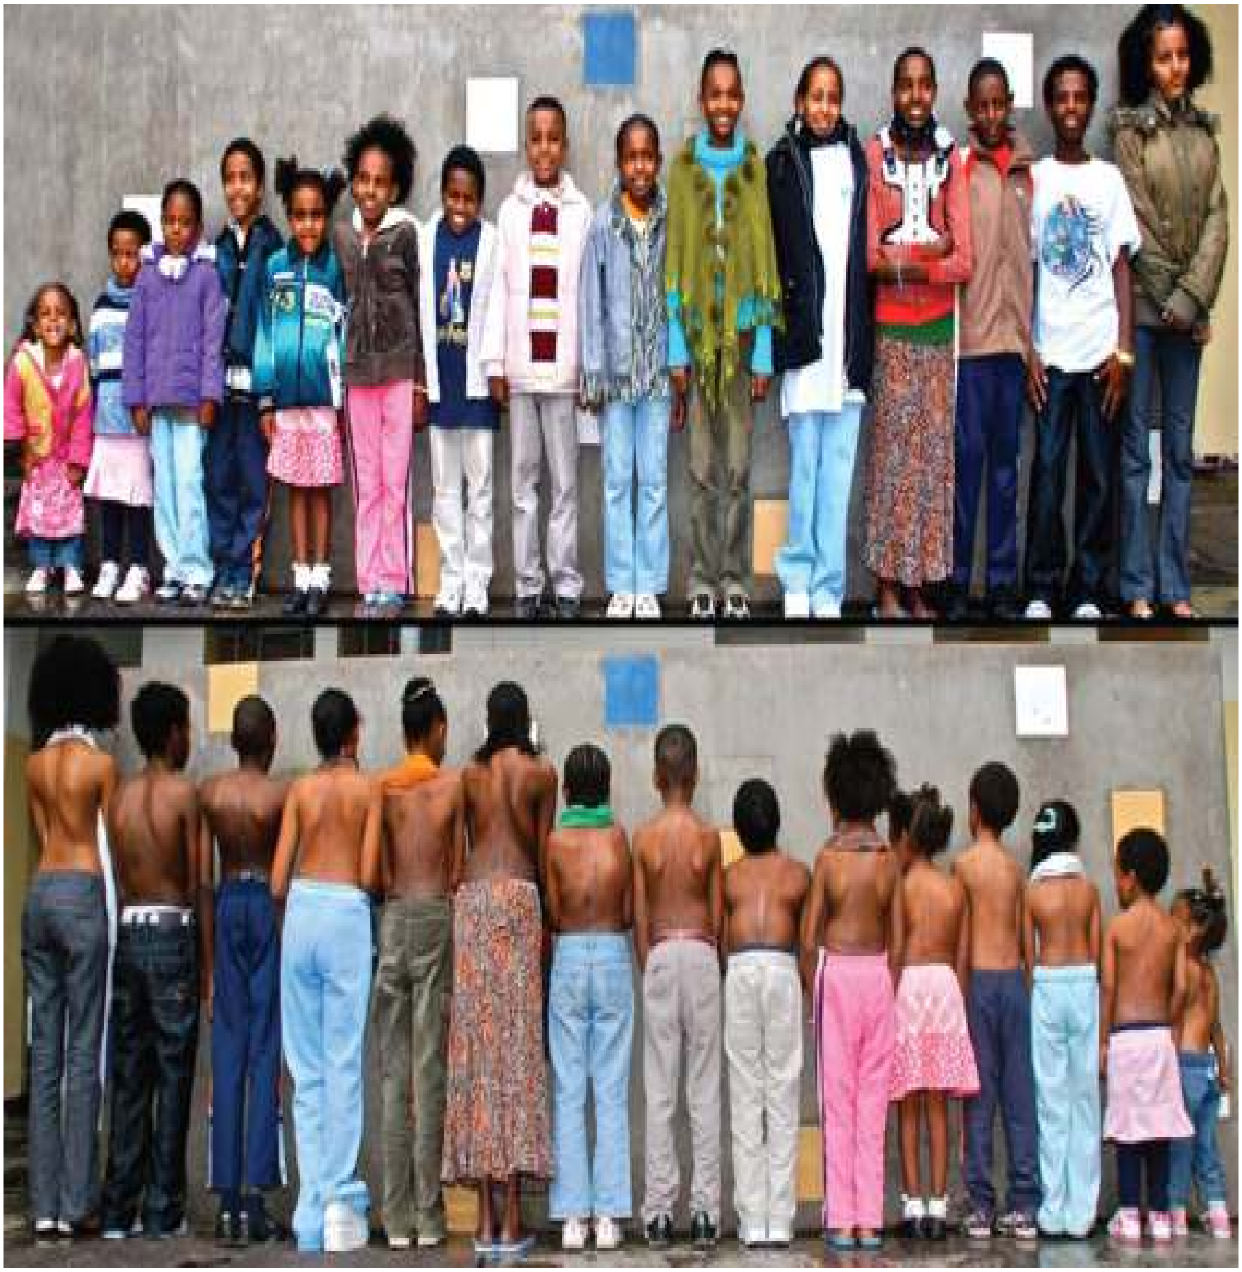

FIGURE 6-7 Ethiopian children with a variety of spine diseases after returning from spine surgery in Ghana Africa. Medical evaluation and funding was arranged by Dr. Rick Hodes and the American Jewish Joint Distribution Committee. They can look forward to improved lives with straighter spines. (*Used with permission from Rick Hodes, MD*.)

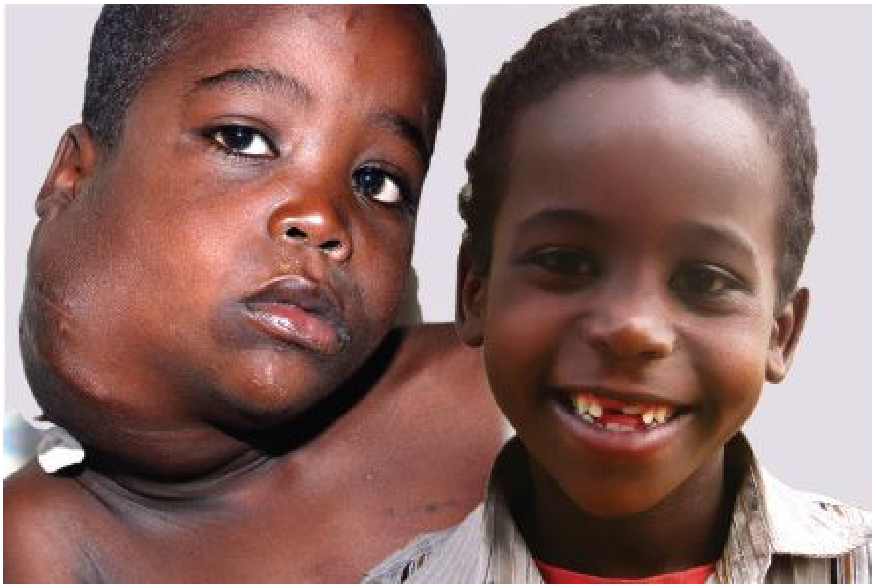

FIGURE 6-8 The same Ethiopian child before and after chemotherapy for Hodgkin's lymphoma. Dr. Hodes diagnosed and treated this young boy. (*Used with permission from Rick Hodes, MD*.)

FIGURE 6-9 Dr. Hodes with some of his Ethiopian patients that have spine disease. (*Used with permission from Richard Lord*.)

Dr. Hodes has worked primarily in Ethiopia for the JDC since 1990. In addition to providing direct patient care, he has arranged for specialized care for hundreds of children in need with neurosurgeons and orthopedic surgeons in the US and Ghana. He has fostered numerous orphaned children and adopted four children, providing needed medical care with his own insurance. Some of these children are now attending schools and colleges around the US. He has also led teams of doctors, who come to work with him as volunteers (**Figure 6-10**). In one interview, Dr. Hodes said, “Getting free medical care in a Catholic hospital by a Jewish doctor is like the whole world coming together. It’s the way the world should work.”

FIGURE 6-10 Dr. Hodes hosting a group of US medical students and doctors in his clinic at the Mother Teresa mission in Ethiopia. (*Used with permission from Richard P. Usatine, MD*.)

CARING FOR THOSE WITH DISABILITIES (LAURIE WOODARD, MD)

EPIDEMIOLOGY

Approximately 54 million Americans currently live with at least 1 disability and the vast majority (52 million) live in their communities (**Figure 6-11**).[15]

FIGURE 6-11 Dr. Laurie Woodard and her daughter Anika share a good laugh following breakfast while on vacation in New Mexico. Although Anika is dependent for all her activities of daily living and is nonverbal because of spastic quadriparetic cerebral palsy, she loves to travel and has a wonderful sense of humor.

- According to data from 1999, the prevalence rate of disability was 24 percent among women and 20 percent among men.[16] Approximately 32 million adults had difficulty with 1 or more functional activities, and approximately 16.7 million adults had a limitation in the ability to work around the house. Two million adults used a wheelchair and 7 million used a cane, crutches, or a walker.
- Of children ages 3 to 17 years, 4.9 million were told that they have some type of learning disability and 12.8 percent (9.4 million) have special health care needs.[15]
- Racial and ethnic minorities have higher rates of disabilities than whites or Asian Americans; 7.3 million individuals (ages 15 to 65 years) with disabilities are of racial or ethnic minorities.
- In 2005, the surgeon general issued a Call to Action to improve the health and wellness of persons with disabilities underscoring the need in this population.[15]

ETIOLOGY

Challenges to a person's health can happen at any age and at any time. Disabilities are not illnesses, rather they are limitations related to a medical condition that have an influence on essential life functions such as walking, seeing, or working.[15] Furthermore, disabilities do not affect all people in the same way.

- Of all the adults with disabilities, 41.2 million (93.4%) reported that their disability was associated with a health condition including arthritis and rheumatism (17.5%), back or spine problems (16.5%), heart trouble/hardening of the arteries (7.8%), lung or respiratory problems (4.7%), deafness or hearing problems (4.2%), mental or emotional problems (3.7%), blindness or visual problems (3.4%), and intellectual disability (2%).[16]
- Rates of disability are increasing in part because of the aging population, better survival of catastrophic illnesses and trauma, and advances in

preventing infant and child mortality.

PROBLEM IDENTIFIED

As a mother of a child with profound disabilities, Dr. Laurie Woodard found that her medical training did little to prepare her for caring for her child or finding help (**Figure 6-11**). She became acutely aware that people with disabilities had great difficulty finding physicians and those who provided care often seemed afraid of them. She said, “I couldn’t imagine someone not wanting to care for her because she had a disability.” Physicians tend to focus on the medical condition and not the whole person and their families; when confronted with the patient’s health care needs and functional issues, the feeling of acting more like a social worker than a physician caused them to fall back into medical model framework. In addition, societal support for those with disabilities, particularly disabilities acquired as an adult, are fragmented and the primary care physician needs to become the link.

BEING PART OF THE SOLUTION

Dr. Woodard began to care for increasing numbers of patients with disabilities, training herself through reading, experience, and asking patients what worked. As she worked with individual students she planned for a time when she could break into the medical student curriculum to provide this training. Eight years ago, when the curriculum for third-year students underwent major reform, she saw her opportunity. Within the primary care 12-week experience, a curriculum on special populations was planned and Laurie made sure that it included teaching about persons with disabilities. Her curriculum, implemented in 2005 with goals ranging from sensitivity training to understanding both the capabilities and needs of individuals with disabilities, contains the following components:

- Clinic-like experience with 8 to 10 patients with physical disabilities (e.g., cerebral palsy, communication issues, wheelchair users) where pairs of students complete brief interview and physical examination under video monitoring. The session ends with a debriefing circle wrap up with students and patients.

- Panel discussion with patients with varying abilities who usually represent an advocacy agency or organization. Special emphasis is placed on community services and opportunities including the arts and sports.
- Home visits where student pairs (2 medical students or a medical student and physical therapy student) receive a preparation sheet and checklist, and learn how disability affects individuals and their family. Following the visit, students prepare reflection plus research reports that are posted on blackboard; part of the assignment is to read and comment on all the papers.
- Service learning project where students give presentations on health topics (e.g., first aid, influenza) selected by staff at an adult daycare facility for individuals with intellectual disabilities or the high school group noted above, or assist in the recreational activities for individuals with disabilities (e.g., free physicals for riders in therapeutic horseback riding program).
- An objective structured clinical examination (OSCE) case involving a manual wheelchair user with shoulder pain; the standardized patients are individuals who are wheelchair users.
- Sensitivity training session, run by Parks and Recreation where students are randomly assigned a disability (e.g., using a wheelchair or other assistive device or blindfold) and complete tasks followed by watching the movie *Murderball* (an informative and proactive documentary about the Paralympics sport, quadriplegic rugby, and its players). A speech pathologist also provides a hands-on assistive/augment communication device tutorial.

“The students learn to see the patient first,” she says, “that caring for these individuals requires recognizing the patient’s expertise about their disability and problem solving together. For most students, even the most jaded, this is simply an eye opening experience as the patients are usually quite physically impaired but lead full and active lives” (**Figure 6-12**).

FIGURE 6-12 Dr. Woodard, daughter Anika, and dog Nikki are part of a team of University of South Florida (USF) medical students, faculty, and family who participated in a "wheel-a-thon" to raise money for Tampa's first fully accessible playground. Teaching medicals students the therapeutic value of sports and recreation for people with disabilities is an important aspect of the USF curriculum.

Dr. Woodard has expanded this program and is co-teaching with faculty from the School of Physical Therapy (PT) so that medical and PT students interview and examine patients together. In addition, she will begin providing training within the courses Doctoring 1 and Doctoring 2 to first- and second-year medical students (the home visit and panel discussion will be moved to the first year) allowing more complex and challenging issues to be addressed during the clerkship. Finally, she is also involved with Alliance for Disability in Health Education, a group mainly out of the Northeast whose mission is to get the American Association of Medical Colleges (AAMC) to require the topic of disability in the curriculum.

Since the initial publication of this chapter, Dr. Woodard's daughter graduated from high school in June 2011. The family is working on helping her structure her day and move beyond the interminable wait list for services to which she is entitled. She is happy and healthy, and the family members consider themselves lucky to have good, affordable caregivers and companions to assist her.

CARING FOR THE HOMELESS (RANDAL CHARLES CHRISTENSEN, MD, MPH)

EPIDEMIOLOGY

At least 643,000 persons were homeless on any given night in 2009 and 1 in every 200 Americans (approximately 1.56 million people) spent at least 1 night in a shelter during that year.[17] Of those who were homeless in one study, 3 percent reported having HIV/AIDS and 26 percent reported other acute health problems, including tuberculosis and other sexually transmitted infections.[18]

Causes of death were investigated in one study of 40 homeless people for more than a 1-year period (1985 to 1986) conducted by the Fulton County Medical Examiner in Georgia. It was thought at that time that between 4,000 and 7,000 individuals were homeless, so the crude death rate for that year was estimated at 5.7 to 10 per 1,000.[19]

- Black males accounted for 19 (48%) of the 40 deaths, white males for 18 (45%), and black females for 3 (8%). The median age for 36 individuals whose age was known was 44 years (range = 21 to 70 years).
- Twenty-two individuals (55%) died or were found dead outdoors. Of the 18 persons who died indoors, 7 were found in vacant buildings and 5 died at shelters.
- Cause of death, based on the medical history, investigation scene information, circumstances of death, and autopsy and toxicologic studies (when performed) was classified as natural (16), accidental (19), or homicide (4) or suicide (1). Natural deaths included alcohol related (9 including 3 with seizures likely from alcohol withdrawal), heart disease (4), and lung disease (3). Accidental deaths were primarily a result of acute alcohol toxicity (7), fire (6), hypothermia (2), and pedestrian–motor

vehicle incidents (2). No deaths were attributed to drugs other than alcohol.

ETIOLOGY

Homeless persons are often extremely poor and socially isolated, the latter is considered a significant contributor to being homeless. Many medical conditions are caused by or exacerbated by the adverse living conditions and lack of health care experienced by the homeless. These include:

- Psychiatric illnesses (affecting as many as 40% of homeless persons).
- Physical health problems, including injuries from trauma, respiratory disease (e.g., tuberculosis), scabies and pediculosis infestations, and chronic illnesses such as diabetes.

PROBLEM IDENTIFIED

Dr. Randal Christensen earned both a medical degree and MPH from Tufts University School of Medicine followed by a four-year combined Pediatrics and Internal Medicine program in Phoenix, Arizona. Medical education became a priority for him and he wanted to find a way to combine the provision of medical care to underserved populations while teaching and inspiring students to get involved with their communities. Throughout his career, Dr. Christensen has maintained a strong desire to care for children who have no voice.

BEING PART OF THE SOLUTION

Dr. Christensen began working for Phoenix Children’s Hospital as the Medical Director of the Crews’n Healthmobile, a mobile medical van that delivers medical care to homeless youth and teens (**Figures 6-13** and **6-14**). As a Clinical Assistant Professorship at the University of Arizona College of Medicine and the Arizona State University School of Nursing, he was in an ideal position to expand this program serving homeless children in Phoenix and the surrounding communities. This mobile medical center provides comprehensive medical and social services; it is essentially a doctor's office on wheels. Dr. Christensen and his team reach out to thousands of children and adolescents living in poverty on the streets of Arizona (**Figures 6-15** to **6-17**). Systems and procedures set up by his team are still in place today and in multiple other mobile medical centers around the country.

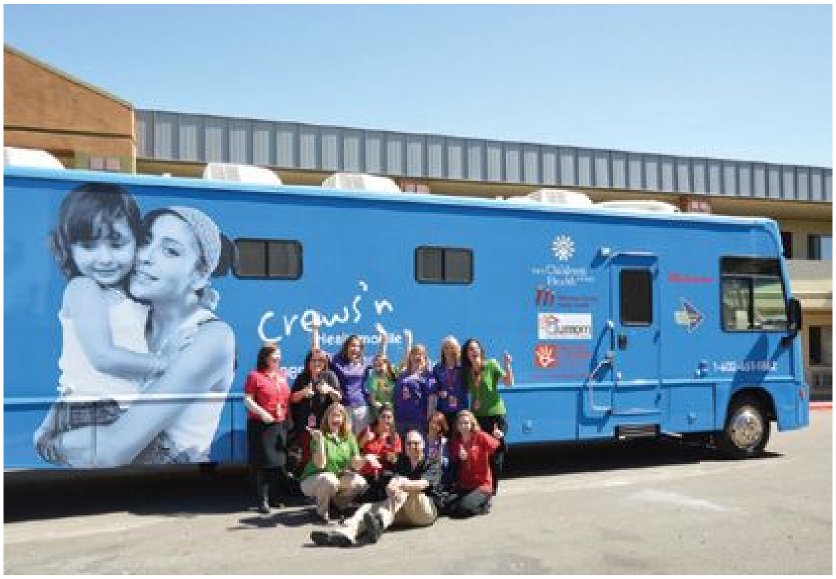

FIGURE 6-13 Dr. Randy Christensen with his team and Healthmobile getting ready to go out on the streets of Phoenix to deliver free health care to homeless and at-risk children and teens. This mobile medical van, nicknamed "Big Blue," is outfitted with three exam rooms and the latest technology. (*Photography used with permission by Phoenix Children's Hospital*.)

FIGURE 6-14 “Say ahhh!” Dr. Christensen visits with Jacob for a routine health check-up inside the Crews’n Healthmobile. In the 12 years Dr. Christensen has been operating the van, he has completed more than 32,000 medical encounters. (*Photography used with permission by Phoenix Children’s Hospital. Photography by Desert Ridge Photography/Charles Siritho*.)

FIGURE 6-15 Dr. Christensen examines this cute baby at a local homeless shelter. (*Photography used with permission by Phoenix Children’s Hospital. Photography by Desert Ridge Photography/Charles Siritho*.)

FIGURE 6-16 The Crews'n Healthmobile visits multiple sites around the Phoenix area where homeless teens gather. This teenage couple was happy to pose for photos that are displayed on the site: http://www.askmewhyihurt.com/big-blue/faces-of-crews/.

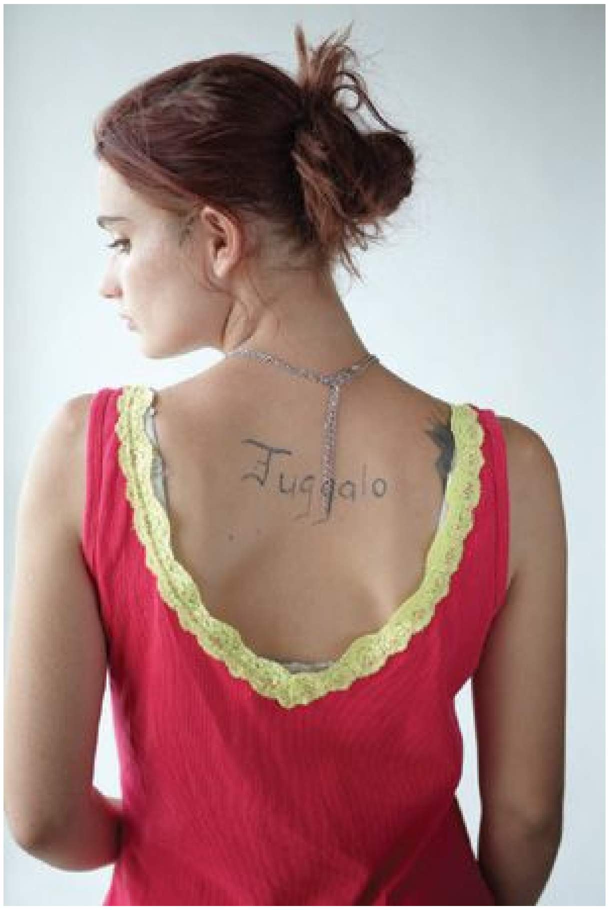

FIGURE 6-17 This teen is showing us her tattoo. Many teens come to the healthmobile after getting a tattoo or piercing to have their skin checked to make sure they "don't get an infection". During those times Dr. Christensen and his team try very hard to establish a rapport and encourage follow up. As trust builds then so does the chance for the teens' success to graduate and get meaningful work (http://www.askmewhyihurt.com/big-blue/faces-of-crews/).

Dr. Christensen has also exercised his leadership abilities on behalf of many community organizations. As the Medical Director for Camp AZDA, one of the largest camps in the US for children with diabetes, he has taken a team approach to expanding numbers of children and staff at camp while providing a safe and perhaps life changing experience for these children. Other memberships include the Executive Board for VisionQuest 20/20 (an organization with a mission to insure all children have proper vision screening through enhanced technology), and the Advisory Board for Health care for the Homeless. His efforts to help underserved populations include yearly trips to Washington, DC, to advocate for children.

Dr. Christensen's contributions extend far beyond the walls of Phoenix Children's Hospital. When Hurricane Katrina hit New Orleans in 2006, Dr. Christensen organized a team to deliver medical care within 10 days of the storm. His team was meet with officials in Louisiana and provided needed health care during more than 330 clinical visits. Most of these families were in dire need of primary care and had not seen a doctor since the hurricane started (**Figure 6-18**). The team also delivered thousands of dollars of medications and supplies to the devastated area.

7 GLOBAL HEALTH

Ruth E. Berggren, MD
Richard P. Usatine, MD

COMMUNITY STORY

Common River is a US-based nongovernmental organization (NGO) implementing a community development program in Aleta Wondo, Ethiopia. This NGO is founded on the principle of positive deviance, in which local best practices are identified and replicated to maximize agricultural production (organically grown coffee is produced in this region), as well as to improve the nutritional status, health, and education of orphaned and vulnerable children. Since 2009, a group from the University of Texas School of Medicine has travelled annually to Aleta Wondo to provide school health screening and free health care, including treatment of endemic helminth infections, trachoma, and skin diseases, while collaborating with and supporting the local government-sponsored health clinic (**Figures 7-1A** and **B**). In **Figure 7-1C**, the schoolchildren of Common River are looking at the new group of American medical students that have just arrived in Africa. In the coming week, these children will receive oral albendazole to treat intestinal parasites and have complete physical exams to detect and treat other common conditions, such as head lice, tinea capitis, trachoma, and foot infections. Note that many of the children are barefoot. In **Figure 7-1D**, a group of women have just completed their woman’s literacy class for the day. Improving women’s literacy can improve the health of the entire community.

FIGURE 7-1 **A.** Many people still live in extreme poverty with no running water and electricity. This is a typical hut in Ethiopia. This one is inhabited by a grandmother, her grandchild, and a cow. The photograph was taken after a home visit to provide IM ceftriaxone to the child after her release from the local hospital where she was treated for a neck abscess and cellulitis. The medical team was staying at Common River and originated from the University of Texas. **B.** A University of Texas medical student is bandaging the hand of a 2-year-old girl in Aleta Wondo. The medical team had just drained an abscess of her hand. **C.** The schoolchildren of Common River in rural -Ethiopia greet the new group of American medical students

that have just arrived in Africa. **D.** Smiling women that have just completed their woman’s literacy class for the day. Improving woman’s literacy is a great way to raise the health status of the community. (*Used with permission from Richard P. Usatine, MD*.)

WHAT IS GLOBAL HEALTH?

For years, the term *international health* has described health work in resource-limited settings with an emphasis on tropical diseases, communicable diseases, and illness caused by poor nutrition and inadequate access to water, sanitation, and maternal care.[1] More recently, *global health* is commonly used to emphasize mutual sharing of experience and knowledge, in a bilateral exchange between industrialized nations and resource-limited countries, and the emphasis is expanding to include noncommunicable diseases and chronic illness.[2] One definition of global health, proposed by the Consortium of Universities for Global Health Executive Board, is “an area for study, research, and practice that places a priority on improving health and achieving equity in health for all people worldwide.”[1] This chapter focuses on a few conditions commonly encountered in developing nations, emphasizing communicable diseases and malnutrition.

Ethical dilemmas abound when professionals from resource-rich settings leave their familiar environment and apply their practices in a severely resource-limited setting. Consider, for example, breastfeeding guidelines in the setting of maternal-to-child HIV prevention. National protocols differ depending on resource availability. In some settings, telling an HIV-positive mother not to breastfeed (because breast-milk can transmit HIV) may sentence her infant to near-certain death from diarrhea. If a program overturns local teaching about exclusive breastfeeding, it must ensure a safe and sustainable alternative form of infant feeding. Imposing the standards of industrialized nations in a community that cannot afford to continue to provide these standards can undo years of program development. Care must be taken not to undermine the trust a community has placed in local health providers, as this can ultimately increase morbidity rather than relieve suffering. Working with local health providers is essential so that a short trip can result in extended benefits to the community (**Figure 7-2**).

FIGURE 7-2 The physician in the front of this picture is pleased to receive medications that are unavailable to her hospital in rural Panama. Before shipping or bringing medications abroad, it is essential to learn what practicing physicians need. Bringing redundant or nearly expired meds or short-term supplies of expensive brand medications causes more harm than good. Donated medications should be locally relevant generics that are not expired. The WHO list of essential medications may be helpful in planning (http://www.who.int/medicines/publications/essentialmedicines/en/index.html). (*Used with permission from Richard P. Usatine, MD.*)

This chapter briefly introduces some of the relevant subject areas with which global health providers should familiarize themselves when preparing for international work. Statistics that aid in understanding the state of a nation's health relative to other countries are the mortality rate of children younger than age of 5 years old and adult life expectancy. Least-developed countries report that as many as 112 of 1,000 children die before age 5 years, compared to 8 per 1,000 in developed countries,[3] and adult life expectancy ranges from 48 or 49 years at birth (Chad, Swaziland) to 88 or 89 years (Japan, Monaco).[3] Another important parameter by which to compare the health status of countries is that of maternal mortality, defined as the number of maternal deaths per 100,000 livebirths. These figures, together with basic epidemiology of disease provide important insights into public health priorities for populations.

What statistics do not provide, however, is the level of importance ascribed to a particular health issue by a community. It is necessary to acknowledge and address the needs expressed by communities themselves, in order of their own priorities, so as to achieve sustained improvements in health outcomes. All health improvements ultimately rely on long-term behavioral changes, whether dietary, pill taking, physical activity, or hygiene related. Group behavioral change requires buy-in from the population with approbation and influence of local leadership.

A useful method of creating a positive impact is to make use of ongoing peer-to-peer adult education techniques through the introduction of community health clubs. This can be effective for empowering resource-limited communities to develop their priorities, and to advocate for their community health and development needs.[4] It is best to learn about and collaborate with the local and governmental community health activities before launching any intervention, be it clinical, infrastructural, or preventive.

WATER AND SANITATION

Many diseases in resource-poor settings are traceable to deficits in clean water supply and storage, lack of soap for bathing, and lack of functioning infrastructure to manage human waste (e.g., garbage collection and latrines) (**Figure 7-3**). Some of the most important ones include typhoid fever, cholera, and intestinal parasites.

A
B

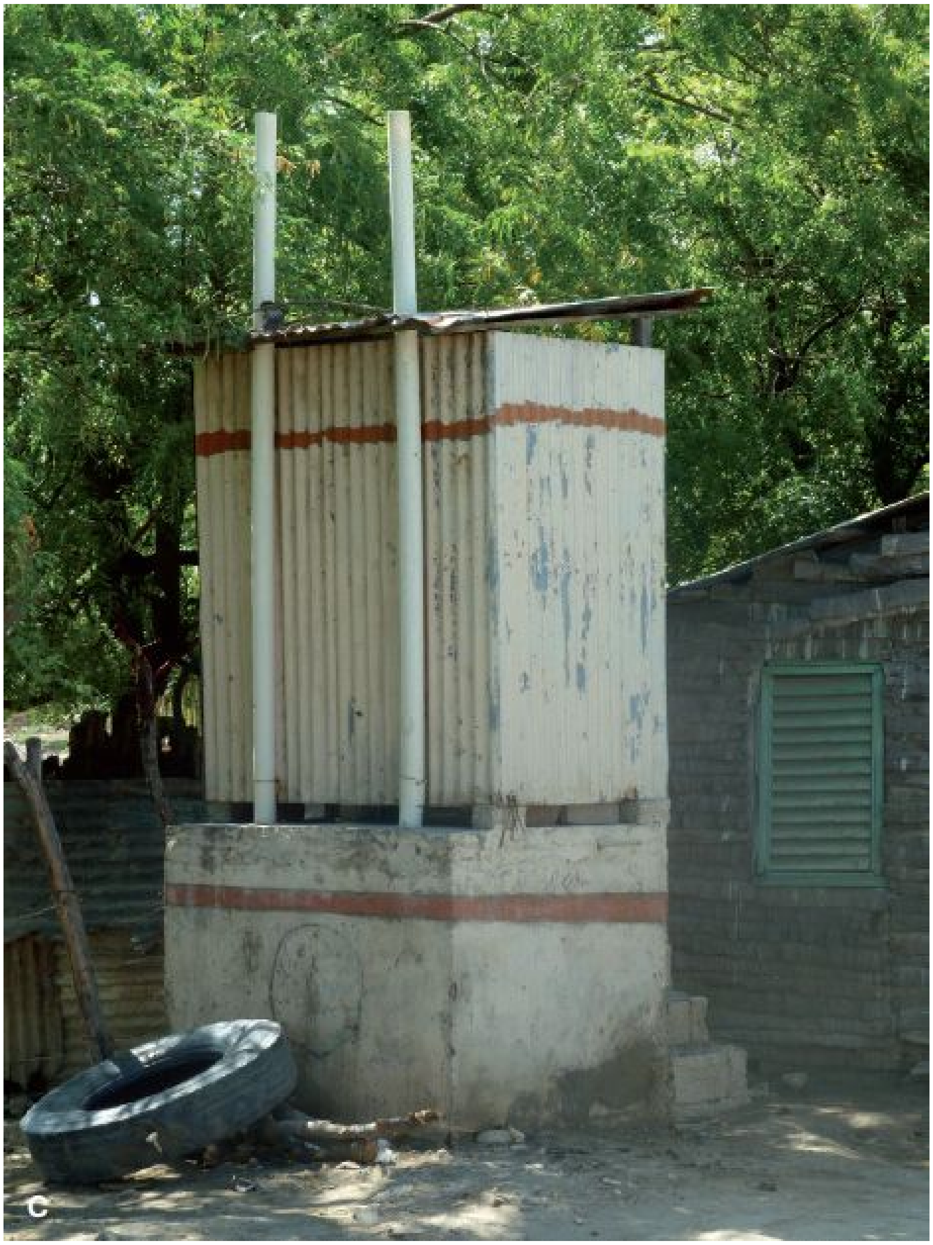

FIGURE 7-3 **A.** A covered pit latrine serving the needs of an Ethiopian family. The latrine is located on the edge of the garden near their home and presents a fall hazard for young children. (*Used with permission from Richard P. Usatine, MD*.) **B.** An Ethiopian pit latrine, which offers no mitigation for flies and is situated in proximity to the water table below. Heavy rains will lead to contamination of the water supply with fecal pathogens. (*Used with permission from Richard P. Usatine, MD*.) **C.** An

elevated, ventilated improved pit latrine can protect the water table and reduce flies. Air circulates down the squat hole, into the pit and up through the pipe. To ensure unhindered flow of air, the top of the vent pipe must be 0.5 meters above the top of the shelter. The latrine interior is kept dark so the main light source in the pit comes from the vent pipe. Flies are attracted to the light, but the pipe has a fly-proof screen at the top, so they cannot escape and eventually die.[5] Many countries consider the ventilated improved pit latrine to be the minimum standard for improved sanitation. (*Used with permission from Jason Rosenfeld, MPH*.)

Lack of governmental and public health infrastructure in the developing world leads to large populations living without clean running water. World Health Organization (WHO) and UNICEF estimate that 780 million persons are without access to improved water sources and 2.5 billion (37% of the world's population) people are without access to improved sanitation sources.[6]

Water and sanitation deficiencies are responsible for most of the global burden of diarrheal disease. The most common diarrheal disease of returning travelers is caused by enterotoxigenic *Escherichia coli*. All over the world, young and malnourished children die of preventable diarrhea caused by rotavirus, *E. coli*, *Salmonella*, *Shigella*, and *Campylobacter*.

Diseases that are particularly deadly as a result of lack of access to clean water include typhoid fever and cholera. Intestinal parasites, while usually not deadly, do lead to chronic problems with malnutrition and anemia, which themselves contribute to cyclical poverty and disease because they lead to impaired learning, reduced productivity, and vulnerability to other infectious diseases.

TYPHOID FEVER

Typhoid fever, also known as enteric fever, is an acute systemic illness caused by the invasive bacterial pathogen, *Salmonella typhi*. *Salmonella* is ingested in contaminated water or food, invades the mucosal surface of the small intestine, and causes bacteremia, with seeding of the liver, spleen, and lymph nodes.

EPIDEMIOLOGY

Typhoid fever is mainly found in countries with poor sanitary conditions. Because most such countries do not routinely confirm the diagnosis with blood cultures, the disease is highly underreported. Outbreaks of typhoid are often seen in the rainy season, and in areas where human fecal material washes into sources of drinking water. Shallow water tables and improperly placed latrines are environmental risk factors for typhoid. Globally there are 16 to 33 million cases annually, with up to a half a million deaths every year.[7]

CLINICAL PRESENTATION

Patients develop an acute systemic illness with prolonged fever, malaise, and abdominal pain after ingesting contaminated food or water. This truly nonspecific syndrome may include headache, mild cough, and constipation, with nausea and vomiting. Diarrhea may be present but it is not the rule. After a 10- to 20-day incubation period, there is a stepwise progression of fever over a period of 3 weeks, and the patient may display a transient rash described as rose spots (2- to 4-mm pink macules on the torso, which fade on pressure). Temperature pulse dissociation with relative bradycardia despite high fever may be noted in fewer than 25 percent of patients. In the second week, the patient becomes more toxic and may develop hepatosplenomegaly. Untreated, typhoid can progress to include delirium, neurologic complications and intestinal perforation caused by a proliferation of *Salmonella* in the Peyer patches (lymphoid tissue) of the intestinal mucosa. Although the mortality rate for untreated typhoid is 20 percent, early antibiotic therapy can decrease mortality. Approximately 1 percent to 4 percent of those who recover from acute typhoid fever become carriers of the disease who continue to shed *Salmonella* in their stool despite not being ill.[7]

DIAGNOSIS

Culture of blood, stool, rectal swab, or bone marrow.[8]

DIFFERENTIAL DIAGNOSIS[9]

- Malaria (often clinically indistinguishable from typhoid; empiric therapy for both malaria and typhoid may be warranted if diagnostic testing is unavailable).
- Enteroinvasive *E. coli*.
- *Campylobacter*.
- Paratyphoid fever (*Salmonella para typhi*, other less virulent *Salmonellae*).
- Dengue fever (mosquito borne arbovirus infection spread by *Aedes aegypti*).
- Rickettsial diseases (typhus, spotted fever, Q fever).
- Brucellosis.
- Leptospirosis.
- Heat stroke.

MANAGEMENT

Prompt diagnosis and initiation of antibiotic therapy is essential and life-saving. Oral rehydration therapy should be initiated first, followed by IV fluids if vomiting cannot be controlled and for patients with altered mental status or hypovolemic shock. Antibiotic resistance patterns differ with geographic location.

For Africa and resource-limited settings in the Americas, the first choice is chloramphenicol or ciprofloxacin. Historically, trimethoprim-sulfamethoxazole has been used,[8] but there has been increasing drug resistance to sulfa in these areas. In Asia, where multidrug resistant *S. typhi* strains are well described, ciprofloxacin, ceftriaxone, or azithromycin may be used for 7 to 14 days.[8–10] Azithromycin should only be used in mild disease. Some guidelines advocate the use of dexamethasone, 3 mg/kg IV followed by 1 mg/kg every 6 hours for 2 days in the setting of shock or altered mental status.[8] See vaccine information at the end of this chapter.

CHOLERA

Cholera is an acute, diarrheal disease caused by *Vibrio cholerae*. It is usually transmitted by contaminated water or food, and is associated with pandemics in countries that lack public health infrastructure and resources for sanitation. Although the infection is often mild or asymptomatic, in 5 to 10 percent of patients it can be severe and life-threatening.[14]

EPIDEMIOLOGY

V. cholerae reservoirs occur in brackish and salt water as well as estuaries. Although the organism occurs in association with copepods and zooplankton, its largest reservoir is in humans. Cholera pandemics have been reported in south Asia, Africa, and Latin America. Characteristically, cholera outbreaks occur in countries that have suffered destruction of public health infrastructure (collapse of water supplies, sanitation, and garbage collection systems). The 2010 outbreak in postearthquake Haiti has been traced to UN peace-keeping soldiers, whose waste contaminated a major Haitian river used for bathing, irrigation, and drinking water. In just 10 months, 300,000 cases were reported, of whom 4500 died, and the outbreak has continued to wax and wane with the rainy seasons for years.[11] A large infective dose is necessary for infection, and although only approximately 10 percent of those infected fall ill, the infection can be fatal for young children, elderly, and malnourished individuals.

PATHOPHYSIOLOGY

V. cholerae is a motile, gram-negative rod. After ingestion via contaminated water or food, it must survive the acid environment of the stomach before colonizing the mucosal surface of the small intestine. The organism is noninvasive and not associated with bloody diarrhea. Rather, it makes a potent toxin causing massive secretion of electrolyte-rich fluid into the gut lumen. Human to human contact spread virtually never occurs. Transmission through contaminated food or water is the rule.[12]

Clinical presentation ranges from mild watery diarrhea to acute, fulminant watery diarrhea which looks like rice water. After an incubation period of 18 to 40 hours, patients may lose up to 30 L of fluid daily, with resulting metabolic acidosis and electrolyte disturbances. Severe dehydration can lead to death in a matter of hours. Vomiting, when present, starts after the onset of diarrhea. Profoundly dehydrated patients present with decreased skin turgor, sunken eyes, and lethargy. Children, but not adults, may have mild fever. Cramping caused by loss of calcium and potassium is common.[12]

DIFFERENTIAL DIAGNOSIS AND LABORATORY TESTS

Early presentation may resemble enterotoxigenic *E. coli*; however, the syndrome is quickly distinguishable because of the extreme volume of “rice water” secretory diarrhea that is the result of cholera toxin. *V. cholerae* may be confirmed by stool culture, polymerase chain reaction (PCR) for toxin genes, or dark-field microscopy with specific antisera, which immobilizes the *V. cholerae*.[13] The Centers for Disease Control and Prevention (CDC) recommends confirmation of cholera by stool specimen culture or rectal swab. For transport, Cary Blair media is used, and for identification, thiosulfate-citrate-bile-salts (TCBS) agar is recommended.[14]

MANAGEMENT

Water, sanitation, and hygiene education is essential, as is education about recognizing the symptoms and immediately seeking medical attention while initiating oral rehydration. Optimally, rehydration should commence with reconstitution of WHO-distributed oral rehydration salts (ORS), which is available in all but the most remote areas of the world. Hydration is the mainstay of therapy, and replacement of fluids should be calibrated to match losses. ORS should be prepared with previously boiled water and consumed within 24 hours of reconstitution. IV or intraosseous hydration with Ringer lactate solution should be initiated if the patient is vomiting or in danger of hypovolemic shock. The volume needed to rehydrate a cholera patient is often underestimated; for this reason, collection and measurement of the watery stool in a bucket placed under the cholera cot is recommended.

Antibiotics are recommended for severe cases of cholera; options include doxycycline, azithromycin, ciprofloxacin, and furazolidone.[15]

PREVENTION OF DISEASES SECONDARY TO CONTAMINATED WATER

Drinking purified or treated water, good handwashing practices, and avoidance of contaminated food are essential. Travellers should be reminded not to brush their teeth with tap water and to avoid having potentially contaminated ice added to their beverages. Carbonated beverages are safe as the carbonation process is bactericidal. Community education about handwashing and treatment of water is essential. In communities lacking running water (**Figure 7-4**), home storage of drinking water should be in containers with protective lids. Local guidelines regarding addition of chlorine to home stored water containers should be followed.

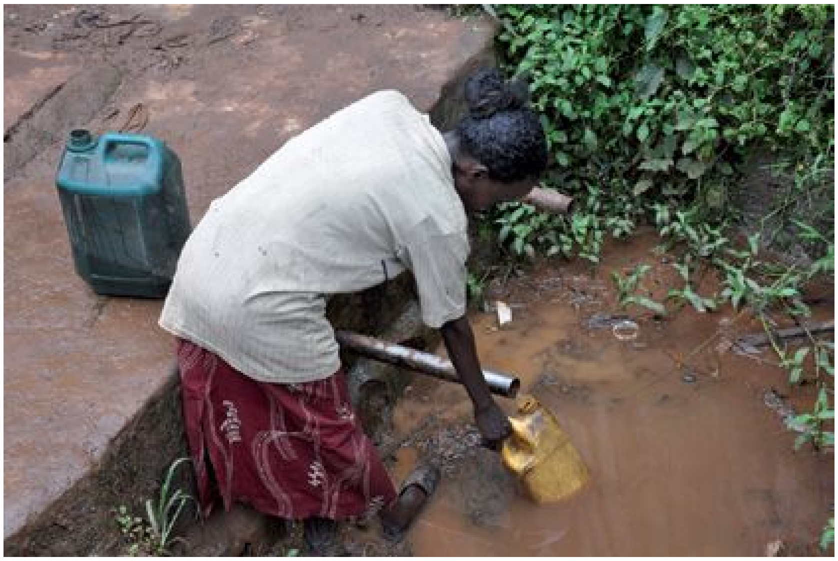

FIGURE 7-4 In this Ethiopian community without running water, water is collected in Jerry cans. Thousands of women carry these heavy, filled cans for miles after filling them up from this single pipe. The local town has provided one single pipe as the water source for the community. Although there is muddy water below, the water coming from the pipe appears clear, although it is likely to harbor bacteria and parasites. (*Used with permission from Richard P. Usatine, MD.*)

INTESTINAL PARASITES

EPIDEMIOLOGY AND GEOGRAPHIC DISTRIBUTION

1/3 of the world’s population is infected with intestinal parasites, and although many parasitic infections are asymptomatic, some have serious health consequences. Especially affected are pregnant women and children, for whom hookworm-associated anemia results in maternal mortality, low-birth-weight babies, growth stunting, and impaired learning. The CDC recommends predeparture albendazole treatment as a single 600-mg dose for all refugees from sub-Saharan Africa and South Asia. While this treatment will eradicate most of the nematodes, it is insufficient for *Strongyloides stercoralis* and schistosomiasis.[16]

CLINICAL PRESENTATION

Abdominal pain, cramps, bloating, anorexia, anemia, fatigue, growth stunting of children, and hepatomegaly (schistosomiasis).

DIAGNOSIS

Stool for ova and parasite studies (**Figure 7-5**). Note that these will not reliably detect *Strongyloides* or schistosomiasis; serologic testing is available for the latter. Eosinophilia is an important diagnostic clue for the presence of parasites; the finding of persistent eosinophilia warrants a careful diagnostic evaluation for parasitic infection.

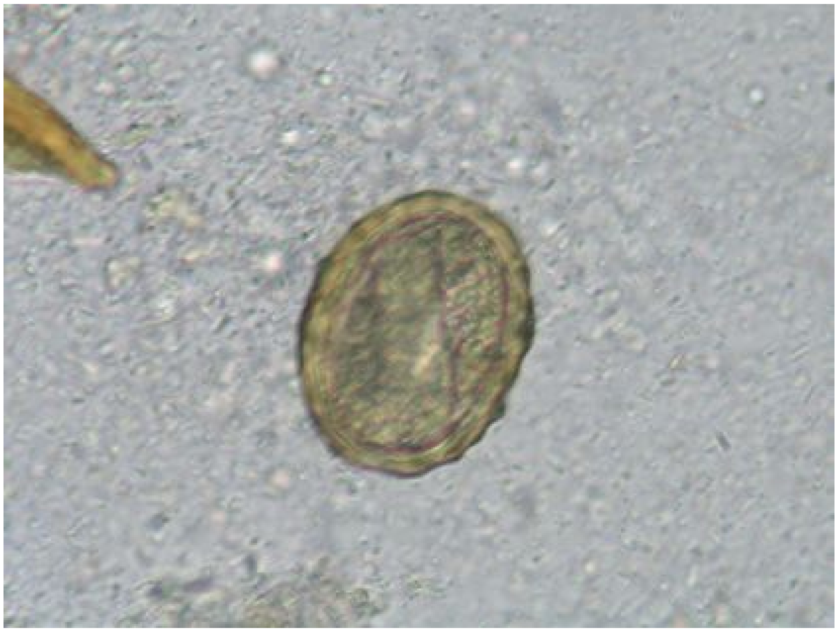

FIGURE 7-5 *Ascaris* egg found in the stool of a child with intestinal parasites. In most developing countries *Ascaris* is treated empirically with albendazole; stool studies are not always available or may not be cost effective. (*Used with permission from Richard P. Usatine, MD.*)

TREATMENT

▶ Older Children and Adults

Albendazole 400 mg orally as single dose will eradicate hookworm, and *Ascaris*, but not *Trichuris* in most people.[17] Eradication of *Trichuris trichiura* requires 3 daily doses of albendazole or adding ivermectin to mebendazole.[18]

▶ Children 12 months to 2 years

Albendazole 200 mg orally as a single dose is recommended by the WHO.[19] *S. stercoralis* requires 7 days of albendazole at 400 mg twice daily. For schistosomiasis, praziquantel is effective against all species of schistosomes. Give 2 doses of 20 mg/kg PO 4 to 6 hours apart (3 doses 4 hours apart for *Schistosoma japonicum*).[20]

PREVENTION

Preventative measures include proper management of human waste, handwashing after defecation and before cooking, and wearing shoes (prevents hookworm and *Strongyloides*). WHO guidelines recommend mass treatment of school children in endemic areas with single-dose albendazole therapy once every 6 months.

MALNUTRITION

Types of malnutrition include:

- Kwashiorkor
- Marasmus
- Micronutrient deficiencies

A global shift is underway, from diseases of undernutrition to overnutrition in tandem with industrialization and advances in transportation and technology. In spite of this global shift, about a quarter of the world's preschool children demonstrate growth stunting caused by nutritional deficiencies. In resource-poor countries, adult obesity and childhood undernutrition may coexist within the same families. The causes of this seeming paradox include many factors associated with poverty: the vulnerability of preschool children to infection when sanitation is inadequate, lack of nutrition education, decreased physical activity with increasing availability of technology and transportation, and mass marketing of inexpensive, calorie-rich foods.

Two classic presentations of malnutrition in children are important to recognize because they signal a patient who is immunocompromised and vulnerable not only to infection but also to preventable developmental delay. The accompanying photographs show an emaciated child with marasmus (severe, nonedematous malnutrition caused by calorie deprivation; **Figure 7-6**), and a puffy child with kwashiorkor (severe, edematous protein energy malnutrition; **Figure 7-7**). Marasmic kwashiorkor is another descriptor, illustrating the high level of overlap in the etiology and presentation of these extreme forms of malnutrition.[21] Whenever possible, one should avoid hospitalizing these children for nutritional rehabilitation as hospitalization will expose them to many infectious pathogens that could be lethal during their vulnerable period of "nutritional AIDS."[22]

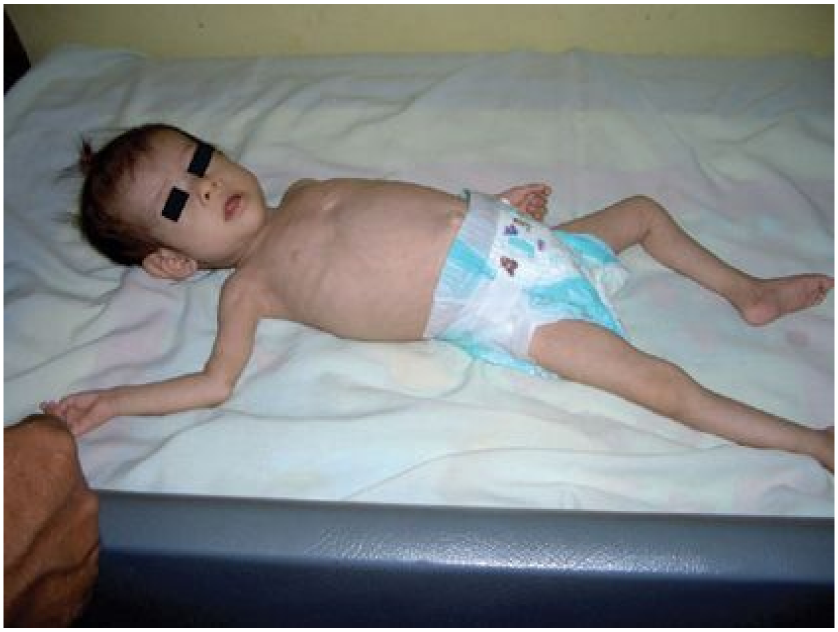

FIGURE 7-6 This 12 month-old Bolivian child with marasmus presented to medical attention with pneumonia. She has severe growth stunting, atrophied limbs, and looks miserable. Her presentation highlights the association between malnutrition and infection. (*Used with permission from Carolina Clark*.)

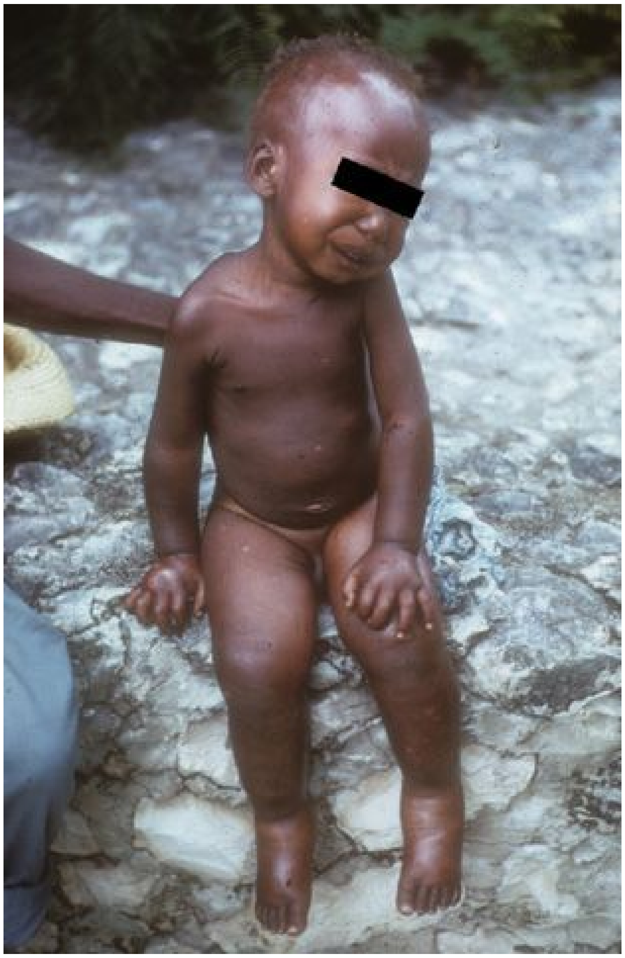

FIGURE 7-7 This 2-year-old child presented with classic signs and symptoms of kwashiorkor, a severe form of protein-energy malnutrition. The word *kwashiorkor*, from a Ghanaian language, refers to the sickness a child develops when it is weaned from breastfeeding. In countries with limited protein sources, newly weaned children are especially vulnerable to this disease. They present with depigmentation, red discoloration of the hair, distended abdomens, and peripheral edema. (*Used with permission from Ruth Berggren, MD.*)

DIAGNOSIS

Growth chart monitoring is important for earliest detection of weight loss, growth stunting, or failure to gain height and weight over time. In most resource-poor countries, growth monitoring is implemented by trained community health workers, who refer mothers for nutrition and education programs upon detecting faltering growth in children younger than the age of 5 years. Children often fail to gain weight normally after an episode of infectious diarrhea or malaria; this should be followed by a period of rapid catchup growth. If a child becomes reinfected before catchup growth is complete, the child will fall further behind on the growth curve.

Depending on the relative protein content of the diet, patients develop marasmus (calorie deprivation), characterized by emaciation and listlessness (**Figure 7-6**), or kwashiorkor, “the disease of weaning”—protein-energy malnutrition. Kwashiorkor is characterized by red discoloration of the hair (**Figure 7-8**), which is also brittle, puffy eyes, bloated bellies, and pitting edema of the extremities (**Figure 7-7**). These children feel miserable and are lethargic and uninterested in food. The differential diagnosis of kwashiorkor includes nephrotic syndrome, renal failure, or right-side congestive heart failure.

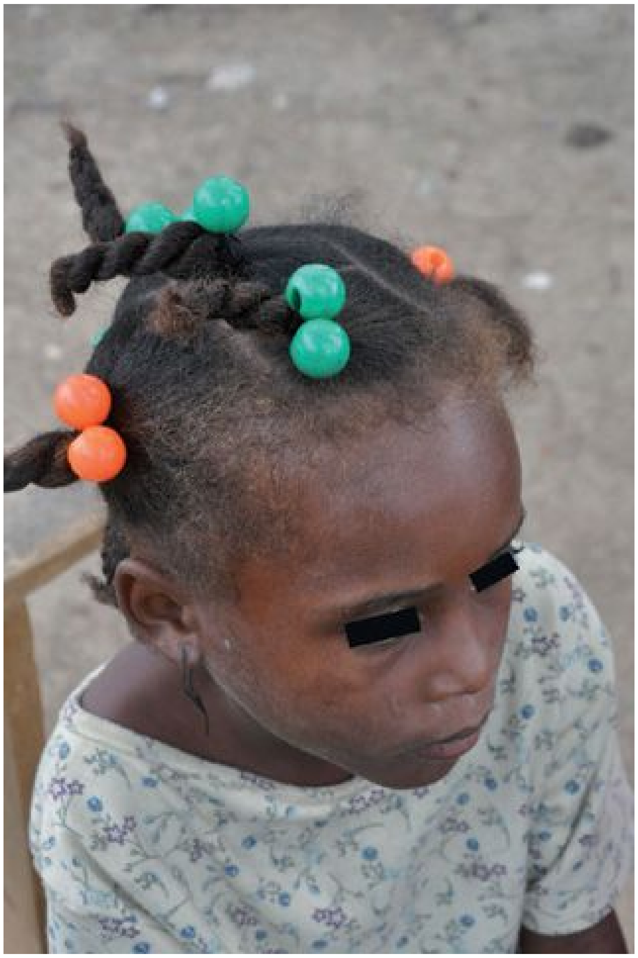

FIGURE 7-8 Child with kwashiorkor, protein-calorie malnutrition and red hair. The red hair is a result of the kwashiorkor. (*Used with permission from Richard P. Usatine, MD.*)

PATHOPHYSIOLOGY

Childhood malnutrition, and especially kwashiorkor, may begin when a breastfeeding mother weans her child from the breast. Deprived of protective maternal antibodies and protein source, weaning infants begin sampling their contaminated environments and ingesting pathogens. Production of cytokines such as tumor necrosis factor (TNF)-α during infectious episodes suppresses appetite and impedes nutritional recovery.[22]

Micronutrient deficiencies coexist,[21] and deficiencies of vitamin A and zinc, in particular, predispose children to increased morbidity from subsequent infections. When parents are unable to replace protein requirements of weaning infants, children eat whatever locally available calorie sources (grains, cereals, bread, fruit) they can find. The poor in many developing countries lack protein sources and toddlers are frequently not prioritized when meat, milk, or eggs become available.

As a result of severe protein deficiency, hypoalbuminemia and decreased intravascular oncotic pressure lead to edema, and the classic puffy appearance of the child with kwashiorkor. For years, it was believed that children with kwashiorkor are disproportionately deprived of protein, whereas children with marasmus are deprived of both protein and carbohydrate calories proportionally; it now appears there is a great deal of overlap between these two presentations of severe malnutrition.[21]

MANAGEMENT

The endless cycle of infection leading to poor appetite and weight loss leading to malnutrition and further risk of infection[22] can be difficult to break unless mothers of malnourished children are taught to introduce calorie-dense weaning food supplements and snacks. Many countries have locally produced ready-to-use therapeutic foods (RUTF),[21] offering products like Plumpy'nut, or Haiti's Nourimanba, made from peanut butter, milk powder, vegetable oil, sugar, and a vitamin mix.[23]

These therapeutic foods are a useful adjunct to breaking the cycle of infection, anorexia, weight loss and malnutrition, but they are not a substitute for educating mothers about how to rehabilitate their malnourished child using locally available and affordable foods. Nonmeat protein substitutes, such as red beans, and locally available green leafy vegetables are easier for mothers to obtain than meat, cow's milk, or expensive imported food supplements.

MICRONUTRIENT DEFICIENCIES

VITAMIN A DEFICIENCY

In contrast to marasmus and kwashiorkor, growth stunting is a more subtle syndrome affecting 200 million children who are younger than the age of 5 years. A variety of micronutrient deficiencies are believed to contribute to stunting syndrome and to accompany developmental delays, reduced cognitive function, impaired immunity, and future risk of obesity and hypertension.[24] There are 4 micronutrient deficiencies of global importance, each with associated clinical syndromes that should be recognized. All can be associated with growth stunting in children, who may present with abnormally short stature but relatively normal weight for height.

Vitamin A is a critical regulator of immune function, which is required for maintaining the integrity of mucosal surfaces. Vitamin A supplementation in countries with malnutrition reduces blindness (from xerophthalmia) as well as the morbidity of infectious diseases (especially measles, diarrhea, and respiratory infections). **Figure 7-9** shows a photograph of blindness caused by vitamin A deficiency. In 2009, the WHO estimated that clinical vitamin A deficiency (night blindness) and biochemical vitamin A deficiency (serum retinol concentration <0.70 μmol/L) affected 5.2 and 190 million preschool-age children, respectively.[26] About 250,000 children develop blindness caused by vitamin A deficiency every year, and half of these die within 12 months of losing sight.[27]

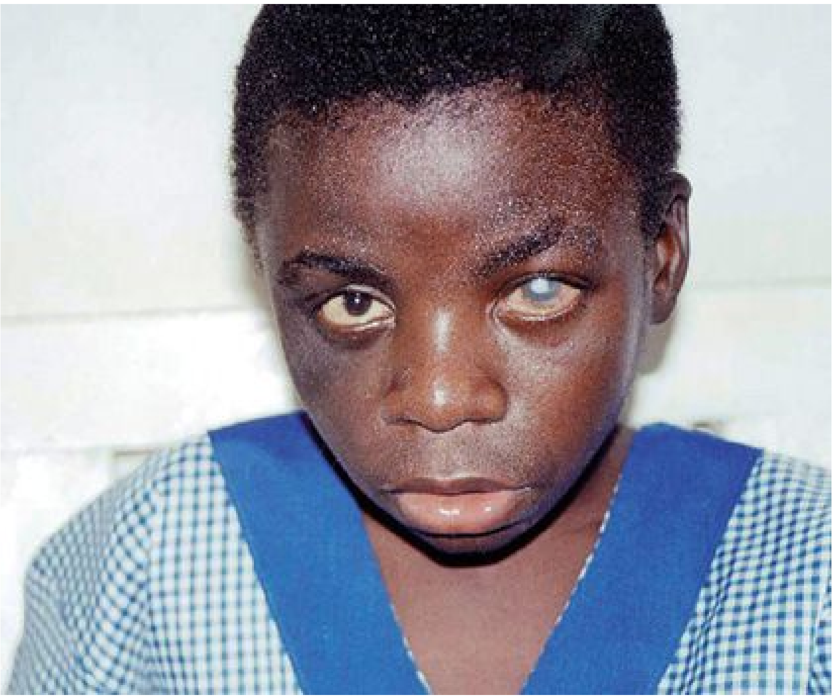

FIGURE 7-9 Child with severe xerophthalmia of the left eye secondary to vitamin A deficiency.[25] (*Used with permission from SIGHT AND LIFE www.sightandlife.org*.)

Clinical presentation

The earliest presentation of vitamin A deficiency is poor night vision, which may progress to night blindness, xerophthalmia, ulceration, and scarring of the cornea, with ultimate blindness. Vitamin A deficiency is also associated with anemia, and is particularly dangerous in patients with measles, for whom mortality rates are high.

Management

A metaanalysis of 43 trials involving 216,000 children younger than the age of 5 years who were given vitamin A supplements revealed striking reductions in mortality and morbidity. Seventeen of these trials reported a 24 percent reduction in mortality, and 7 trials reported a 28 percent reduction in mortality associated with diarrhea. Vitamin A reduced diarrhea and measles incidence. Vitamin A significantly reduces morbidity, mortality, and eye disease. Vitamin A supplements are recommended to all children who are at risk in low- and middle-income countries.[28] Most countries implement WHO guidelines for vitamin A supplementation synchronized with childhood vaccine schedules.

ZINC DEFICIENCY

Zinc plays a central role in cellular growth, differentiation, and metabolism. It is necessary for physical growth, GI, and immune function. Many zinc studies show improved growth of children and decreased infections when supplements are given to vulnerable populations. Studies suggest that the global prevalence of zinc deficiency approaches 31 percent, especially in Africa, the eastern Mediterranean, and South Asia.[29]

▶ Clinical presentation

The most common presentation of zinc deficiency is nonspecific and may include growth stunting, delayed sexual maturation, dermatitis, and defective immunity. Zinc deficiency is associated with decreased macrophage chemotaxis, decreased neutrophil activity, and decreased T-cell responses.[22] It is widely acknowledged that zinc deficiency contributes significantly to child mortality from pneumonia, diarrhea, and malaria. A rare but characteristic presentation of profound zinc deficiency is acrodermatitis enteropathica (**Figure 7-10**).

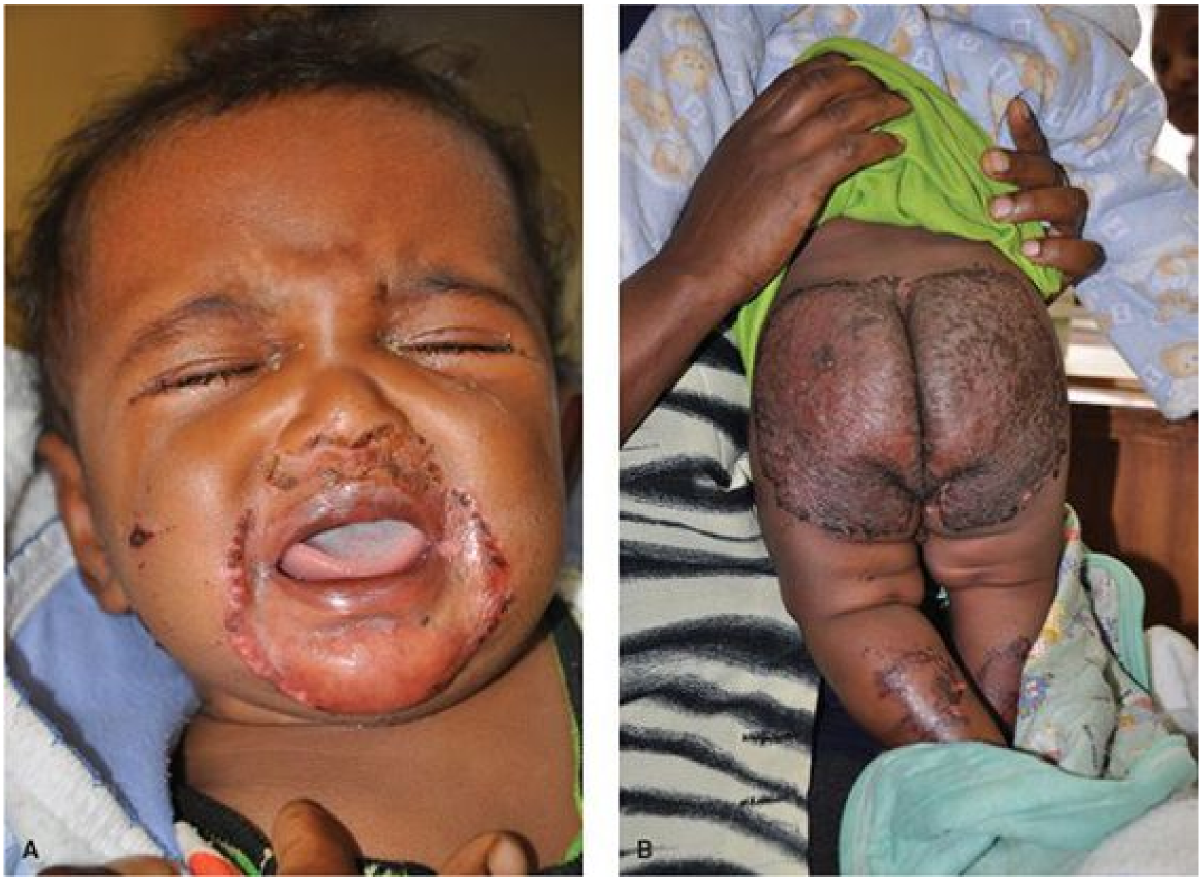

FIGURE 7-10 Acrodermatitis enteropathica caused by a zinc deficiency. Zinc supplementation is a standard recommendation from WHO in treatment of childhood diarrhea. Even children who do not have skin findings of zinc deficiency benefit with reduced duration of diarrhea and reduced mortality from all infectious causes in the ensuing months after receiving supplementation. Note the typical lesions around the (**A**) mouth and (**B**) buttocks. (*Used with permission from Richard P. Usatine, MD.*)

▶ Diagnosis

Because there is no good biomarker for zinc deficiency, diagnosis must rest on clinical suspicion and documentation of therapeutic response to supplementation.

▶ Management

WHO guidelines for diarrhea recommend use of low concentration ORS together with routine zinc supplementation for 10 to 14 days. Children older than age 6 months should get 20 mg daily; infants younger than age 6 months should get 10 mg daily.[30] Zinc supplementation decreases the duration and volume of diarrheal stools by 25 percent and 30 percent, respectively. More importantly, 14 days of zinc supplementation for a diarrheal episode reduces the incidence of diarrhea and pneumonia in the subsequent 2 to 3 months, reduces hospital admissions for diarrhea, and brings approximately a 50 percent reduction in noninjury deaths in the year following the treatment.[31] Unfortunately, zinc supplementation benefits are still not widely known by health care workers in developing countries.[32]

IRON

Iron deficiency is the most common micronutrient deficiency in the world, and 2 billion people (nearly 1/3 of the global population) are anemic. In resource-limited countries, iron-deficiency anemia is either caused or aggravated by malaria, intestinal parasites such as hookworm, and other chronic infections such as HIV, tuberculosis, or schistosomiasis. Iron deficiency causes enormous morbidity and contributes to 20 percent of global maternal mortality. Because the consequences include impaired cognition and physical development, increased risk of illness in children and reduced work productivity, iron deficiency is a real barrier to economic development in resource-poor countries.[33] As with zinc and vitamin A, iron deficiency can be detrimental to host immunity, causing decreased neutrophil chemotaxis.[22]

► Interventions

The WHO has developed a three-pronged strategy for addressing global iron deficiency: increasing iron uptake through dietary diversification and supplementation, improvement of nutritional status, and controlling infections, especially worms. In countries with significant iron-deficiency anemia, malaria, and helminth infections, these interventions can restore individual health as well as raise national productivity levels, thereby interrupting the cycle of poverty and disease.[33]

IODINE

Insufficient dietary iodine can significantly lower the IQ of whole populations and is the leading preventable cause of brain damage. Although iodine deficiency is easily solved through food fortification costing 2 cents per person annually, prevalences of 60 percent to 90 percent iodine deficiency among school-age children are observed in multiple African, Asian, and eastern Mediterranean countries. There is tremendous variance of iodine deficiency within individual countries and deficiency is not linked to poor or disadvantaged districts.[34] Iodine deficiency occurs where the soil has low iodine content because of past glaciation or repeated leaching effects of precipitation. Food crops grown in iodine-deficient soil provide inadequate dietary iodine.[35]

► Clinical presentation

Because iodine is required for thyroid hormone synthesis, iodine deficiency results in hypothyroidism and goiter (**Figure 7-11**). Congenital iodine deficiency results in a form of profound cognitive impairment known as *cretinism*. Other consequences include stillbirths, deaf mutism, subclinical hyper- or hypothyroidism, impaired mental function, and retarded physical development.[35]

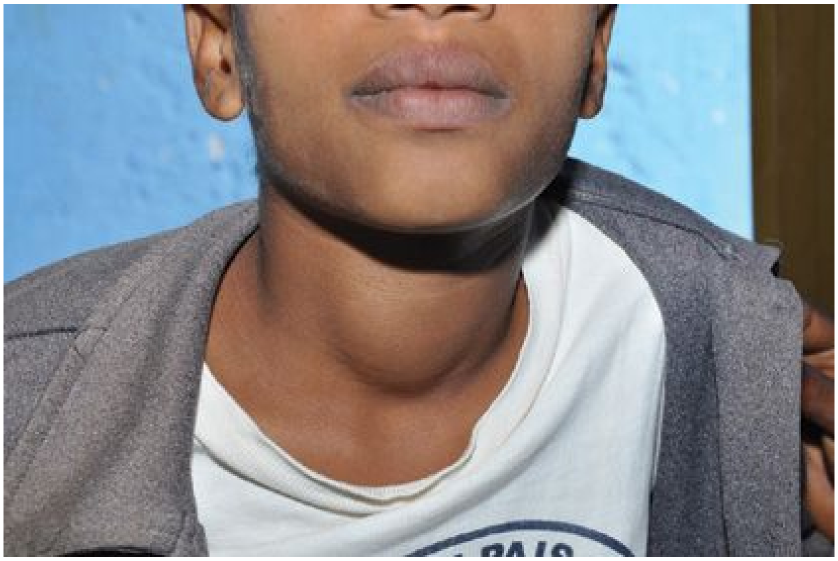

FIGURE 7-11 A goiter caused by iodine deficiency in this teen from a country in Africa where iodine is not routinely supplemented in the diet and goiter is endemic. (*Used with permission from Richard P. Usatine, MD.*)

▶ Interventions

Iodine may be supplied in tablets or liquid form and taken daily; in adults, 150 µg/day is sufficient for thyroid function and an adult multivitamin typically contains 150 µg of iodine per tablet, but this is impractical. Population-based interventions should include iodization of salt, and in some developing countries, eradication of iodine deficiency has been accomplished by adding iodine drops to well water.

VECTOR BORNE DISEASES

MALARIA

Malaria is a protozoan infection spread by the *Anopheles* mosquito vector in endemic areas. Of the four species of malaria (*Plasmodium falciparum*, *Plasmodium ovale*, *Plasmodium malariae*, and *Plasmodium vivax*), *P. falciparum* is the most important to address, because if unrecognized and untreated, it can be rapidly fatal. Only *P. falciparum* exhibits high levels of parasitemia in blood, and it is the only type of malaria that causes sequestration of parasitized erythrocytes in microvasculature. This unique feature of *P. falciparum* is responsible for the severe end-organ damage, including renal failure, acute respiratory distress syndrome, and coma that is seen with untreated disease.[36]

▶ Epidemiology and geographic distribution

There are more than 200 million cases of malaria in the world every year. According to the WHO, up to 1 million people worldwide die annually from malaria, with 89 percent of these deaths occurring in Africa. Most of the deaths caused by malaria occur in children younger than age 5 years. *P. falciparum*, *P. vivax*, *P. malariae*, and *P. ovale* are globally distributed in the tropics. *P. vivax* is more common in Asia, South America, Oceania, and India. *P. ovale* is found mainly in West Africa, and *P. malariae* is much less common than *P. vivax* or *P. falciparum*.

The risk for malaria varies greatly within a given country, and depends on altitude (higher altitudes have lower risk), season (greatest risk in rainy season), and urbanization (rural areas have greater risk than urban areas). Thus, travelers should be aware of these differences and plan for prophylaxis accordingly.

The CDC publication, *Health Information for International Travel*, is available online at http://www.cdc.gov/travel/ and should be consulted for updates about regional patterns of malaria risk, as well as drug resistance and guidelines, which are subject to frequent changes.[37]

▶ Clinical presentation

After a 1- to 3-week incubation period following the bite of an infected female mosquito, patients develop a nonspecific syndrome of high fever, headache, myalgia, and shaking chills. This syndrome is frequently accompanied by nausea, vomiting, and back pain, and occasional diarrhea. Splenomegaly and anemia (related to hemolysis) are common in all four types of malaria.

As untreated *P. falciparum* progresses, there is a risk of cerebral malaria, which is caused by parasitized erythrocytes sequestered in the capillaries of the brain, with secondary metabolic consequences. Cerebral malaria is characterized by severe headache and altered consciousness. These patients may also develop acute respiratory distress syndrome (ARDS), hypoglycemia, acidosis, and shock in the setting of hyperparasitemia. Untreated patients with cerebral malaria ultimately progress to coma, respiratory failure, and death.[38]

▶ Differential diagnosis

The initial presentation of malaria is so nonspecific that it mimics influenza (without the respiratory symptoms), enteric fever (see section on typhoid), dengue fever, rickettsial infections, brucellosis, and leishmaniasis. If hemolysis has been extensive, the patient may present with jaundice, and viral hepatitis or leptospirosis may also be on the differential diagnosis.[36]

▶ Laboratory diagnosis

Malaria is usually diagnosed by light microscopy of peripheral blood smears prepared with a Giemsa, Field, or modified Wright stain (**Figures 7-12** and **7-13**). A thick-and-thin smear should be obtained whenever possible in every febrile patient in whom malaria is suspected, especially from febrile travelers returning from malaria endemic areas. Thin smears allow relative quantification and speciation of parasites when the parasitemia is high; thick smears are useful to rule in malaria, especially when parasitemia is low. Because a single negative smear does not rule out malaria, the test must be repeated on at least three occasions at 12- to 24-hour intervals.[39] Patients with high levels of parasitemia (>5%) have a worse prognosis and should be considered for inpatient care.

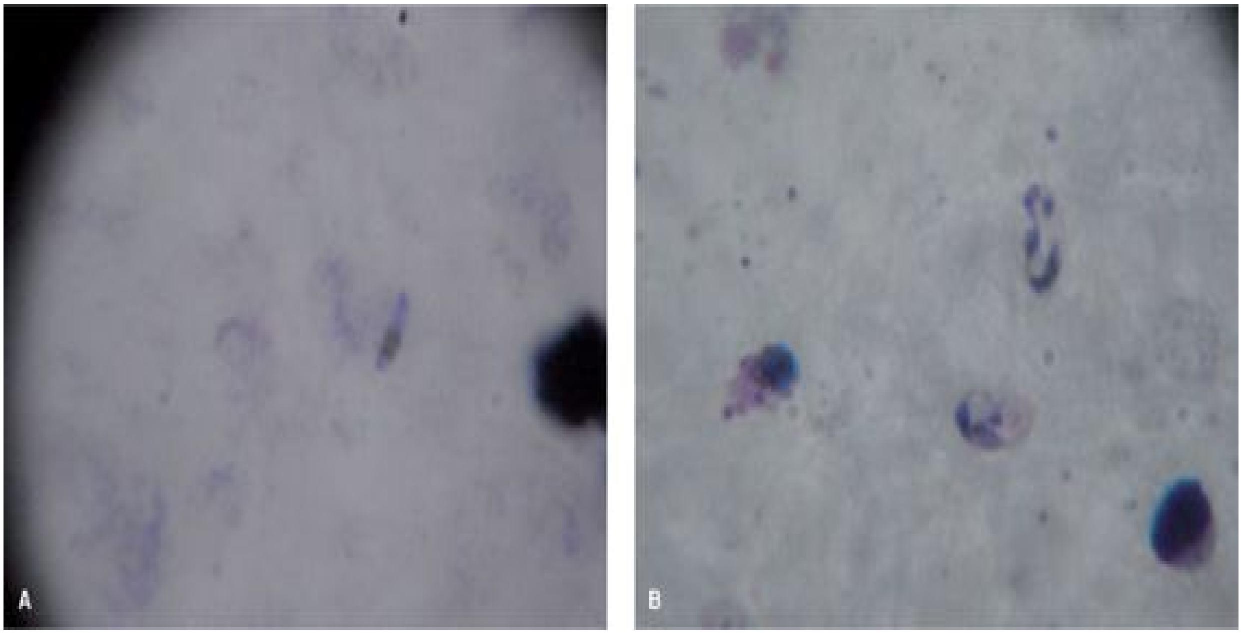

FIGURE 7-12 **A.** *Plasmodium falciparum* with a banana-shaped gametocyte. Of all the species of malaria, *P. falciparum* is the most likely to cause severe morbidity and mortality. **B.** *Plasmodium falciparum* with chromatin in rings. (*Used with permission from Richard P. Usatine, MD.*)

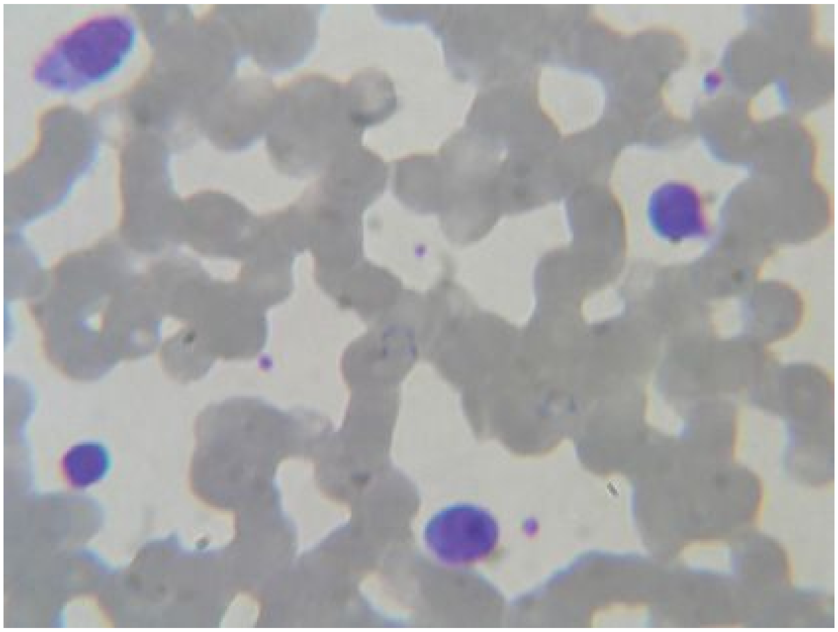

FIGURE 7-13 Blood smear for malaria diagnosis showing *Plasmodium vivax*. Rapid field tests are now available but still more expensive than microscopy. (*Used with permission from Richard P. Usatine, MD*.)

Other diagnostic modalities include the fluorochrome acridine orange stain for fluorescence microscopy and PCR (not yet widely available but helpful for very low levels of parasitemia). Rapid antigen assays using fingerstick blood samples on cards impregnated with specific antibodies are alternative methods for laboratory diagnosis of malaria. In the US, the US Food and Drug Administration has approved the BinaxNOW Malaria test, which, although costly, is convenient for rapid field use. Unfortunately, this and other immunochromatographic strip assays are not able to determine parasite load.[37]

▶ Treatment

Many cases of malaria can be treated effectively with oral medication and parenteral therapy is reserved for severe disease or for patients who are vomiting. Before prescribing therapy, determine which species is most likely involved based on microscopy or rapid diagnostic test; consider the geographic area and local drug resistance patterns.

After the patient has been given the first dose of medication, the patient should be observed for an hour. Vomiting can be managed with metoclopramide, 10 mg orally, and if the vomiting occurs within 30 minutes, the full initial dose can be repeated. The WHO recommends artemisinin-based combination treatments as first-line for uncomplicated *P. falciparum*: artemether-lumefantrine 1 dose at hours 1, 8, 24, 36, 48, and 60 based on body weight: 5 to 14 kg: 1 tablet per dose; 15 to 24 kg: 2 tablets per dose; 25 to 34 kg: 3 tablets per dose; >34 kg: 4 tablets per dose.

Other artemisinin combinations can be used as follows: artesunate plus amodiaquine, artesunate plus mefloquine, and artesunate plus sulfadoxine-pyrimethamine. The combination of choice depends on the level of resistance of the partner medication in a given region. Artemisinin and derivatives should not be given as monotherapy.

For US-returning travelers, the choice of malaria chemotherapy is based on the infecting species, possible drug resistance, and severity of disease. Options for therapy include atovaquone-proguanil, quinine in combination with tetracycline, artemether-lumefantrine, mefloquine, or artesunate.

Treatment of severe P. falciparum

All cases of severe malaria should be managed as medical emergencies. Give IV or IM artesunate, artemether, or quinine dihydrochloride (not available in the US).

In the US, give quinidine gluconate, 10 mg base/kg (up to 600 mg) in 0.9 percent saline by rate-controlled IV infusion over 1 to 2 hours, followed by a maintenance dose of 0.02 mg base/kg per minute with electrocardiogram (ECG) monitoring until patient can take oral drugs. Quinine and quinidine must never be given by IV bolus because of the potential for fatal hypotension. For patients with severe malaria in the US who do not tolerate or cannot easily access quinidine, intravenous artesunate has become available through a CDC investigational new drug protocol. Clinicians may contact the physician on call through the CDC malaria hotline (770-488-7788, Monday–Friday, 9:00 AM–5:00 PM Eastern Time; or 777-488-7100 at all other times) for additional information and release of the drug.

Patients with cerebral malaria should undergo lumbar puncture to rule out bacterial meningitis (**Figure 7-14**) and their blood glucose should be checked every 4 hours because of the significant risk of hypoglycemia in severe malaria. Careful hemodynamic monitoring and management of seizures (with intravenous benzodiazepines) are essential.

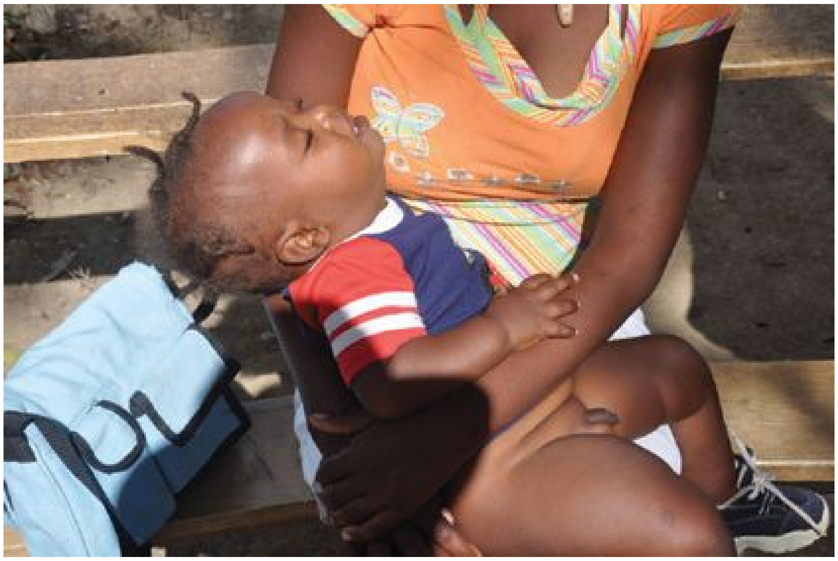

FIGURE 7-14 Meningitis in a child with a very rigid neck. Cerebral malaria should be in the differential diagnosis for this child. Most bacterial meningitis in children can now be prevented by vaccines frequently still not available in developing countries. (*Used with permission from Richard P. Usatine, MD.*)

▶ Prevention

Prevention measures are a public health priority and should include mosquito control, elimination of standing water in households and gardens, insect repellant containing at least 10 percent to 50 percent diethyltoluamide (DEET; 30 percent DEET provides 6 to 8 hours of protection), and permethrin-impregnated bed nets. Since 2000, prevention and control measures have reduced malaria mortality by more than 25 percent globally and by 33 percent in Africa.[40]

Prevention for travelers

Choice of chemoprophylaxis depends on drug resistance patterns for *P. falciparum* in the country being visited. Generally, prophylaxis should start 1 week before arrival and should continue through 4 weeks after leaving the endemic area. In the case of atovaquone-proguanil, prophylaxis may start the day before arrival and end 7 days after departure. Drugs commonly used in prophylaxis include atovaquone-proguanil (Malarone, which is expensive in the US), mefloquine (may cause central nervous system side effects), and doxycycline (causes photosensitivity). Chloroquine can be used only in a few areas; chloroquine-susceptible malaria is restricted to the Caribbean, Central America, and parts of the Middle East.

LEISHMANIASIS

Leishmaniasis is a vector-borne disease transmitted by the sandfly. It can be divided into two major forms, a cutaneous form, which is the most common, and the visceral form. There is also a more rare mucocutaneous form that can cause significant facial disfigurement around the nose and mouth.

▶ Synonyms

Kala-azar is another name for visceral leishmaniasis.

▶ Epidemiology

- New World leishmaniasis is found in Mexico, Central America, and South America. Old World leishmaniasis is found in India, Africa, the Middle East, southern Europe, and parts of Asia.
- Most leishmaniasis diagnosed in the US occurs in travelers returning from endemic areas including military personnel who served in Iraq or Afghanistan.
- Some cutaneous leishmaniasis cases acquired in the US have been reported in Texas and Oklahoma.[41]
- Ninety percent of cutaneous leishmaniasis occurs in Afghanistan, Algeria, Iran, Saudi Arabia, Syria, Brazil, Colombia, Peru, and Bolivia.[41]
- Ninety percent of visceral leishmaniasis cases occur in parts of India, Bangladesh, Nepal, Sudan, Ethiopia, and Brazil.[41]

▶ Etiology and pathophysiology

- Leishmaniasis is caused by more than 20 species of the protozoan genus *Leishmania*.
- Leishmaniasis is transmitted to people through the bite of the sandfly.
- The intracellular amastigotes of *Leishmania* replicate within macrophages.
- The disease can also be transmitted like any bloodborne infection, but human-to-human transmission is rare.

► Risk factors

- Living in and traveling to endemic countries.
- Rural areas have a higher prevalence of disease in the endemic countries.
- Not protecting the skin from sandfly bites during the time from dusk to dawn.
- Blood transfusions, needle sharing in injection-drug users, needle-stick injuries, and congenital transmission also are all reported risk factors for visceral leishmaniasis.[42]

► Diagnosis

Clinical features

- Six weeks after a sandfly bite, the cutaneous form may be localized to a single ulcer or nodule (**Figure 7-15**) or may be disseminated widely (**Figure 7-16**).

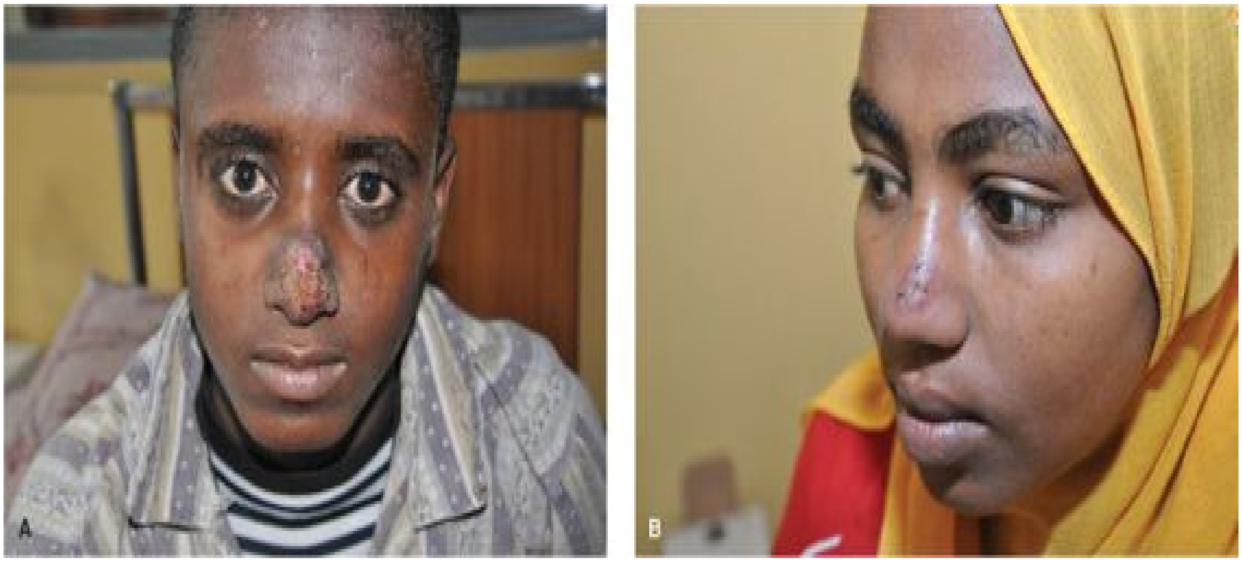

FIGURE 7-15 Examples of leishmaniasis on the face. Lesions emerge in the site of the sandfly bite; the nose is commonly affected as seen in the children in figures **A** and **B** from Africa. (*Used with permission from Richard P. Usatine, MD.*)

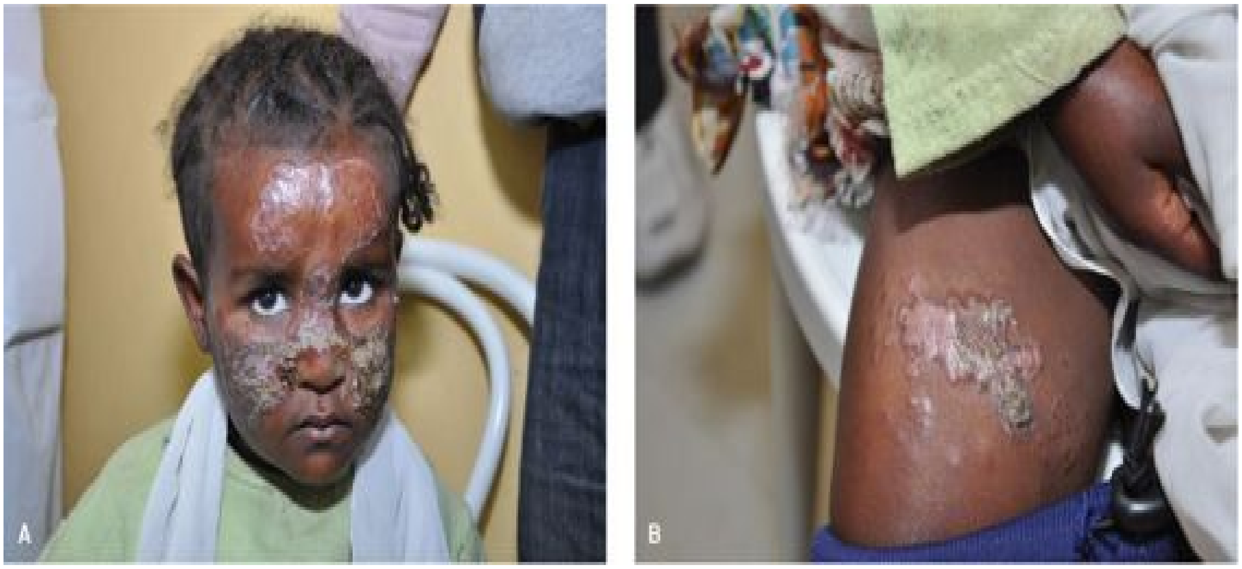

FIGURE 7-16 Widespread leishmaniasis in a young African girl with involvement from the face and trunk. The multiple nodules on the face could be lepromatous leprosy or lupus but by skin snip testing, the diagnosis of leishmaniasis was confirmed. Figures **A** shows a type of leishmaniasis that is called lupoid leishmania. (*Used with permission from Richard P. Usatine, MD.*)

- After a 2- to 6-month incubation period, the visceral form can involve the liver, spleen, and bone marrow and causes systemic illness. The patient may present with fever, anemia, night sweats, weight loss, and an enlarged abdomen because of hepatosplenomegaly.[43]
- Mucocutaneous leishmaniasis affects the nose and mouth and may affect the nasal septum and palate (**Figure 7-17**). This form may occur months to years after what appears to be healing of cutaneous leishmaniasis.

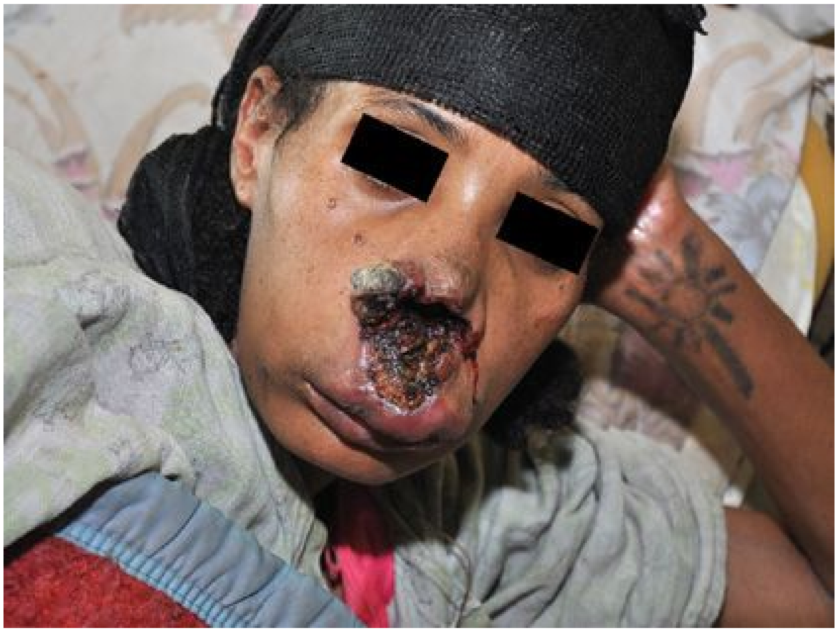

FIGURE 7-17 Severe mucocutaneous leishmaniasis causing destruction of the nose. (*Used with permission from Richard P. Usatine, MD.*)

Distribution

- A cutaneous form of leishmaniasis has a predilection for the nose and face (**Figure 7-15**).
- Cutaneous leishmaniasis is also commonly seen on the extremities. Note that the sandfly would generally have more access to bite the face and extremities where clothing is less likely to be a protective barrier.
- Disseminated cutaneous leishmaniasis can be seen from the head to the toes (**Figure 7-16**).

Laboratory testing

- Cutaneous leishmaniasis may be diagnosed by clinical appearance and a biopsy or a scraping of the ulcer. A Giemsa stain will demonstrate parasites in the skin smears taken from the edge of an active ulcer.[43] In some centers, PCR is available and is considered the method of choice.[44]
- Visceral leishmaniasis is diagnosed from a blood sample or a bone marrow biopsy. Several serologic agglutination tests (direct agglutination test [DAT] or fluorescent allergosorbent test [FAST]) are highly sensitive for detection of leishmania antibodies. Culture of a bone marrow aspirate or PCR improve diagnostic yield.[43]

▸ Differential diagnosis

- The differential diagnosis of cutaneous leishmaniasis includes leprosy, sarcoidosis, pyoderma gangrenosum, primary syphilis, and venous stasis ulcers.
- The differential diagnosis of visceral leishmaniasis includes malaria, typhoid fever, and lymphoma.

▸ Management

Nonpharmacologic

- Wound care for ulcers.

Medications

- The main drugs used to treat leishmaniasis include sodium stibogluconate (available from the CDC) and meglumine antimonate.[45,46] Other medications used include miltefosine (the only oral drug for leishmaniasis) fluconazole and liposomal amphotericin b (this is the only drug with FDA approval for visceral leishmaniasis in the US).[45,46] Amphotericin b is the standard of care in India because of antimonial resistance.[44]

Surgery

- Plastic surgery may be used to treat the disfigurement of mucocutaneous or cutaneous leishmaniasis.

PREVENTION OF VECTOR-BORNE DISEASES

Prevention is a public health priority that must include vector (mosquito and sandfly) control, elimination of standing water in households and gardens, insect repellant containing 20 percent to 30 percent DEET, and permethrin-coated bednets. Sandflies and *Anopheles* mosquitoes bite from dusk to dawn, but the *Aedes aegypti* vector of dengue fever bites any time during the day, making daytime use of mosquito repellant especially important in dengue-endemic areas.

PROGNOSIS

- Cutaneous leishmaniasis does resolve spontaneously in some cases and in other cases it may persist and resist treatments. The prognosis is related to the severity of the case and the community of the host. Even in those cases that resolve scarring is frequent.
- Visceral leishmaniasis is fatal if not diagnosed and treated.

EYES—TRACHOMA

EPIDEMIOLOGY AND GEOGRAPHIC DISTRIBUTION

Chlamydia trachomatis is the leading infectious cause of blindness, accounting for 3 percent of the world’s blindness. Globally, 21.4 million people have trachoma, and of these, 1.2 million are blind.[47] Trachoma is associated with poor sanitation, inadequate water supply, and lack of personal hygiene. It is transmitted from person to person via unwashed fingers, flies, and close family contact (sharing of face towels and bedclothes). Trachoma is endemic in Africa (especially in the driest regions) India, South Asia, Australia, and parts of South America.

CLINICAL PRESENTATION

Patients experience inflammation of the eye with watery discharge, itching, burning, and blurry vision. Examination of the tarsal conjunctiva reveals follicles (round swellings that are paler than the surrounding conjunctiva, at least 0.5 mm in diameter). With progression, intense trachomatous inflammation develops, producing inflammatory thickening of the tarsal conjunctiva, which appears red and thickened with numerous follicles (**Figure 7-18**).

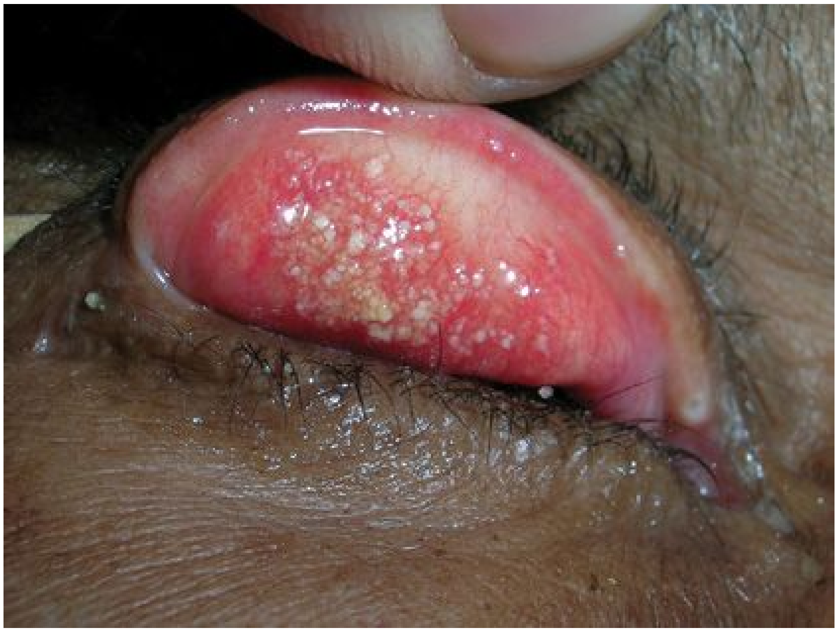

FIGURE 7-18 Trachoma causing prominent follicles on the upper eyelid in a person infected with *C. trachomatis*. Note how flipping the eyelid is needed to see the follicles under the upper eyelid. (*Used with permission from Richard P. Usatine, MD.*)

Eventually, trachoma causes scarring, with white lines or bands in the tarsal conjunctiva as well as trichiasis, in which eyelashes turn inward and begin to rub against the cornea, and entropion, or inward turning of the eyelid itself. With time, this chronic rubbing causes corneal opacity and blindness (**Figure 7-19**).

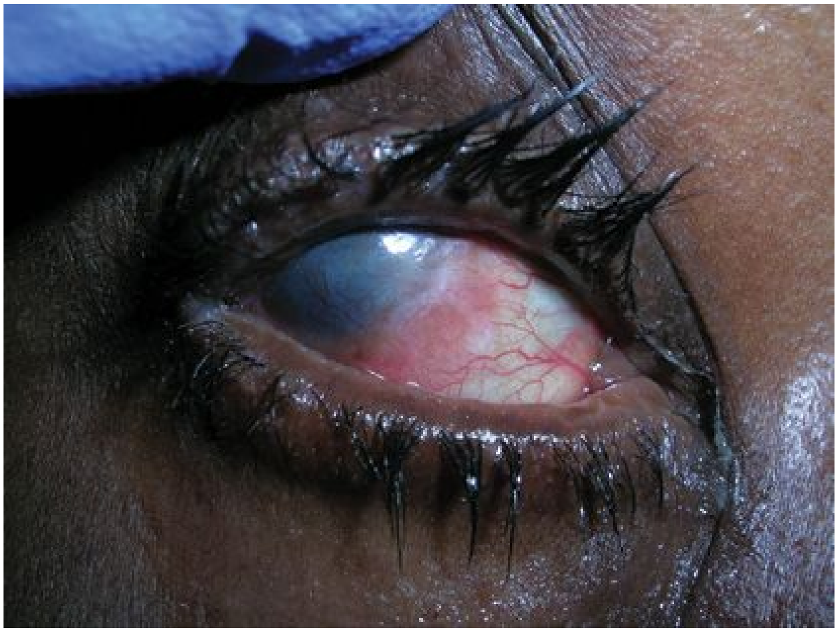

FIGURE 7-19 Blindness caused by untreated trachoma. Although this is one of the most common causes of blindness worldwide, trachoma is easily treatable with a single dose of oral azithromycin. Prevention is achieved through better access to water and soap, together with education about the three "Fs": flies, fingers, facial hygiene. (*Used with permission from Richard P. Usatine, MD.*)

DIAGNOSIS

Although laboratory diagnostic testing is available for staining *C. trachomatis* in scrapings from the tarsal plate, most settings where trachoma is endemic do not offer this resource, and visual inspection of the everted upper eyelid must suffice. Each eye should be examined for trichiasis and corneal opacities. The upper eyelid is everted by asking the patient to look down, holding eyelashes between thumb and finger, and everting the lid using a cotton-tipped applicator. The everted lid is then checked for follicles, inflammation, and scarring. The differential diagnosis of trachoma includes allergic conjunctivitis (which can also produce follicles of the tarsal plate), and bacterial or viral conjunctivitis.

MANAGEMENT

- Azithromycin, 1 g single oral dose for adults and 20 mg/kg for children in a single dose.
- In pregnancy: erythromycin 500 mg twice daily for 7 days.
- Less effective: topical erythromycin and tetracycline.[10]
- In some settings, surgery is available to correct entropion and trichiasis.

PREVENTION

Preventive measures include community hygiene education, use of soap and water for washing hands and faces, and control of flies through use of ventilated improved pit (VIP) latrines. The WHO has developed the acronym "SAFE" for the global elimination of trachoma:

S Surgery for entropion and trichiasis
A Antibiotics for infectious trachoma
F Facial cleanliness to reduce transmission
E Environmental improvements such as control of disease-spreading flies and access to clean water[48]

SKIN

INFECTIOUS SKIN DISEASES

Many of the skin diseases encountered in resource-limited countries are secondary to crowded living conditions and lack of clean water and soap. Scabies mites and human lice are endemic in many populations that are unable to wash frequently. If clean water is scarce, it is more likely to be used for drinking and cooking than bathing. In developed countries, we take clean running water (hot and cold), soap, and shampoo for granted. In developing countries, even if water is available, it may not be accessible as warm running water for showers or baths.

When an intervention as simple as mass distribution of free soap for personal hygiene draws enormous crowds to a mobile clinic, the vastness of inequality in access to basic health measures around the world becomes painfully obvious. Although people recognize the importance of access to soap and clean water, the absence of this luxury results in skin infections and infestations that are highly prevalent and spread from person-to-person (**Figure 7-20**).

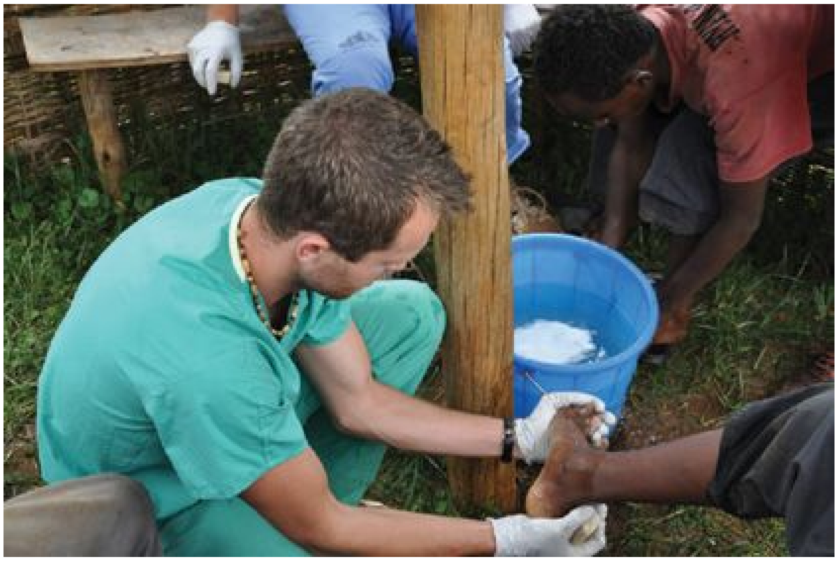

FIGURE 7-20 An American medical student is washing the feet of Ethiopian schoolchildren to treat skin infections and to educate them on preventive hygiene measures. (*Used with permission from Richard P. Usatine, MD.*)

We can divide the skin diseases into infestations, bacterial, viral, and fungal infections. All of these skin infections are covered in the dermatology section of this book. Here we highlight some cases seen in developing countries.

Scabies (see Chapter 128, Scabies) is caused by a human mite that burrows under the skin causing itching and leading to scratching. The itching and scratching may keep the person awake at night and may lead to bacterial superinfections (**Figure 7-21**). Scabies is spread by direct skin contact (**Figures 7-22** and **7-23**), shared bedding and clothing, and occasionally by fomites.

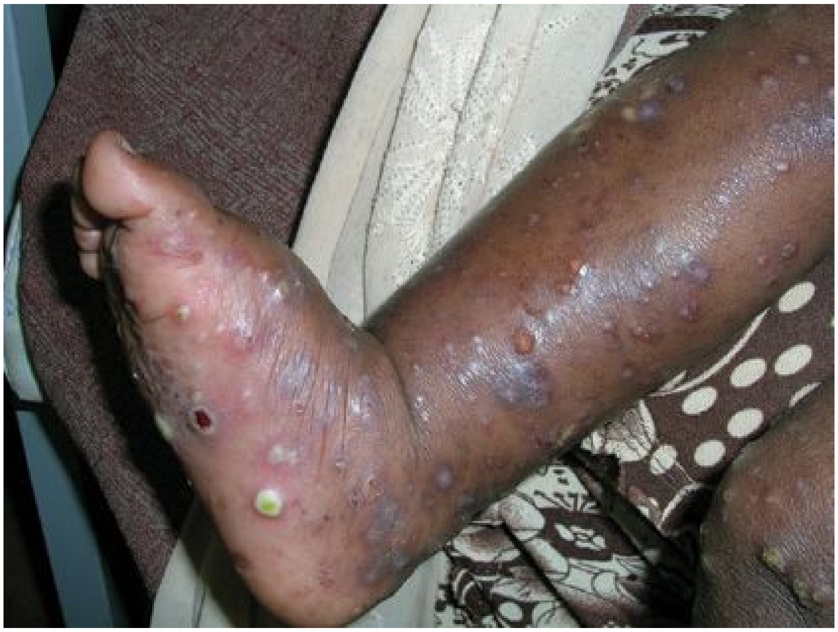

FIGURE 7-21 Badly superinfected scabies with pustules and crusting sores on this young child’s leg. (*Used with permission from Richard P. Usatine, MD*.)

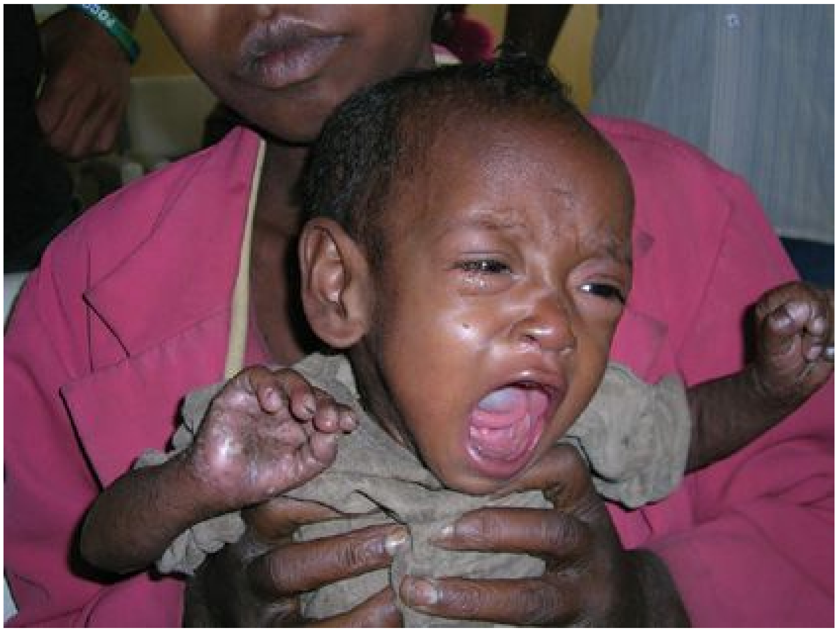

FIGURE 7-22 A malnourished baby with marasmus is infested with scabies seen on the hands and arms. Lack of adequate nutrition also is a risk factor for many infections and diseases. The scabies infestation is a marker for scarcity of clean water; the consequences of both may be contributing to the

child’s irritability and poor feeding. (*Used with permission from Richard P. Usatine, MD.*)

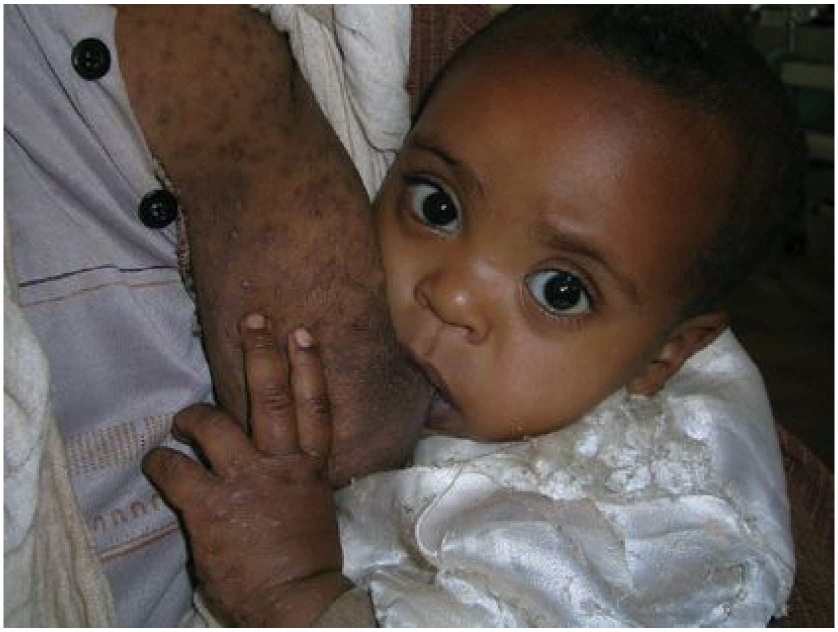

FIGURE 7-23 Scabies infestation covering the mother’s breast and her baby’s hand. With poor access to health care, this infestation would likely remain untreated, and could lead to bacterial superinfection and impetigo on the baby’s skin. (*Used with permission from Richard P. Usatine, MD.*)

Human lice (see Chapter 127, Lice) exist as 3 separate species that are known as head lice, body lice, and pubic lice. Schoolchildren are particularly at risk for head lice, and in areas with limited head washing, the majority of kids may be infested. Body lice live on clothing and feed on the blood of their host. Body lice are more prevalent on adults that bathe rarely and wear the same unwashed clothing day after day. Pubic lice are transmitted through sexual contact and are not known to be more prevalent in developing countries. Water and hygiene issues do predispose to increased head and body lice in developing countries.

Bacterial infections of the skin (see Chapter 99, Impetigo) are ubiquitous throughout the world. Impetigo is a superficial bacterial infection that presents with honey crusts (**Figure 7-24**) or bullae. Good hygiene can prevent impetigo and therefore is not surprising that many cases of impetigo will be seen in countries that lack access to soap and clean water. Impetigo is often secondary to other skin diseases such as scabies or fungal infections that create breaks in the skin barrier function. Cases of secondarily infected scabies and tinea are seen commonly in developing countries.

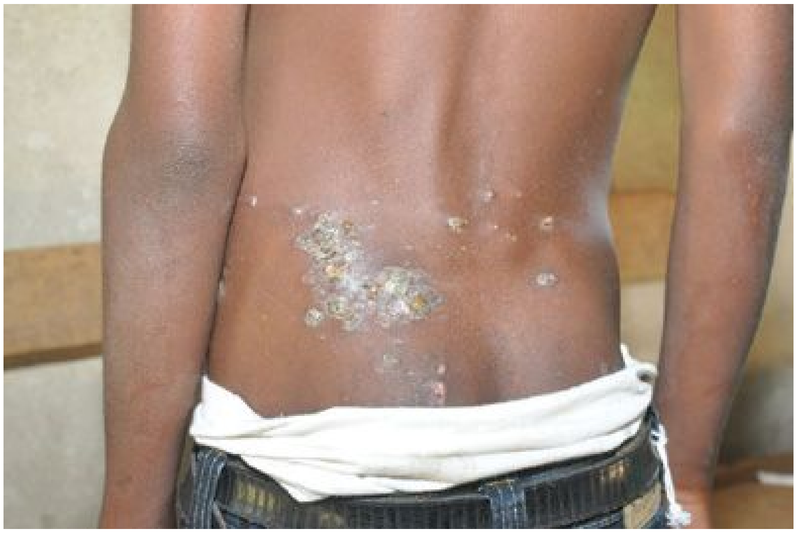

FIGURE 7-24 Impetigo caused by a bacterial infection on the buttocks of this child in Haiti. Impetigo is more prevalent when there is inadequate hygiene and lack of access to health care. (*Used with permission from Richard P. Usatine, MD.*)

Viral infections of the skin (see Chapters 108, Varicella; 109, Zoster; 110, Zoster Ophthalmicus; 111, Measles; 112, Fifth Disease; 113, Hand Foot and Mouth Disease; 114, Herpes Simplex; 115, Molluscum Contagiosum; 116, Common Warts; 117, Flat Warts; 118, Genital Warts; and 119, Plantar Warts) include herpes simplex, varicella zoster, molluscum contagiosum, and human papilloma virus infections. These infections are seen commonly in HIV-infected persons who are not receiving optimal antiretroviral therapy. In countries with a high prevalence of HIV-infected persons, a severe case of molluscum, warts, or shingles in a young person should prompt a clinician to consider HIV testing, if possible. Molluscum infections and warts are so ubiquitous throughout the world that it is important to realize that healthy people with healthy immune systems can get these infections too. Viral exanthems caused by such diseases as varicella and measles may be more prevalent in countries where vaccinations are less available.

Fungal infections of the skin (see Chapters 120, Fungal Overview; 121, Candidiasis; 122, Tinea Capitis; 123, Tinea Corporis; 124, Tinea Cruris; 125, Tinea Pedis; and 126, Tinea Versicolor) can occur from the head down to the toes. Heat, humidity, and lack of bathing are predisposing factors to fungal skin infections. Therefore, tropical developing countries provide good environments for tinea capitis (**Figure 7-25**), tinea corporis, and tinea pedis.

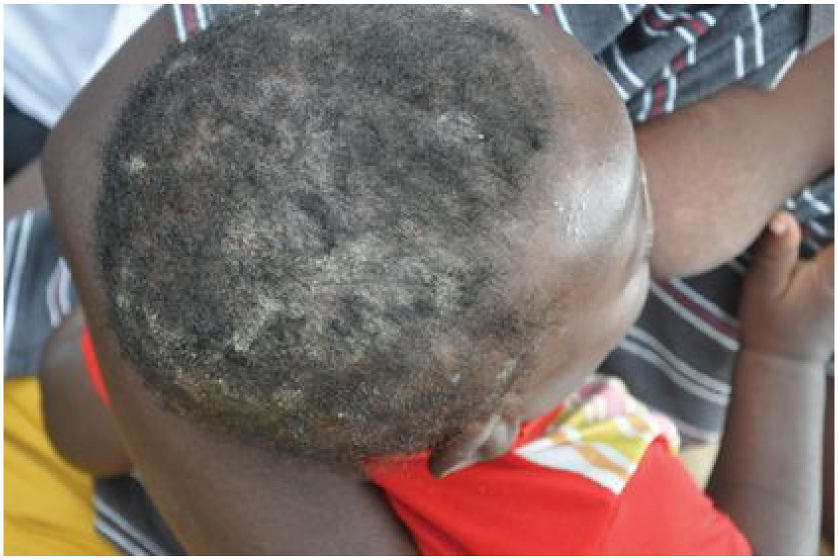

FIGURE 7-25 Tinea capitis in this young boy living in a developing country. Many children live with untreated tinea capitis in developing countries because of limited hygiene resources and poor access to health care. (*Used with permission from Richard P. Usatine, MD.*)

MYCOBACTERIUM (LEPROSY AND TUBERCULOSIS-HIV COINFECTION)

LEPROSY

▶ Patient story

A young boy presents with significant changes to his face (**Figure 7-26**). The boy and his father are from rural Africa, and it is obvious to the physician that the boy has lepromatous leprosy. The father is also examined and he has more subtle signs of leprosy present (several patches of hypopigmented anesthetic skin). A slit skin exam is performed on the ear lobe of the boy and many acid-fast bacilli, characteristic of *Mycobacterium* *leprae*, are found. The boy is started on the WHO-standard multidrug therapy using rifampin, clofazimine, and dapsone. The father is also examined and treated.

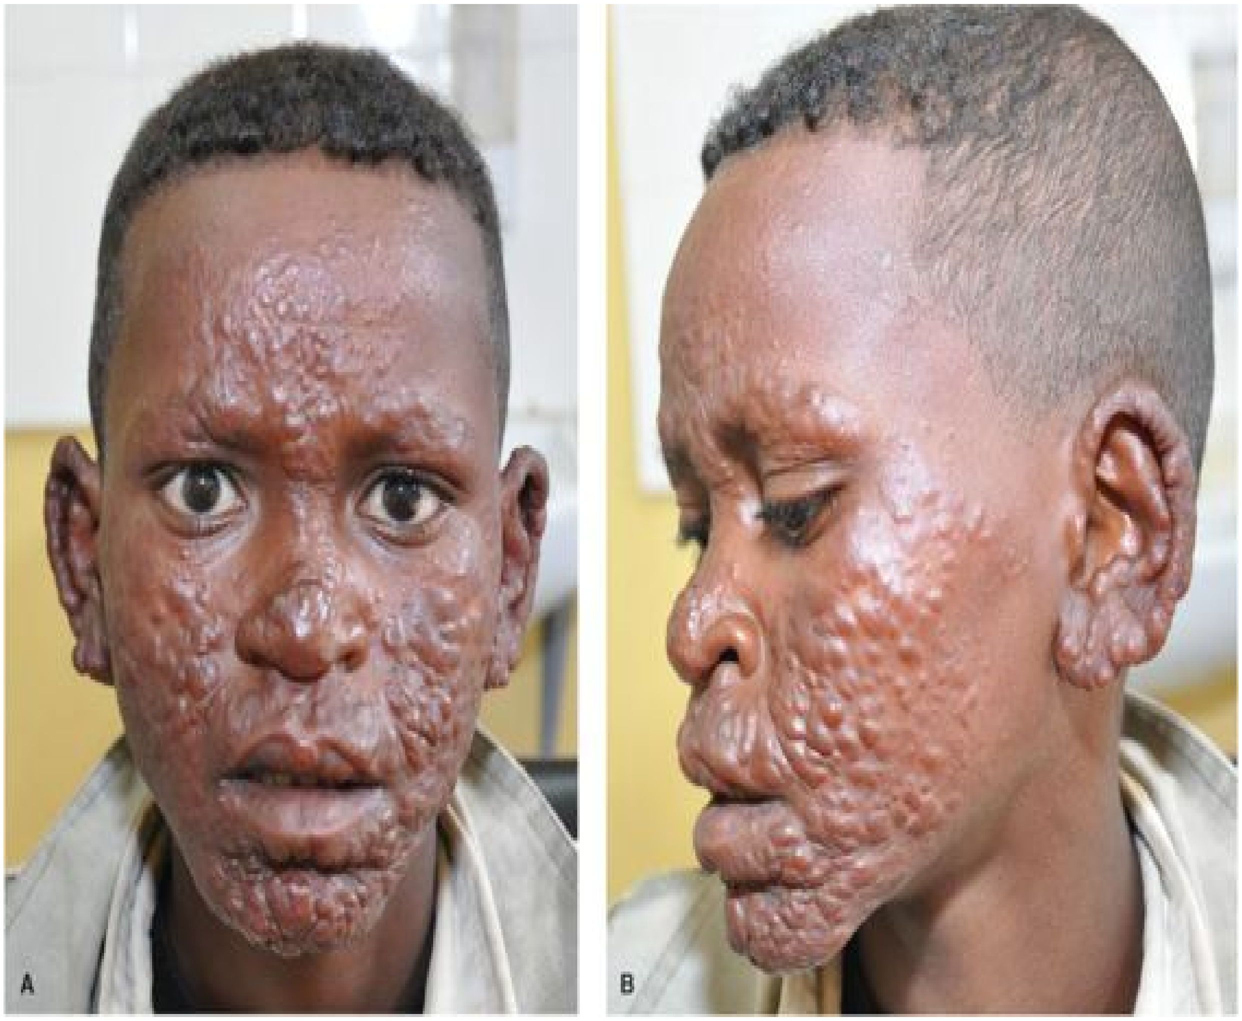

FIGURE 7-26 Lepromatous leprosy with leonine facies in a young boy. **A.** Note the loss of eyebrows called madarosis. **B.** Also note the prominent ear involvement. (*Used with permission from Richard P. Usatine, MD*.)

▶ Introduction

Leprosy (Hansen disease) is caused by *M. leprae* and is still endemic in many parts of the developing world where there is poverty and poor access to clean water. At one time, persons with leprosy were called “lepers” and isolated to leper colonies because the disease was disfiguring and the communities were afraid that it was highly contagious. Current science and epidemiology tell us that leprosy is transmitted via droplets from the nose and mouth during close and frequent contact over a period of years, and not by casual contact. Thus doctors working with patients who have leprosy are at no real risk of becoming infected. Issues related to stigma and discrimination still do exist.

▶ Epidemiology

- There were 219,075 new cases reported in the world by 105 countries in 2011.[49]
- The US reported 173 new cases reported in 2011.[49]
- Since 1990, more than 14 million leprosy patients have been cured, about 4 million from 2000 to 2010.[50]

▶ Etiology and pathophysiology

- The clinical manifestations of leprosy depend upon the immunologic reaction to the infection. The 2 opposite ends of the spectrum consist of:
    - Lepromatous leprosy in which there is a strong antibody response and a poor cell-mediated community resulting in larger amounts of *M. leprae* in the tissues (**Figure 7-26**).
    - Tuberculoid leprosy in which there is a strong cell-mediated immunity and a poor antibody response resulting in less *M. leprae* in the tissues. This tends to present with hypopigmented anesthetic patches (**Figure 7-27**).

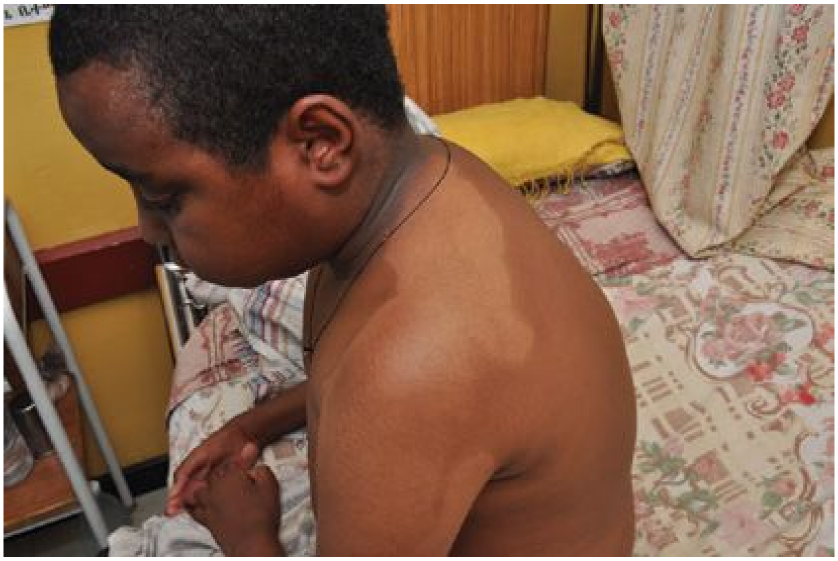

FIGURE 7-27 Leprosy with hypopigmented patches on the back of this young boy. These patches are numb due to cutaneous nerve damage from mycobacterial infection. He also has a Bell’s palsy. (*Used with permission from Richard P. Usatine, MD*.)

- There is also borderline leprosy in which there is a mixed cell-mediated immunity and antibody response showing features of both lepromatous leprosy and tuberculoid leprosy.
- Treatment regimens differ depending on whether the patient has paucibacillary (fewer organisms) or multibacillary leprosy. Lepromatous leprosy and borderline lepromatous leprosy are most likely to be multibacillary.

▶ Risk factors

- Poverty and living in an endemic area.
- Inadequate access to clean water and poor hygiene.
- Living in the household of an infected person.
- Eating or handling armadillos as these animals are natural hosts for *M. leprae*.

▶ Diagnosis

Clinical features

- Facial features include leonine facies, madarosis (loss of eyebrows as seen in **Figure 7-26**), elongated and dysmorphic earlobes, and saddle-nose deformities from destruction of the nasal cartilage and bone.
- Visible skin changes include nodules in lepromatous leprosy, hypopigmented patches in tuberculoid (**Figure 7-27**) and borderline leprosy, and annular saucer-like lesions in borderline leprosy.
- Nerve involvement can cause a clawhand (flexion contractures of the fingers as seen in **Figure 7-28**), wristdrop, footdrop, Bell's palsy, hammertoes, and sensory neuropathy leading to neurotropic ulcers and traumatic blisters.

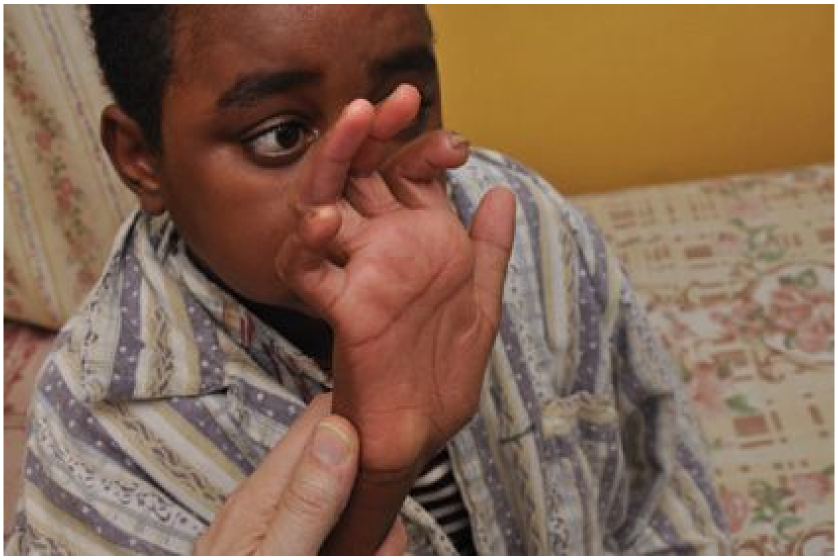

FIGURE 7-28 Clawhand caused by the neurological damage of leprosy in the same boy as in the previous photo. This condition may be amenable to surgical intervention involving tendon transfer. (*Used with permission from Richard P. Usatine, MD.*)

- Eye involvement can cause corneal anesthesia, keratitis, episcleritis, lagophthalmos (the inability to close the eyelid completely), and blindness.
- Advanced untreated leprosy can lead to shortening and/or loss of fingers as a result of bone resorption in hands that have become anesthetic and not protected from repeated trauma (**Figure 7-29**).

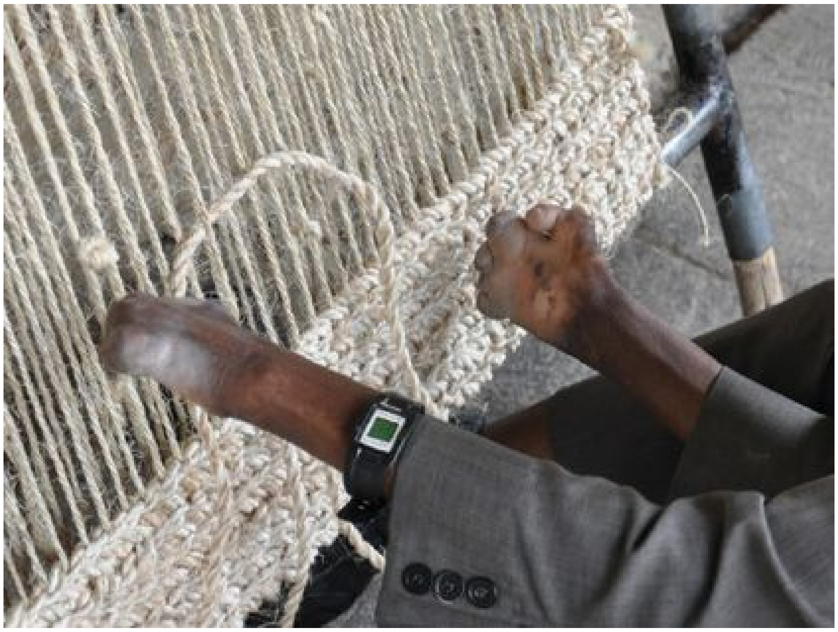

FIGURE 7-29 Leprosy has caused this older man to lose his fingers but he continues to lead a productive life weaving rugs for sale at a leprosy hospital. (*Used with permission from Richard P. Usatine, MD*.)

Distribution

The nodules of lepromatous leprosy are mostly seen on the face and ears but can be seen in other areas. Hypopigmented patches can be seen anywhere on the body including the face.

Laboratory testing

- In obvious cases of leprosy, the slit skin exam done on the ear lobe for bacillary index is the most important test to determine if the patient has multibacillary or paucibacillary leprosy.
- In cases that are suspicious for leprosy (especially outside of endemic areas), a skin punch biopsy of a suspicious lesion is useful for finding *M. leprae* in the tissues.

▶ Differential diagnosis

Superficial mycoses, vitiligo, and cutaneous filariasis all cause changes in pigmentation similar to leprosy. Infiltrated lesions that resemble leprosy include those of leishmaniasis, psoriasis, and sarcoidosis.[52]

▶ Management

Early diagnosis and multidrug therapy are essential to reducing the disease burden of leprosy worldwide. The WHO has supplied multidrug therapy free of cost to leprosy patients in all endemic countries.[51]

- Leprosy is curable and treatment in an early stage can prevent disability.
- Multidrug therapy is a combination of rifampin, dapsone, and clofazimine for multibacillary leprosy patients, and rifampin and dapsone for paucibacillary patients.
- Duration of multidrug therapy is 12 to 24 months for multibacillary and 6 months for paucibacillary patients.[52]
- Treatment with a single antileprosy drug will always result in development of drug resistance to that drug and is therefore an unethical practice.
- Strategies to increase early access to care and provide easy-to-obtain free multidrug treatment are essential to eliminating leprosy in the world. Research on a preventive vaccine continues in tandem with *Mycobacterium tuberculosis* vaccine research.[53]
- Comprehensive treatment of advanced cases with neuropathy should include foot and hand care to prevent further damage to these insensitive limbs.[52]
- Surgical management for some leprosy-associated problems, such as tendon transfer to correct the clawhand, may be available in some centers.[54]

TUBERCULOSIS AND HIV

▶ Epidemiology

Tuberculosis (TB) is a very common HIV-associated infection, and causes at least 13 percent of HIV-associated deaths worldwide.[55] In 2010 alone, the WHO estimated there were 1.1 million HIV-associated new cases of TB, the majority of who live in sub-Saharan Africa (**Figure 7-30**). Globally, about 1/3 of HIV-infected people are co-infected with TB (at least 11 million people) (**Figure 7-31**).[56]

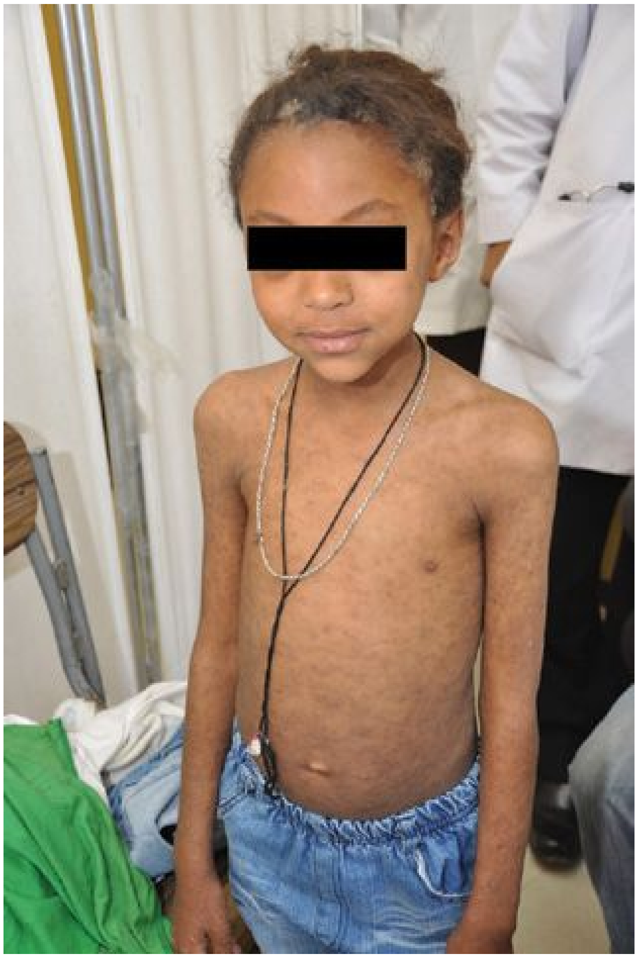

FIGURE 7-30 Young girl who acquired HIV at birth and now has papular pruritic eruption. One in three children born to HIV-infected mothers may be infected; mother-to-child transmission is preventable with simple and affordable antiviral regimens. Fortunately this girl had no signs or symptoms of tuberculosis. (*Used with permission from Richard P. Usatine, MD*.)

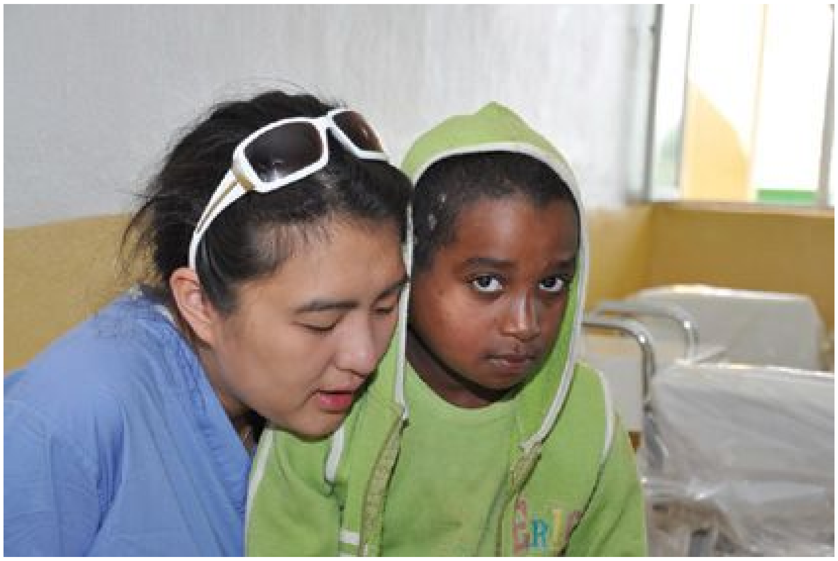

FIGURE 7-31 Young Ethiopian girl with HIV since birth who has neck swelling secondary to tuberculosis. She also has tinea capitis. HIV is a highly stigmatizing disease in most cultures, and clinicians can play an important role in mitigating community stigma by modeling compassionate care. (*Used with permission from Richard P. Usatine, MD*.)

▶ Pathogenesis

TB is transmitted by aerosolized respiratory droplet nuclei (see Chapter 186, Pediatric Tuberculosis). Weakened cell-mediated immunity in HIV-infected individuals allows more rapid disease progression and causes higher mortality rates from TB. At the same time, untreated TB infection accelerates immunologic decline in HIV infection. Because these two diseases preferentially afflict populations with reduced access to medications and supportive care, the emergence of multidrug resistant TB has become an increasing threat.

▶ Clinical presentation

The clinical presentation of TB in an HIV-infected person with a relatively preserved immune system (CD4+ T-cell count greater than 350 cells/μL) is identical to that seen in HIV-negative patients. With increasing immunodeficiency, however, TB often presents atypically. Chest radiographs may not demonstrate classic findings of upper lobe fibronodular or cavitary disease, and extrapulmonary presentations (lymphadenitis, pleuritis, pericarditis, or meningitis) are seen. Tuberculous lymphadenitis and cutaneous TB (designated scrofula when it affects the neck) are illustrated in **Figures 7-31** and **7-32**. Tuberculous lymphadenitis and cutaneous TB can also affect the inguinal lymph nodes and groin (**Figures 7-33** and **7-34**).

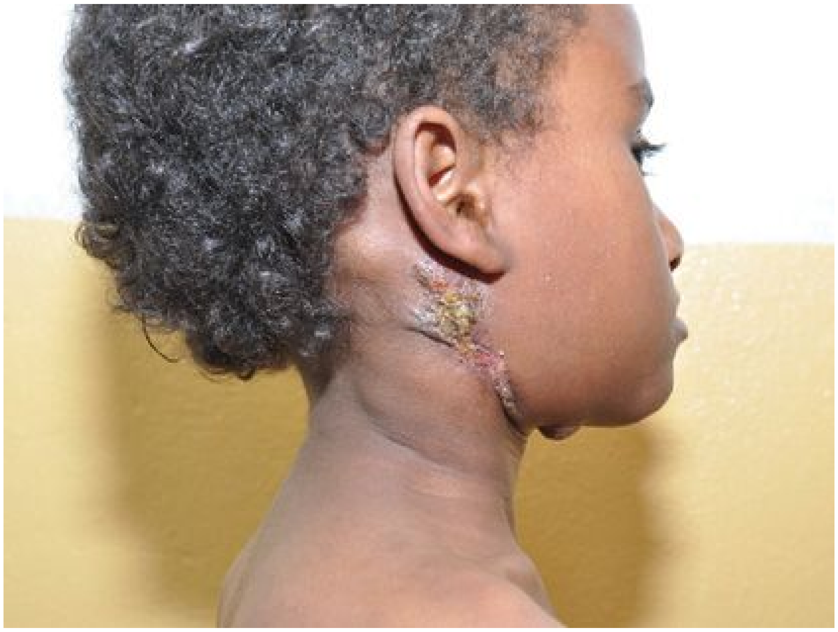

FIGURE 7-32 Scrofula of the neck caused by *M. tuberculosis* in a child. Chronic drainage and fistulous tract formation are commonly associated with this entity, and therapy is the same as for pulmonary tuberculosis. (*Used with permission from Richard P. Usatine, MD.*)

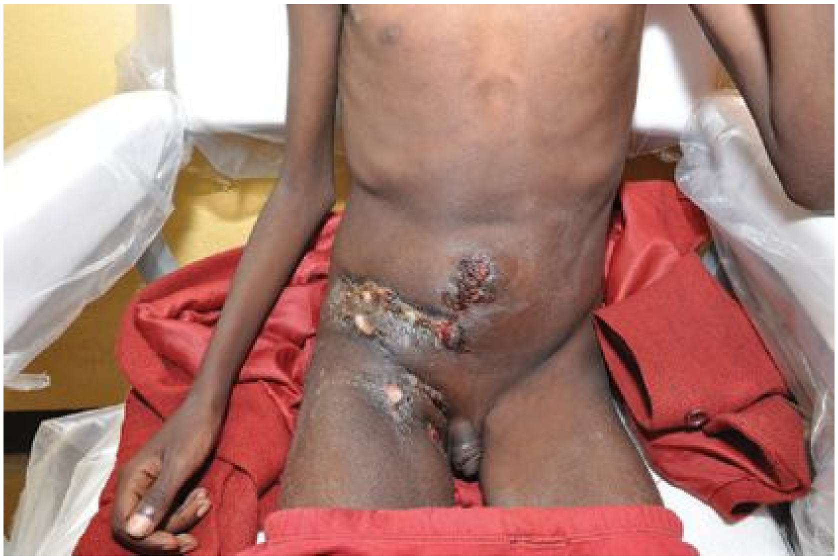

FIGURE 7-33 Scrofula in the inguinal area caused by *M. tuberculosis*. The patient appears systemically ill with weight loss. (*Used with permission from Richard P. Usatine, MD*.)

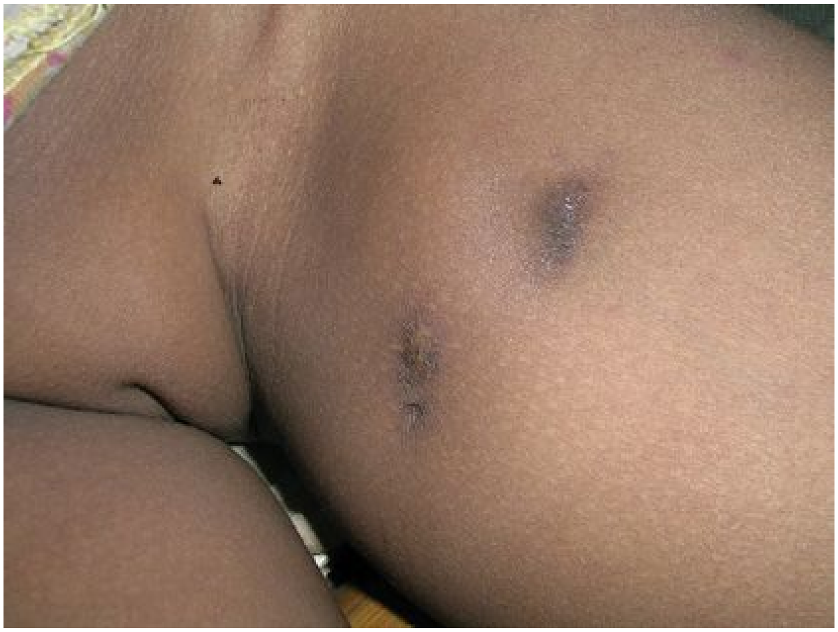

FIGURE 7-34 Scrofula of the groin caused by *M. tuberculosis* in 4-year-old girl. This is an early case and rapid recognition should lead to early treatment. (*Used with permission from Richard P. Usatine, MD*.)

▶ Diagnosis

HIV screening should be performed in all patients diagnosed with TB, and HIV-infected patients should be screened annually for *M. tuberculosis* with purified protein derivative (PPD) skin testing, chest x-ray, and/or blood test for interferon-γ release assay (IGRA) depending on availability. Patients with low CD4 cell counts and percentages, as defined by age, commonly have poorly reactive skin tests for TB, and thus need a careful history of exposures, review of symptoms, physical examinations, and monitoring of the chest x-ray for evidence of active disease, with repeat TB screening when the CD4 cell count rises above reference levels for age.

▶ Management

Management of TB in HIV-positive adolescents is generally similar to adults and is discussed in the following section. Optimal treatment regimens for younger children however have not been established.

Latent TB infection

HIV-positive patients with latent tuberculosis infection (LTBI) should have a chest x-ray and three sputum smears or gastric aspirates for acid-fast bacilli to rule out active disease. Once active TB is ruled out, isoniazid prophylaxis should be initiated regardless of age for any HIV-positive person with the following characteristics: (a) a positive diagnostic test for LTBI, (b) a negative LTBI test but with evidence of old or poorly healed fibrotic lesions on chest x-ray, or (c) negative LTBI diagnostic test in a close contact of a person with infectious pulmonary TB.

Duration of LTBI prophylaxis: Isoniazid 300 mg daily or twice weekly for 9 months given with vitamin B6 (pyridoxine 25 mg daily). An alternative regimen of 12 doses of once weekly isoniazid-rifapentine has recently been validated. Pyridoxine prevents isoniazid-associated peripheral neuropathy.[57]

Active M. tuberculosis disease

Any HIV-positive patient with cough and pulmonary infiltrates should be placed in respiratory isolation until TB is ruled out by 3 separately obtained sputum smears (Ziehl-Neelsen) with cultures sent for acid-fast bacilli. This rule applies even when the chest radiograph does not demonstrate cavitary or upper lobe infiltrates. Smear-negative, culture-positive *M. tuberculosis* is not uncommon.

Treatment regimens for HIV-TB coinfected patients are largely identical to those of TB mono-infected patients. It is important not to start antiretroviral therapy (ART) and TB therapy simultaneously, to avoid confusion about drug allergies and side effects. In addition, there is a risk of immune reconstitution syndrome (IRIS [immune reconstitution inflammatory reaction]: inflammatory response that worsens manifestations of any opportunistic infection) when ART is started too soon after initiating TB medication.

Guidelines for ART in TB coinfection are specific. If the CD4 cell count is less than 50, ART should start within 2 weeks of TB therapy. If the CD4 count is greater than 50, ART should start within 8 to 12 weeks of TB therapy. If IRIS does occur, both ART and TB treatment should be continued while managing the IRIS.[58]

Directly observed therapy (DOT) for TB is strongly recommended for HIV-TB coinfected patients.

PROVIDER AND PATIENT RESOURCES

- Traveler's Health from the Centers for Disease Control and Prevention is a comprehensive site that includes information on more than 200 international destinations, travel vaccinations, diseases related to travel, illness and injury abroad, finding travel health specialists, insect protection, safe food and water, and a survival guide—**http://wwwnc.cdc.gov/travel/**.
- The Yellow Book 2012 is available online as a reference for those who advised international travelers about health risks—**http://wwwnc.cdc.gov/travel/page/yellowbook-2012-home.htm**.
- Detailed vaccine information for travel can be obtained at the CDC website on vaccinations. This includes information on yellow fever vaccine, typhoid vaccine, and routine vaccines—**http://wwwnc.cdc.gov/travel/page/vaccinations.htm**.
- Vaccine information can be looked up by specific destination on the traveler's health website—**http://wwwnc.cdc.gov/travel/**.
- U. S. Department of State International Travel Site, including country specific information, travel alert, and travel warnings—**http://travel.state.gov/travel/travel_1744.html**.

CONCLUSION

Medical students and health professionals are increasingly drawn to global health for reasons ranging from the desire for enhanced cultural understanding, to the mission to work for global health equity, to alleviate suffering, or to broaden medical experience beyond geographic boundaries. Whatever one's personal motivation, such experiences should never be undertaken without disciplined preparation. Medical professionals should learn in advance of their travels about the culture, language, and expressed needs and priorities of the local government and health providers and their service populations. In addition, they need to learn about the diagnoses and locally appropriate management of prevalent diseases in the population they plan to serve. Equally important, they should take appropriate preventive measures (vaccines and malaria prophylaxis) to protect their own health. Lack of personal and professional preparation can easily turn the tide from net benefit to major burdens for host country organizations. Ultimately, well-prepared medical educators and clinicians, wherever they may come from, are uniquely positioned to share knowledge that saves lives and leads to a more equitable world.

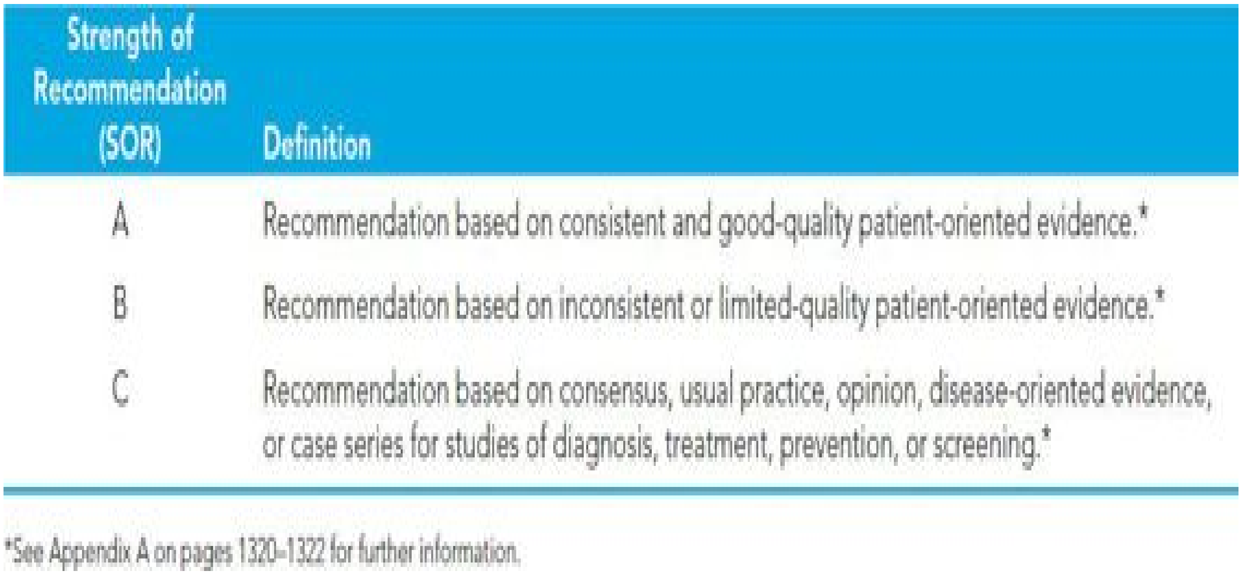
PART 3

PHYSICAL AND SEXUAL ABUSE



Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1320–1322 for further information.

8 CHILD PHYSICAL ABUSE

James Anderst, MD, MS
Ashley D. Hopkins, MD

PATIENT STORIES

CASE 1

A 1-month-old child was seen in the emergency department for bruising. Physical examination revealed bruises to the buttocks, chest, and eye. The parents reported that the child received the buttock bruise (**Figure 8-1**) after being dropped by the father, that the chest bruise was from the child's seat belt, and the eye bruise from accidentally hitting the child with an elbow while co-sleeping. The social worker was consulted and found no concerning "red flags" in the family. The emergency department physician felt the findings were because of inexperienced parents. The child was sent home with the parents and the emergency department later reported the case to Child Protective Services (CPS) in hopes of providing the family with support services. A child abuse pediatrician (CAP) was consulted by CPS to review the case the next day. The CAP requested that the child be brought back to the hospital emergently for further evaluation. At that time, a skeletal survey, including oblique views of the ribs, showed a healing fracture of the eighth posterior rib (**Figure 8-2**). A head CT and liver function tests were performed to screen for occult trauma and laboratory tests were done to evaluate for a bleeding diathesis. All were negative. Law enforcement was contacted and coinvestigated with CPS. The child was placed in the home of a relative. Two weeks later, a repeat skeletal survey showed new bone formation over the right femur, indicating a healing fracture.

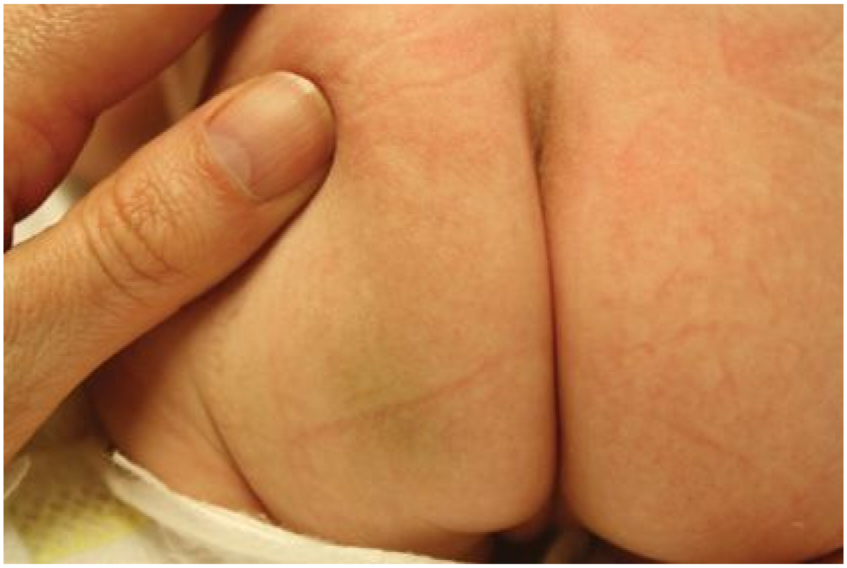


FIGURE 8-1 Bruising to the left buttock noted in a 1-month-old child. Any bruising on an immobile child is highly concerning for child physical abuse. Bleeding disorders must be considered in the differential diagnosis. (*Used with permission from James Anderst, MD, MS.*)

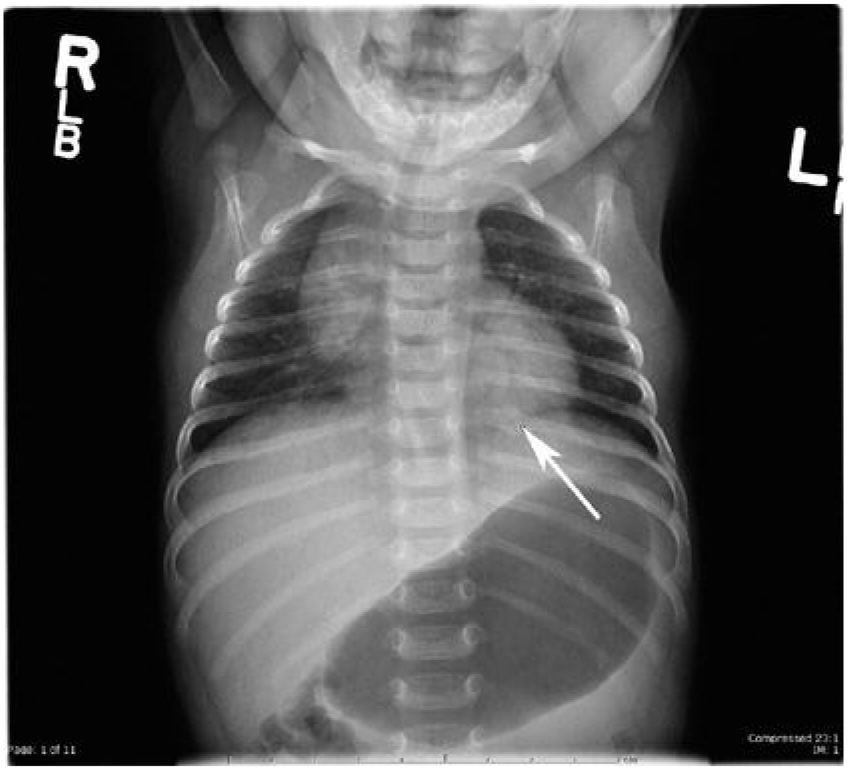

FIGURE 8-2 Healing eighth posterior rib fracture in the same child from Figure 8-1. A skeletal survey is indicated in any child younger than 2 years

of age where suspicions of physical abuse exist. (*Used with permission from James Anderst, MD, MS.*)

CASE 2

A 15-month-old child is brought to the emergency department by the police after a relative called 911. The child and his mother attended a family gathering where concerned relatives viewed the mother’s story that the child “falls a lot” with suspicion. On examination there were many signs of physical abuse (**Figures 8-3** to **8-5**). His face was covered with bruises, especially around the right eye and cheek (**Figure 8-3**). His axilla showed signs of being gouged with fingernails (**Figure 8-4**). Although an initial skeletal survey did not show any fractures, a repeat skeletal survey and oblique views of the ribs were done 2 weeks later. The second skeletal series showed eight healing rib fractures. Repeat skeletal surveys are recommended in children younger than 4 years of age, who are confirmed or suspected victims of abuse (**Figure 8-5**). The child was admitted to the hospital and the police, hospital social workers, and CPS were notified. In the emergency department, the child was evaluated by a forensic nurse examiner trained in child-abuse photo documentation. The child was then referred to a CAP who assessed mechanisms of injuries, reexamined the child, and interpreted the initial and follow-up skeletal surveys.

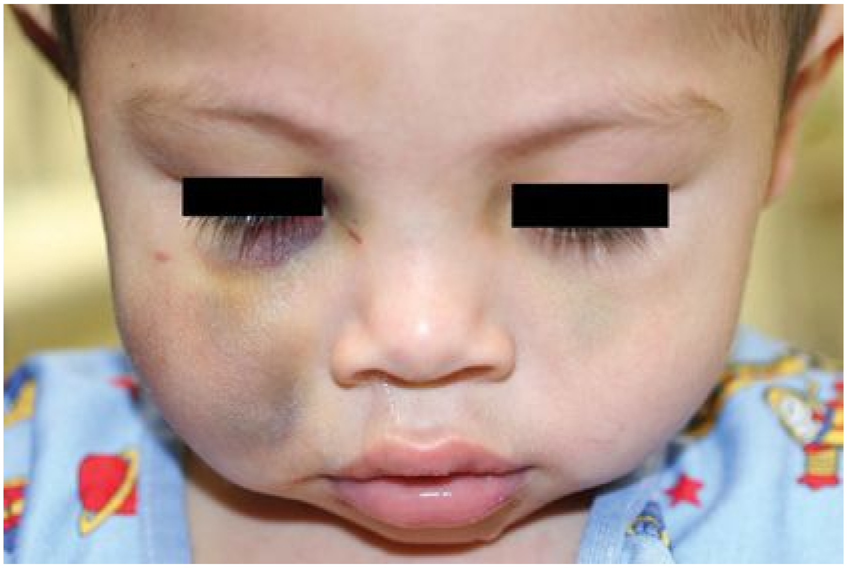

FIGURE 8-3 A 15-month-old boy who has been physically abused by his mother's boyfriend for several weeks. There is bruising under both eyes, with the greatest degree of bruising seen under the right eye and on the right cheek. The boy is in the emergency department after concerned relatives called the police. (*Used with permission from James Anderst, MD, MS*.)

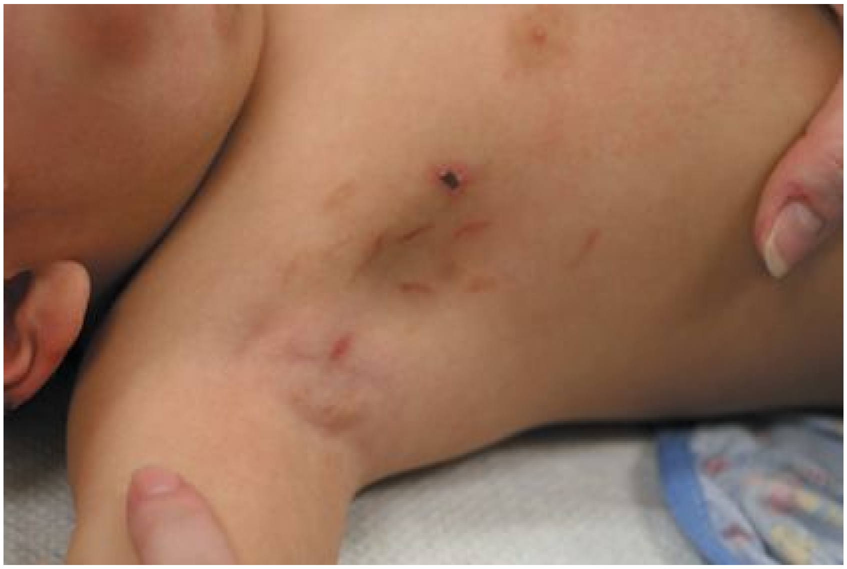

FIGURE 8-4 Same 15-month-old boy from Figure 8-3 with multiple fingernail gouges in his right axilla. Some are fresh and one appears to be older and somewhat crusted. Injuries in different stages of healing may indicate chronicity of abuse. (*Used with permission from James Anderst, MD, MS*.)

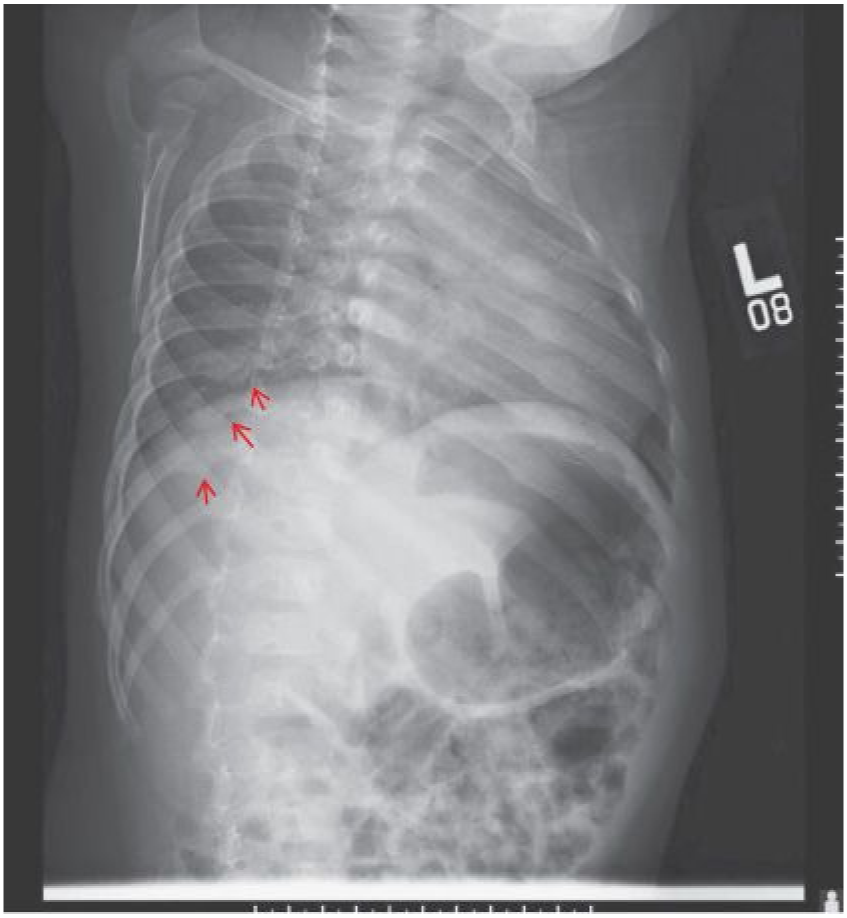

FIGURE 8-5 Same boy from Figure 8-3 with oblique x-ray showing healing rib fractures with callus in eight different locations as marked by the *arrows*. The degree of callus formation shows that these rib fractures are not new. Oblique radiographs should be requested in addition to a “skeletal survey” because lateral rib fractures are best seen with this view. (*Used with permission from James Anderst, MD, MS*.)

INTRODUCTION

The appropriate identification of child physical abuse is critical. Misdiagnoses in either direction (missed abuse or inappropriate diagnosis of abuse) are extremely harmful to the child and family. A careful evaluation of each case, coupled with an application of the existing scientific data on child physical abuse, may result in improved outcomes for the child and family.

EPIDEMIOLOGY

- Occurs in 9.2 per 1000 children, with highest rate of victimization in the birth to 1 year age group (20.6 per 1000).
- The Department of Health and Human Services compilation of State CPS Child Maltreatment 2010 had 3.3 million CPS reports filed in 2010, with 695,000 confirmed child victims.[1] Of these:
  - Seventy-eight percent were neglected.
  - Eighteen percent were physically abused.
  - Nine percent were sexually abused.
  - Eight percent were psychologically abused.
- Nearly 81 percent of victims were abused by a parent acting alone or with another person.
- Medical personnel made only 8.2 percent of the referrals to CPS.

RISK FACTORS

Caregiver factors associated with child abuse include the following:[2–4]

- Inappropriate parental expectations of the child.
- Lack of empathy toward the child’s needs.
- The parent’s belief in physical punishment.
- Parental role reversal.
- Caregiver’s personal history:
  - Was abused during childhood.

  - Parents’ rearing practices modeled.
  - Mental illness or substance abuse.

Factors specific to the child that are associated with abuse:[2]

- Prematurity.
- Disabilities.
- Difficult temperament.

Environmental factors associated with abuse:

- Domestic violence.
- Financial, family, or work stressors.
- Housing issues.

DIAGNOSIS

CONCERNING HISTORY[5]

- History inconsistent with child’s developmental stage.
- Injuries inconsistent with history given.
- History changes over time.
- History differs among witnesses.
- Delay in seeking medical care (must consider family’s access to care and availability of transportation).
- Sibling blamed.
- Magical injury—No one knows how it happened.

CLINICAL FEATURES

- Bruising:[6]
    - In children who are not independently mobile.
    - Seen away from boney prominences.
    - To the face, hands, ears, buttocks, back, abdomen, and arms.
    - In the shape of an imprint of an object or hand, or a ligature (**Figure 8-6**).

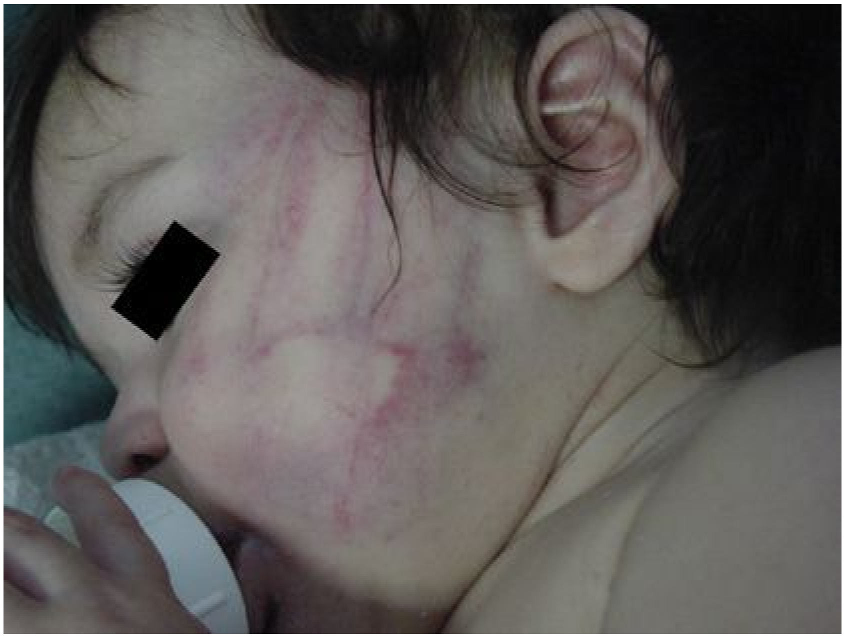

FIGURE 8-6 Linear ecchymosis on the cheek of a baby who was slapped in the face by an abusive parent. (*Used with permission from James Anderst, MD, MS*.)

    - Multiple bruises in clusters.

- Burns:[7]
    - Inconsistent with history (**Figure 8-7**).

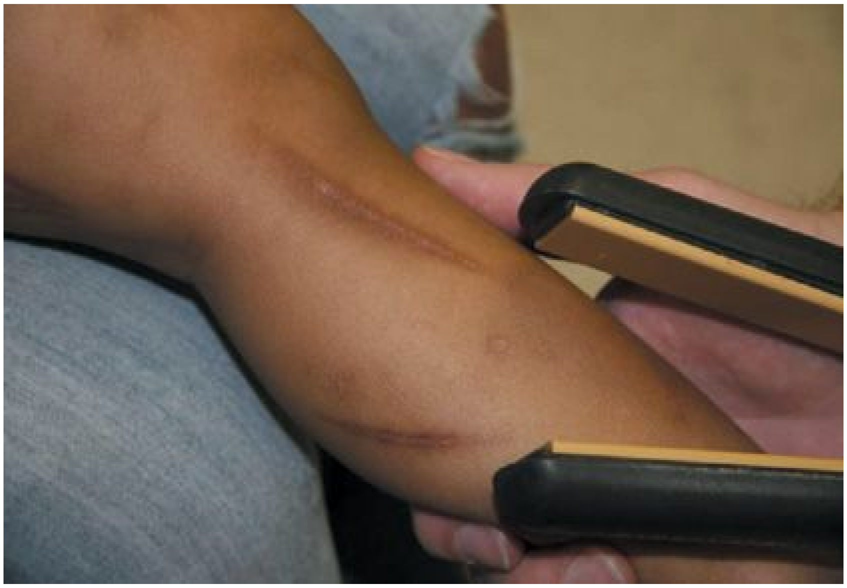

FIGURE 8-7 Toddler being seen for a burn caused by hair straightener. The family claimed the iron fell onto the leg but further investigation seemed to indicate that the iron was applied to the child by an angry parent to control a crying child. Although the iron falling could explain the injury on the calf, it does not explain the additional injury higher up on the leg. (*Used with permission from James Anderst, MD, MS*.)

  - Stocking/glove distribution.
  - Well-demarcated edges.
  - Symmetrical burns.
  - No splash marks.
- Fractures:[8]
  - Rib fractures.
  - Fractures in immobile children that are not attributable to birth injury.
  - Multiple fractures and/or multiple fractures of different ages.
  - Fractures in the absence of a history of trauma.
  - Any fracture that is inconsistent with the reported mechanism.
- Intracranial injury:
  - Highly variable clinical presentation; however, presence of apnea, retinal hemorrhages, and/or rib fractures is more strongly associated with inflicted (versus noninflicted) intracranial injury.[9,10]

  - Mild abusive head injury may present with isolated vomiting or fussiness.[11]
- Oral lesions—Torn frenula, palatal petechiae, contusions, or lacerations (typically from a bottle, finger, or other object forced into the child's mouth).[12]
- Failure to thrive and signs of malnutrition as a result of intentional withholding of food and/or liquids.

LABORATORY STUDIES AND IMAGING

- Concerning bruising that is not obviously abusive—Prothrombin time/partial thromboplastin time (PT/PTT), complete blood count (CBC), von Willebrand testing, factor 8 and factor 9 levels. Testing best done in collaboration with a CAP or pediatric hematologist.[13]
- Detection of occult abdominal trauma—Liver function tests (LFTs), amylase, lipase, urinalysis; CT of abdomen recommended if laboratory results are elevated or urinalysis positive for blood.[14]
- Detection of occult fractures—Skeletal survey (including oblique views of the ribs) in children younger than 2 years of age or nonverbal children; consider radionuclide bone scan to look for acute fractures, or a follow-up skeletal survey 2 weeks after initial presentation.[15]
- Detection of occult intracranial injury—CT/MR of head in all young children, even if there are no clinical signs of intracranial injury; ophthalmology examination for retinal hemorrhages.[16]

DIFFERENTIAL DIAGNOSIS

- Bruises and other skin findings:
  - Accidental bruises—Any bruising in an infant or precruiser is very concerning for abuse. Accidental bruising is much more common in cruising or walking children.[17] Any inflicted bruising or skin markings

(including those from spanking or other punishment) lasting more than 24 hours constitutes abuse.[18] Ear bruising is very specific for abuse (**Figure 8-8**).[19] It is not possible to accurately date bruises.[20] Accidental bruising is typically located on the shins, lower arms, under chin, forehead, hips, elbows, ankles, and bony prominences. Loop-like bruising is suspicious for blows with a cord or a looped belt (**Figure 8-9**).

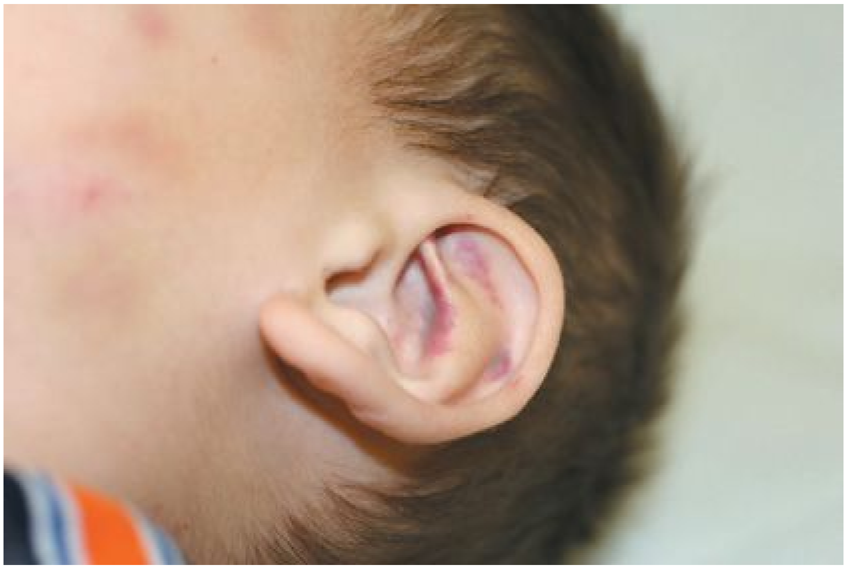

FIGURE 8-8 Bruising of the ear in a young boy who was physically abused by a parent. Ear bruising is rarely accidental. The additional bruising on the cheek suggests this child was hit with a hand or another object to produce the bruising seen in this photo. (*Used with permission from James Anderst, MD, MS.*)

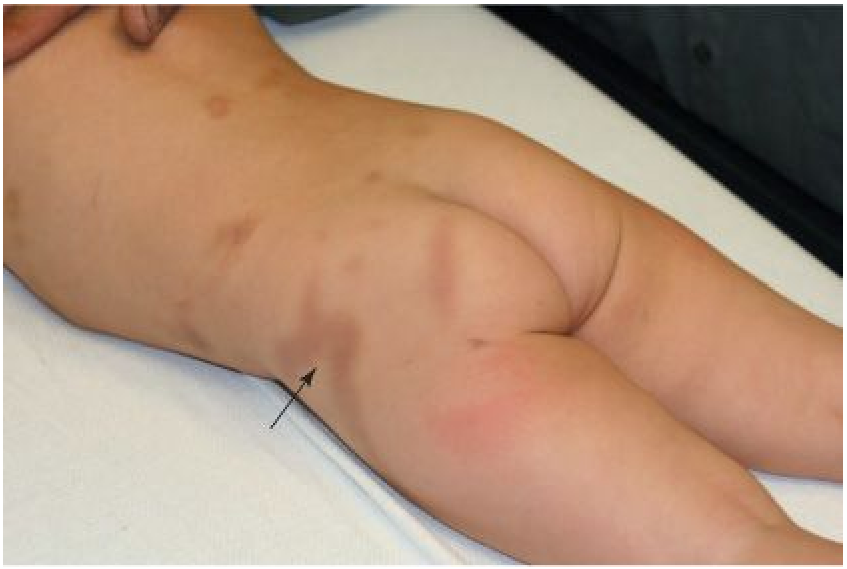

FIGURE 8-9 Young girl with linear bruising on the back, buttocks, and thigh from being hit with a belt. One bruise appears to have a loop-like form (*arrow*) and was likely caused by blows with a cord or a looped belt. Blows with flexible objects produce patterns that tend to conform to the curved surfaces of the body, whereas inflexible objects may produce a discontinuous pattern over curved surfaces. (*Used with permission from Nancy Kellogg, MD*.)

- Bruising with tracking of blood (subgaleal hematoma) can be seen with severe injuries to the head from violent hair pulling (**Figure 8-10**).

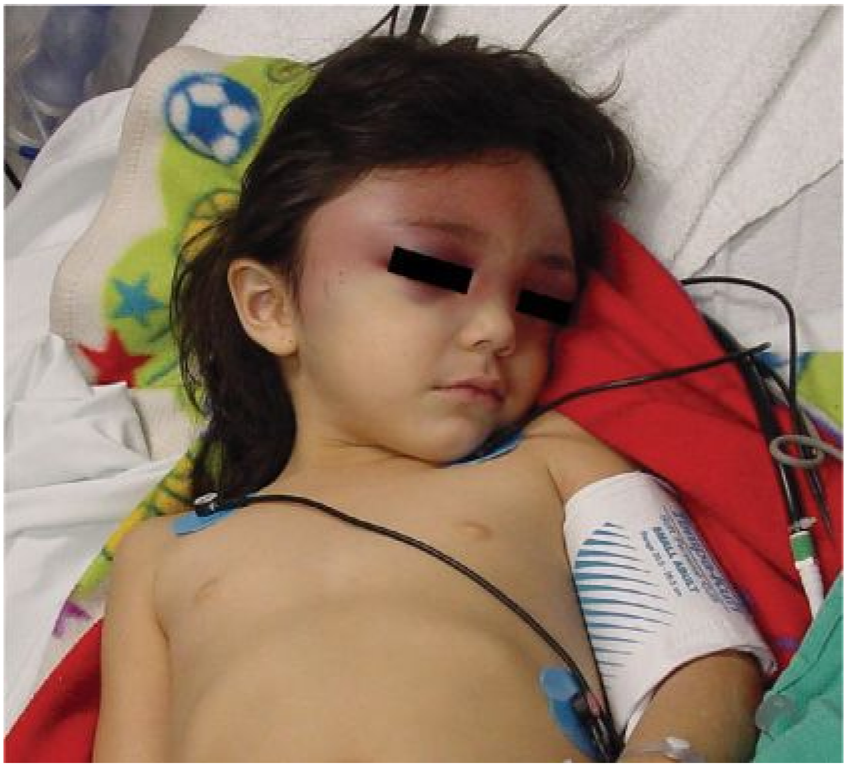

FIGURE 8-10 Young girl with severe subgaleal hematoma with extensive blood tracking into the upper face after being lifted off the ground by her hair. Blood tracking after significant injury is most commonly seen on the face, although some injuries to the genitals may also track into the perineum. (*Used with permission from James Anderst, MD, MS*.)

  - Bleeding disorders—Familial history, abnormal coagulation laboratory test results, vitamin K deficiency.
  - Other rare diseases associated with bruising—Ehlers-Danlos, Henoch-Schönlein purpura, phytophotodermatitis (skin reaction to psoralens, most commonly found in limes), osteogenesis imperfecta (brittle bones).
  - Skin discoloration—Common examples are allergic shiners (dark, puffy lower eyelids) and Mongolian spots (macular blue-gray pigmentation usually on the sacral area of normal infants, usually present at birth or appear within the first weeks of life; see Chapter 92, Normal Skin Changes).

- Burns:
  - Accidental burns (splash marks usually seen).

  - Bullous impetigo, cellulitis, scalded skin syndrome, diaper rash.
  - Chemical burn caused by senna containing laxatives.
  - Drug reaction.
- Fractures from other diseases occurring in infants and young children:
  - Osteogenesis imperfecta—A congenital disorder with bone fragility; patients may have repeated fractures after mild trauma that heal readily. Other features seen in some cases include blue sclera, easy bruising, and deafness (see Chapter 225, Osteogenesis Imperfecta).
  - Rickets—Usually from vitamin D deficiency, consider in exclusively breastfed infants, dark-skinned children, children with little sun exposure. The metaphyses show widening and cupping with irregular calcification as a result of poor calcification of osteoid (see Chapter 198, Rickets).
- Failure to thrive from other causes including improper mixing of formula, breastfeeding difficulty, organic diseases such as cystic fibrosis, HIV, metabolic disorders, celiac disease, and renal disease[21] (see Chapter 53, Failure to Thrive).

Intracranial bleeding—Other causes include accidental injury, infection, coagulation disorders, birth injury, and rare metabolic conditions (glutaric aciduria).

Cultural practices—Coining (**Figure 8-11**), cupping, moxibustion (cultural practice of burning herbs on skin).

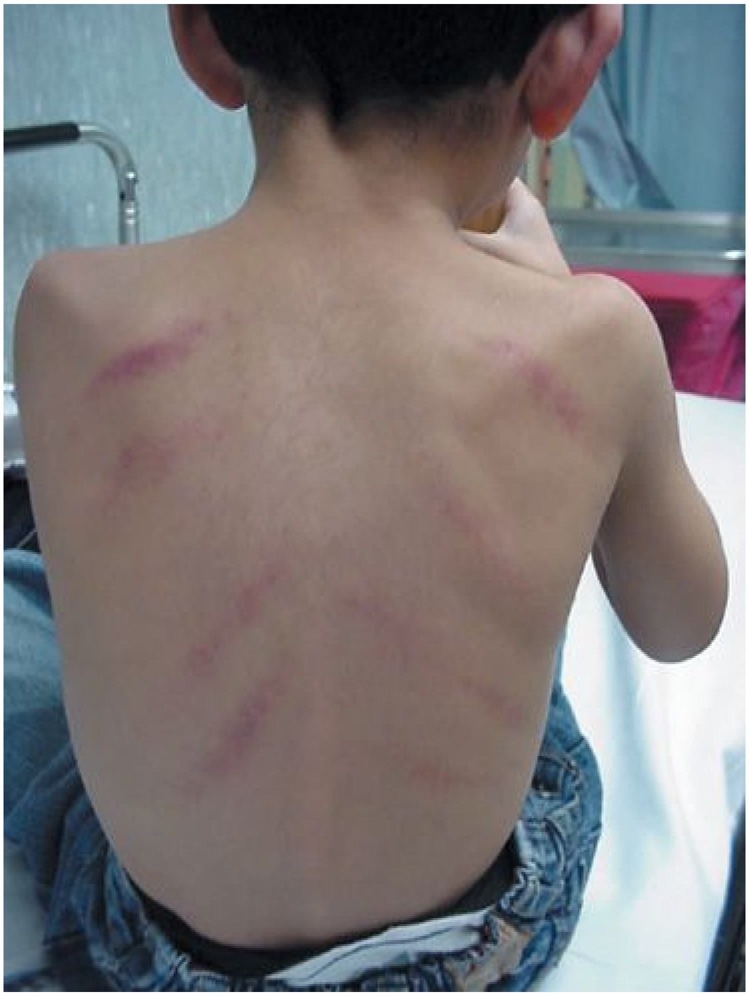

FIGURE 8-11 Young boy with the marks of coining on his back. A coin was rubbed across his back leaving ecchymoses over bony prominences with the intent to help the child heal from an acute illness. This cultural practice is more common among Asian immigrants to this country and mimics child abuse. (*Used with permission from Maria McColgan, MD*.)

MANAGEMENT

- Emergent care first; treat injuries, burns, failure to thrive accordingly.
- Careful examination of the skin and oral cavity, palpation for bony tenderness or callus formation, signs of abdominal trauma or neurologic abnormalities, ophthalmologic evaluation for retinal hemorrhages.

- Document the history provided by caregivers and physical findings accurately, including pictures.
- Consider consultation with a CAP or a family physician with additional training or expertise. Child abuse pediatrics is a new subspecialty of pediatrics requiring an additional 3 years of fellowship training.
- In cases where the injury was truly caused by an accidental mechanism, the role of neglect must be considered.
- Mandated reporting:
  - All 50 states require that all professionals who work with children report suspected child abuse and neglect.
  - Reporter of abuse is granted legal immunity.
  - Once the case is reported, further collaboration with CPS or law enforcement is usually necessary to ensure appropriate outcomes.[22]

PATIENT EDUCATION

- Prevention programs:
  - Home visitation programs have been shown to reduce child abuse and child mortality.[23]
  - Nursery-based prevention of abusive head trauma.[24]
  - Specific models of primary care may reduce abuse.[25]
  - Population-based prevention.[26]
  - Parent–child interactive therapy (PCIT) reduces repeat abuse.[27]

FOLLOW-UP

- If there is suspicion of fractures, obtain repeat skeletal x-ray in 2 weeks to look for evidence of healing fractures.

- Siblings of abused children should be interviewed and examined for findings concerning abuse.
- Counseling for child and family as appropriate.
- Frequent follow-up with primary care provider to evaluate for signs of abuse and neglect.
- Report to CPS.

9 CHILD SEXUAL ABUSE

Nancy D. Kellogg, MD
Maria D. McColgan, MD

PATIENT STORY

A 12-year-old girl is being seen for chronic abdominal pain by her family physician. The physician asks the mother to step out of the room and does a complete history including the HEADSS (home life, education level, activities, drug use, sexual activity, suicide ideation/attempts) questions. The girl tearfully reports that her stepfather has been touching her in her private areas when her mother is not home. On examination with a female nurse chaperone in the room, the physician finds that the girl's hymen initially appears normal (**Figure 9-1**). However, when the girl is more carefully examined with a cotton-tip applicator, a healed posterior hymenal transection is seen (**Figure 9-2**). When the girl is asked whether any other types of sexual abuse occurred with her stepfather, she admits to repeated penile penetration. Although rare, sometimes the examination reveals more than what the child is willing to disclose about the abuse. Partial disclosures of abuse are common in children. In addition, the findings of sexual abuse tend to be subtle and are easily missed if a careful examination and special techniques are not used. Attempts are made to reassure the girl that this should never happen and that this is not her fault. Her mother is brought back into the room and after a sensitive discussion, the police are called and Child Protective Services (CPS) notified.

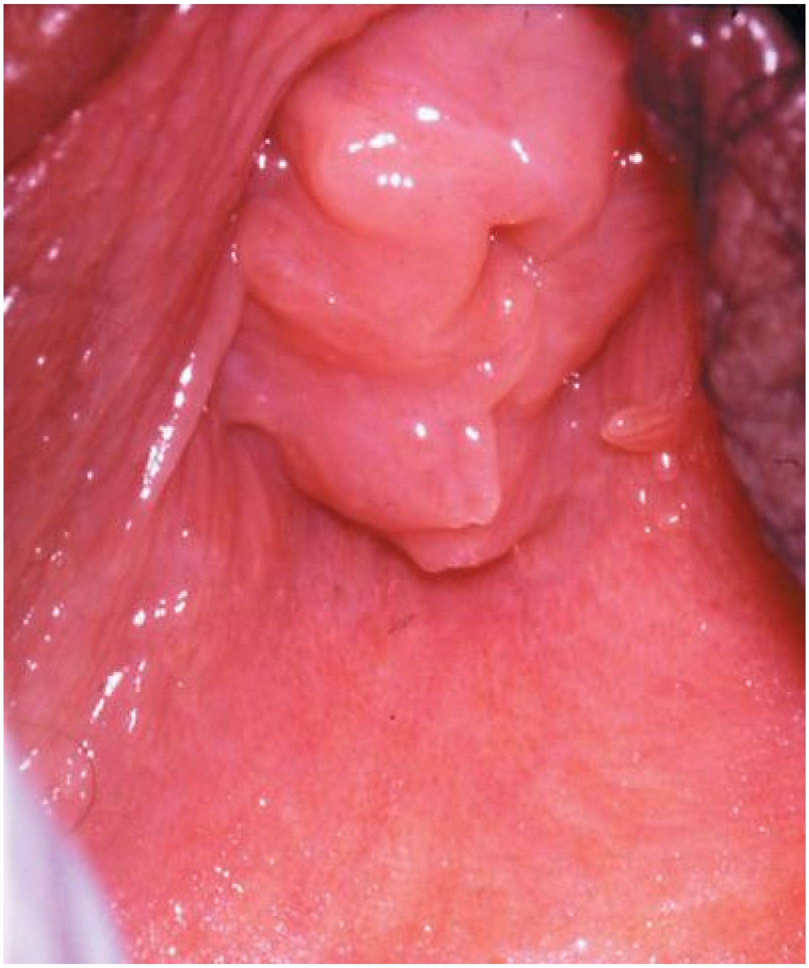

FIGURE 9-1 Typical appearance of the hymen and perihymenal tissues in a 12-year-old girl. Once females have entered puberty, the hymen becomes redundant with overlapping folds and is more difficult to examine for subtle signs of acute or healed injury. (*Used with permission from Nancy D. Kellogg, MD*.)

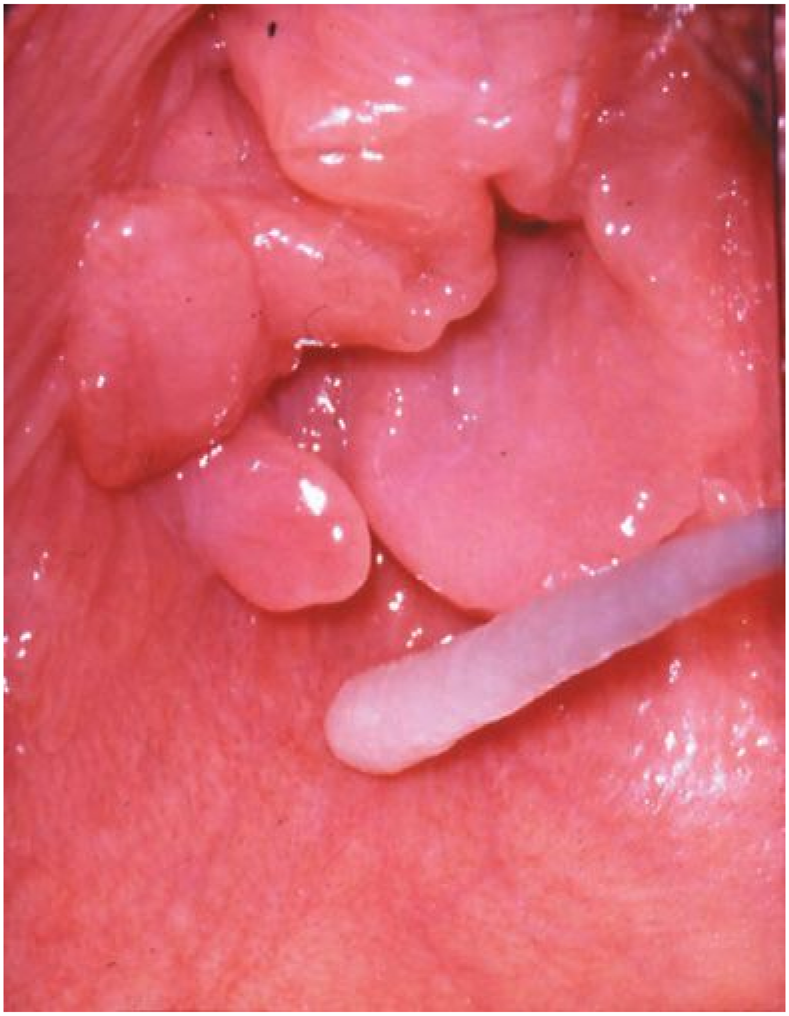

FIGURE 9-2 Hymenal cleft visible when the girl in **Figure 9-1** is more carefully examined using a saline moistened cotton-tip applicator to gently separate and demonstrate the edges of the hymen. This injury was caused by sexual abuse and may have been missed without the more careful examination. (*Used with permission from Nancy D. Kellogg, MD*.)

HEADSS is an acronym that provides a framework for interviewing adolescents and children about health risks. The questions start from easiest and least sensitive to more sensitive questions that need to be asked:

H—home
E—education
A—activities
D—depression and drugs

S—sex and sexual abuse
S—suicide

EPIDEMIOLOGY

- The US Department of Health and Human Services compilation of CPS data from 48 states in 2008 indicates there were 772,000 children confirmed as victims of abuse.[1] Of these, 9 percent were victims of sexual abuse. Not included in these numbers are several thousand additional victims who are sexually assaulted by nonfamily members; these cases are reported to law enforcement but not CPS.
- Sexual abuse of girls occurs at much higher rate than boys: 2.3 per 1000 females versus 0.6 per 1000 males.[2]
- Up to 50 percent of abusive sexual acts involve penetration of the vagina, anus, or oral cavity, or oral–genital contact.[3] In general, penetrative types of abuse are associated with poorer medical and mental health outcomes.

ETIOLOGY AND PATHOPHYSIOLOGY

Child sexual abuse occurs when a child is involved in sexual activities that he or she cannot comprehend, for which the child is developmentally unprepared and cannot or does not give consent, and/or that violate laws. All states have laws that require physicians to report a suspicion of abuse to child protection or law enforcement agencies.

Most sexual abuse involves an adult perpetrator the child knows and is expected to trust who uses deception and position of authority to gain the child’s acquiescence and accommodation to the abuse;[4] it is not unusual for the abuse to progress from less to more severe and intrusive sexual acts, and for the child to wait months or years to disclose the abuse.

DIAGNOSIS

CLINICAL FEATURES

- Child victims of sexual abuse may have behavior changes, depression, increased sexual behaviors, somatic complaints (e.g., headaches or abdominal pain, constipation, enuresis/encopresis, genital/anal pain), or may be asymptomatic.
- Child may present to a medical provider for the following reasons:
  - Child has disclosed abuse (most common); it is rare for the abuse to be witnessed. Referrals to specialized programs with clinicians trained in the assessment of child sexual abuse is recommended, and are generally accessible in most areas of the US.
  - Caregiver suspects abuse and presents to the clinician because of behavioral or physical symptoms.
  - Child is brought for routine care and sexual abuse is suspected based on clinical findings (e.g., acute or healed genital injuries, vaginal discharge in a prepubertal child, lesions suggestive of human papillomavirus [HPV] or herpes simplex virus [HSV]).
- Recent studies show that less than 5 percent of child sexual abuse victims have physical examination findings indicative of penetrative trauma because the type of sexual act either does not result in tissue damage or because when tissue damage occurs, most injuries heal quickly and completely.[5–7] In a study of 36 pregnant adolescents, only two had evidence of penetrative trauma.[8] The medical diagnosis relies predominantly on the child’s history and clinicians should remember that “normal” does not mean “nothing happened.”
- Tips for doing the physical examination:
  - The anogenital inspection should utilize optimal direct light source, magnification, and appropriate examination positions and techniques.
  - Recommended examination positions include supine frogleg or lithotomy and prone knee-chest; the latter position is particularly important to confirm any posterior (between the 4 and 8 o’clock

positions of the hymen in supine) defects of the hymen that are seen in supine position.

  - Various examination techniques include labial separation and traction (gently pulling the labia outward and inferiorly), gluteal lifting in prone knee-chest, and using cotton-tipped applicator for separating tissues.
  - In some cases, it may help to have an assistant gently squirt a small amount of nonbacteriostatic saline onto the hymen as the examiner uses gentle labial traction; this procedure is used to free folded hymenal edges.
  - A speculum examination and use of a cotton-tipped applicator to separate hymenal edges are traumatic procedures for prepubertal females and should not be used.
  - Most findings of anal trauma can be visualized by gently spreading the anal folds.

- Physical findings concerning for abuse include:[9]
  - Abrasions or bruising of the hymen, perihymenal structures, or anus (**Figures 9-3** and **9-4**).

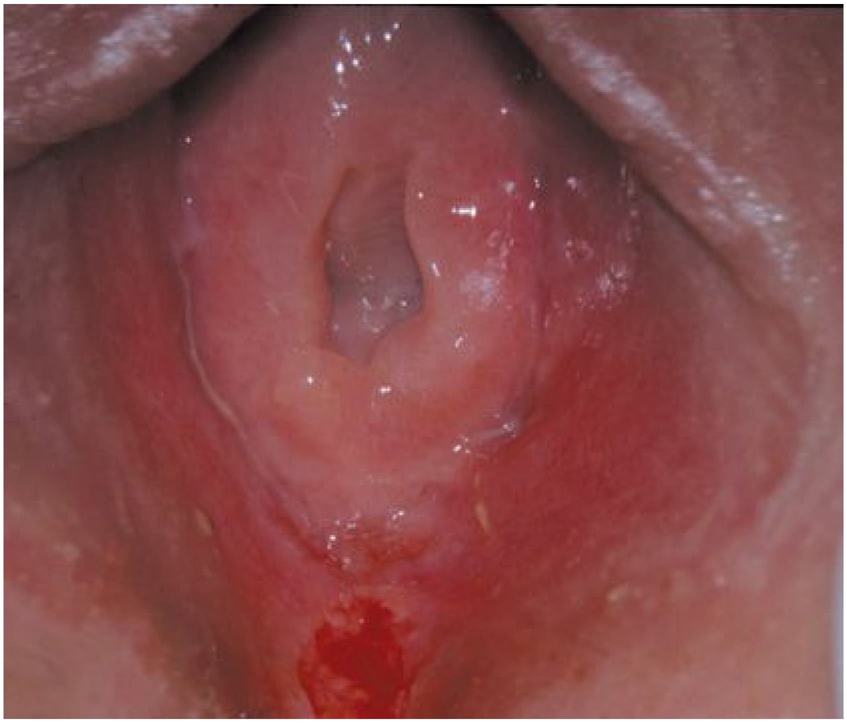

FIGURE 9-3 A 10-year-old girl with an acute tear of the posterior vestibule after recent sexual assault by a stranger. The posterior vestibule is

the most common location for acute penetrative trauma in females. (*Used with permission from Nancy D. Kellogg, MD*.)

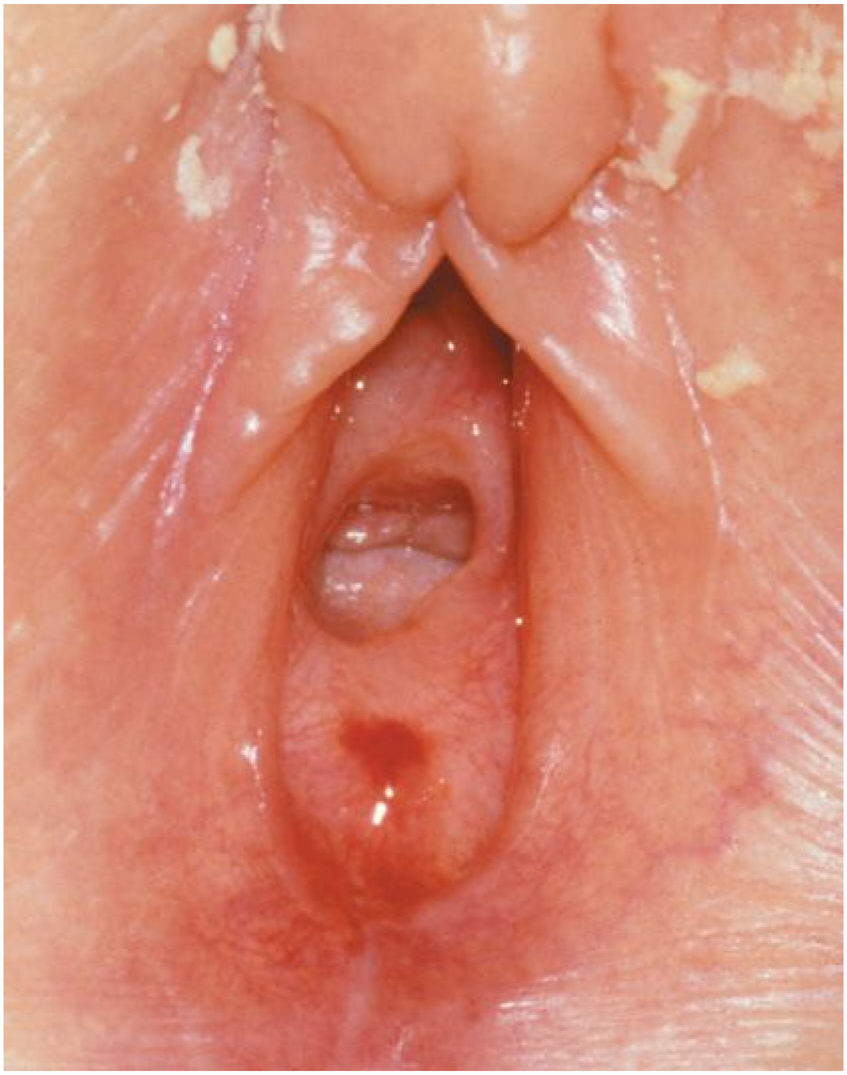

FIGURE 9-4 Acute hymenal hematoma in a prepubertal girl from penile penetration/contact. One reason why the considerable majority of examinations are normal may be that contact is more common than complete penetration and injuries resulting from penile contact are uncommon or are minor injuries that heal quickly and completely within days. (*Used with permission from Nancy D. Kellogg, MD*.)

  - Acute or healed tear in the posterior aspect of the hymen extending to, or nearly to, the base of the hymen or further to the posterior vestibule (**Figure 9-2**).

- Anal bruising or lacerations (**Figure 9-5**).

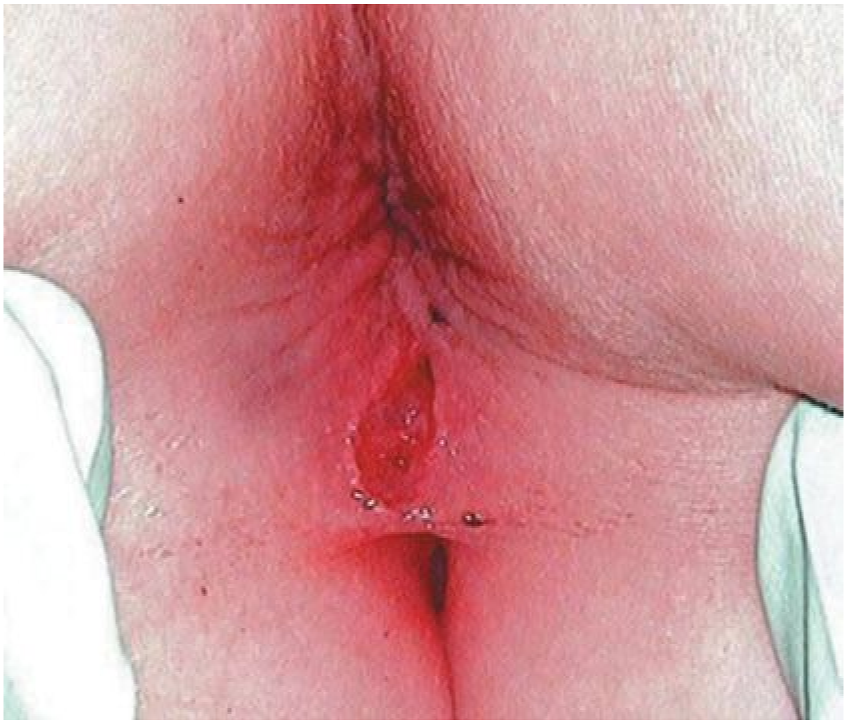

FIGURE 9-5 Acute rectal laceration in a young boy who was sexually abused by a relative. More than 95 percent of anal examinations in children with a history of anal penetration are normal or nonspecific. (*Used with permission from Nancy D. Kellogg, MD.*)

- Petechiae or bruising on the soft palate following a history of forced oral penetration.

LABORATORY TESTS AND IMAGING

- Forensic evidence collection if sexual assault occurred less than 72 to 96 hours (protocols vary from region to region) prior to clinical presentation (consider referring to an emergency department or rape crisis center skilled in performing forensic evidence collection on children).
- Approximately 5 percent of sexually abused children and adolescents acquire a sexually transmitted infection (STI) from the abuse[9] (**Figure 9-6**).

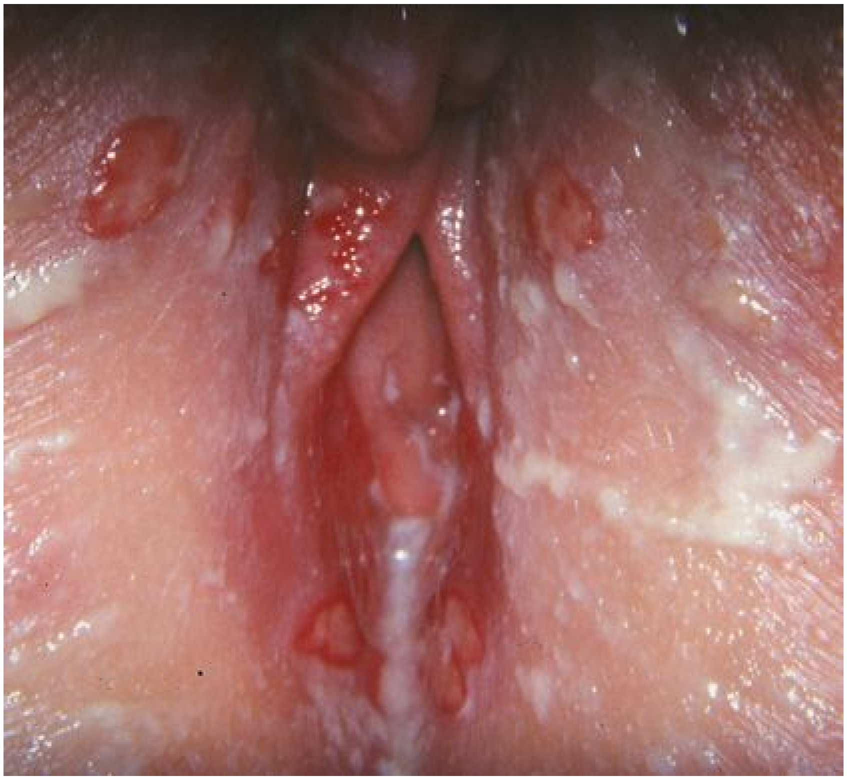

FIGURE 9-6 Herpes simplex virus (HSV) type 1 infection on the vulva of the prepubertal girl caused by sexual abuse. HSV type 1 of the genitals from sexual contact is increasing in prevalence relative to HSV type 2 infections of the genitals. (*Used with permission from Nancy D. Kellogg, MD*.)

- Consider STI testing in all postpubescent patients and in prepubescent children with a history of genital contact with any orifice.
- HIV, hepatitis B (if unimmunized), rapid plasma reagin (RPR) (for syphilis), cultures or nucleic acid amplification tests (with confirmation) for chlamydia, and gonorrhea and culture or polymerase chain reaction (PCR) for trichomonas.
- Culture or PCR for HSV1 and HSV2 if ulcers or vesicles are present (**Figure 9-6**).
- Condylomata acuminata is a clinical diagnosis and biopsy is required only if lesions are atypical or resistant to treatment (molluscum contagiosum is a mimic and not sexually transmitted in children).

- Pregnancy testing in postpubescent children; consider prophylaxis (e.g., plan B) if the event occurred less than 96 hours prior to evaluation.
- Follow-up examinations 2 to 3 weeks after an acute assault to complete testing for STIs with prolonged incubation periods (especially HPV), assess resolution of injuries, and ensure emotional recovery.

DIFFERENTIAL DIAGNOSIS

In females, the following may be confused with abuse:

- Straddle injury (or other accidental trauma)—This occurs when a child falls onto an object. Bruising or lacerations to the labia majora, labia minora, or posterior fourchette may be seen. Although rare, accidental penetrating injury involving perihymenal tissues occurs, but rarely.
- Anatomic variants of normal, including shallow hymenal notches, anterior hymenal clefts, midline vestibule white lines, perineal defects, and narrow hymenal rims.
- Vulvar dermatitis—This may be caused by atopy, contact irritation, or seborrhea.
- Vulvovaginitis (e.g., nonspecific vaginal flora, shigella, streptococcus, poor hygiene, candidiasis)—Complaints include vaginal irritation or itching and vaginal discharge; wet prep and/or culture may be helpful.
- Lichen sclerosus et atrophicus is a cutaneous disease not caused by sexual abuse. It may present with bleeding, bruising, and/or vulvar itching, and the examination shows subepidermal hemorrhages and/or atrophic changes with areas of hypopigmentation over the vulva, perineum, and/or anus, an “hourglass” configuration (**Figure 9-7**).

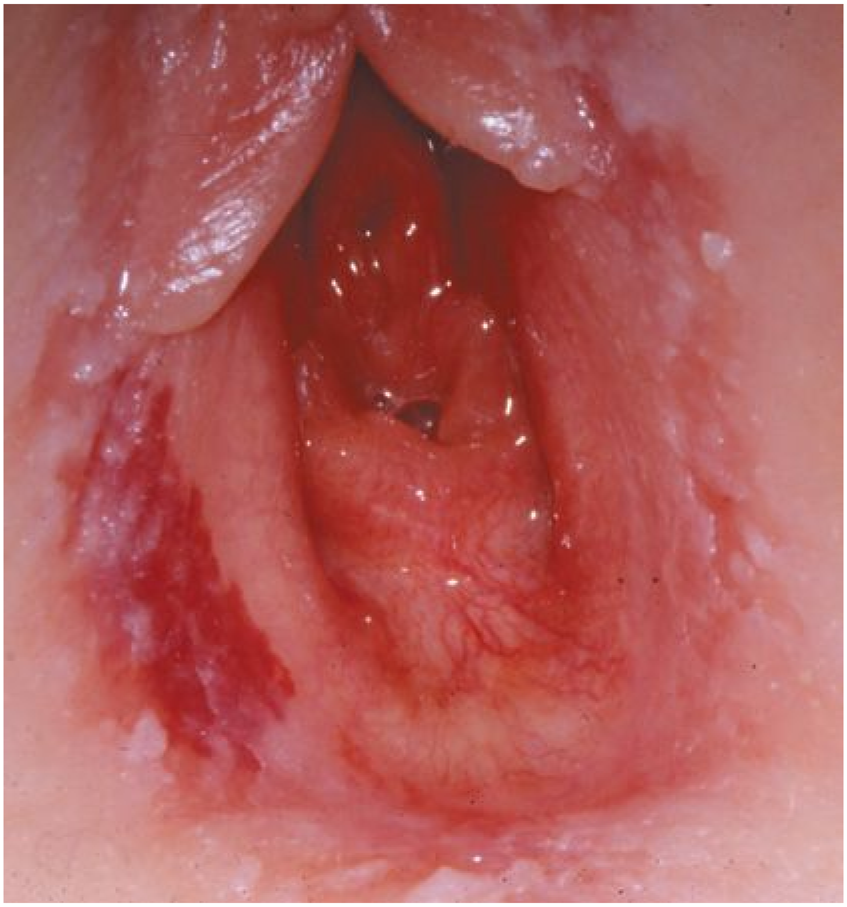

FIGURE 9-7 Lichen sclerosus et atrophicus in a young girl. This is a cutaneous disease, but commonly confused with sexual abuse because of the subepidermal hemorrhages. (*Used with permission from Nancy D. Kellogg, MD.*)

- Anogenital irritation or bleeding—Causes may be infectious (pinworms, candidiasis, group B streptococcal infection), irritative (overgrowth of normal flora, sensitivity to laundry detergent or fabric softeners, sequelae of pubic hair shaving) or anatomic (urethral prolapse, dehiscence of a labial adhesion) (**Figure 9-8**).

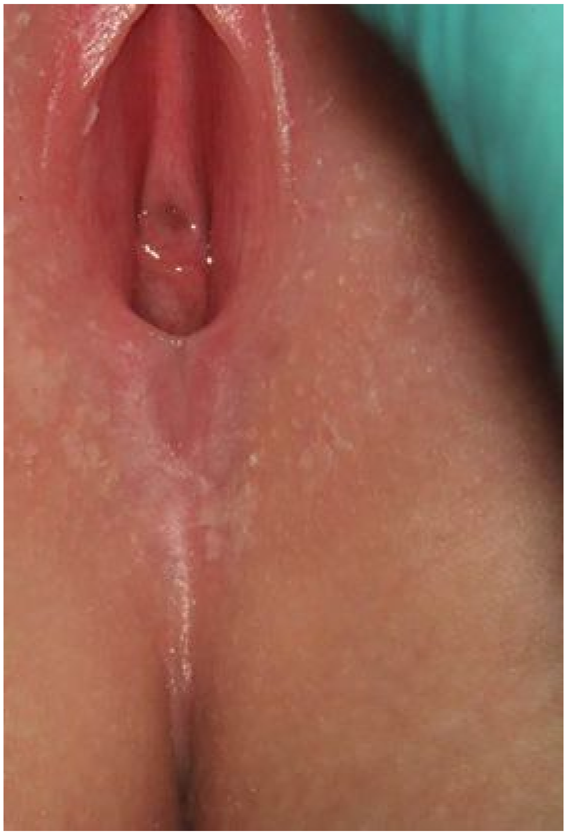

FIGURE 9-8 Labial adhesion can be confused with scarring secondary to child sexual abuse. This acquired condition is common in prepubertal girls and thought to be related to hygiene, irritation, and possibly trauma. The young girl is in supine frog-leg position. (*Used with permission from Nancy D. Kellogg, MD.*)

- Normal physiologic leukorrhea—Scant, whitish tenacious discharge in pubertal females. Wet mount is normal.

In males, the following may be confused with abuse:

- Accidental trauma (e.g., penis caught in zipper)—History should support pattern of injury. Most intentionally inflicted injuries of male genitals are physical, not sexual, abuse.
- Phimosis—Unretractable foreskin. Irritation and redness occurs as a result of trapped debris.
- Additional findings that may be confused with abuse:

- Anal fissure(s), which is a superficial excoriation or tear that extends from the anal verge into the anal canal, may or may not cause pain or bleeding during bowel movements. Sometimes, but not always, associated with diarrhea or constipation.
- Perianal venous pooling is sometimes mistaken for bruising.

MANAGEMENT

- Children may present with nonspecific behavioral and physical symptoms (but no disclosure of abuse) that include chronic stomachaches or headaches, school difficulties, mood changes, and sleeping difficulties. These children should be questioned in a careful and nonleading manner about the possibility of sexual abuse. For example, the clinician may state: “I treat other children who have problems like you do with school and headaches. Some of these children have told me about things that have happened to their body or feelings that made them sad, scared, or confused. Has anything like that ever happened to you?”
- Take a history from the child if necessary to make a medical diagnosis and to determine appropriate testing, treatment, and the need to report suspected abuse to child protection or law enforcement. The clinician may opt not to take a history if the child was or will be interviewed elsewhere; in this case, information necessary to determine what type of medical assessment and testing should be obtained from other sources.
    - Ensure that the parent is not in the room for the history. Parents may be present for the physical examination.
    - Use open-ended questions, such as “What happened?” or “Tell me more …” as opposed to suggestive questions such as “Did Daddy touch your private parts?”
    - Take careful notes and document with quotations whenever possible.
- Conduct a full physical examination including genitalia. Elicit cooperation from the child by explaining all procedures and earning his or her trust.
- Consider STI and pregnancy prophylaxis for postpubertal patients.

- Withhold STI treatment in asymptomatic prepubescent children until STI tests are confirmed positive, as the incidence of STI in asymptomatic prepubertal children is relatively low.
- Consult with an infectious disease specialist regarding HIV prophylaxis. If HIV prevalence is high in local regions, assailant risk factors are unknown or high for HIV, and if the child is evaluated within 72 hours of a high-risk exposure, then HIV prophylaxis may be appropriate.
- Examine closely for signs of physical and emotional abuse and neglect.

FOLLOW-UP

- Laws vary by state; however, all states have mandated reporting laws (see Child Welfare Information Gateway—http://www.childwelfare.gov/).
- All victims of sexual abuse and their families should be referred to local counseling agencies and to a Children’s Advocacy Center, or other child abuse agency if available in the community.

PATIENT EDUCATION

At well-child visits, provider should discuss touches that make children sad, scared, or confused, or that give them an “uh-oh” feeling inside, and encourage parents to reinforce these themes at home.

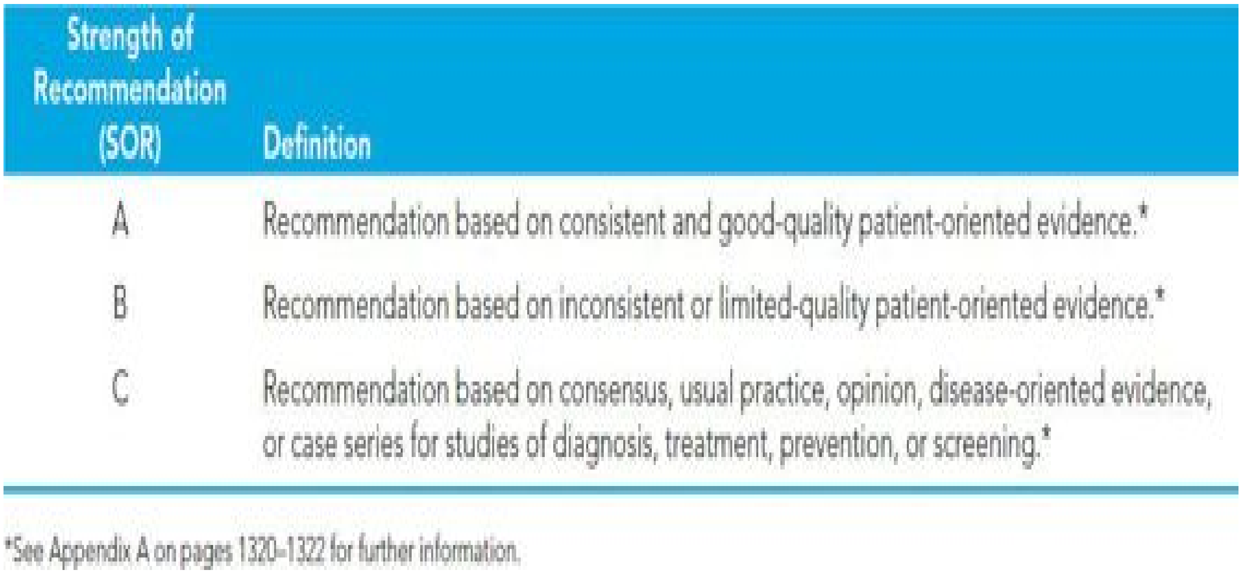
OPHTHALMOLOGY



Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1320–1322 for further information.

10 HORDEOLUM AND CHALAZION

Heidi Chumley, MD

PATIENT STORY

A 5-year-old girl presented with a tender nodule on the lower eyelid for 3 days (**Figure 10-1**). The clinician diagnosed an external hordeolum (stye) and recommended that the mother apply warm moist compresses to the affected eyelid 4 times a day. Her hordeolum resolved within 7 days.

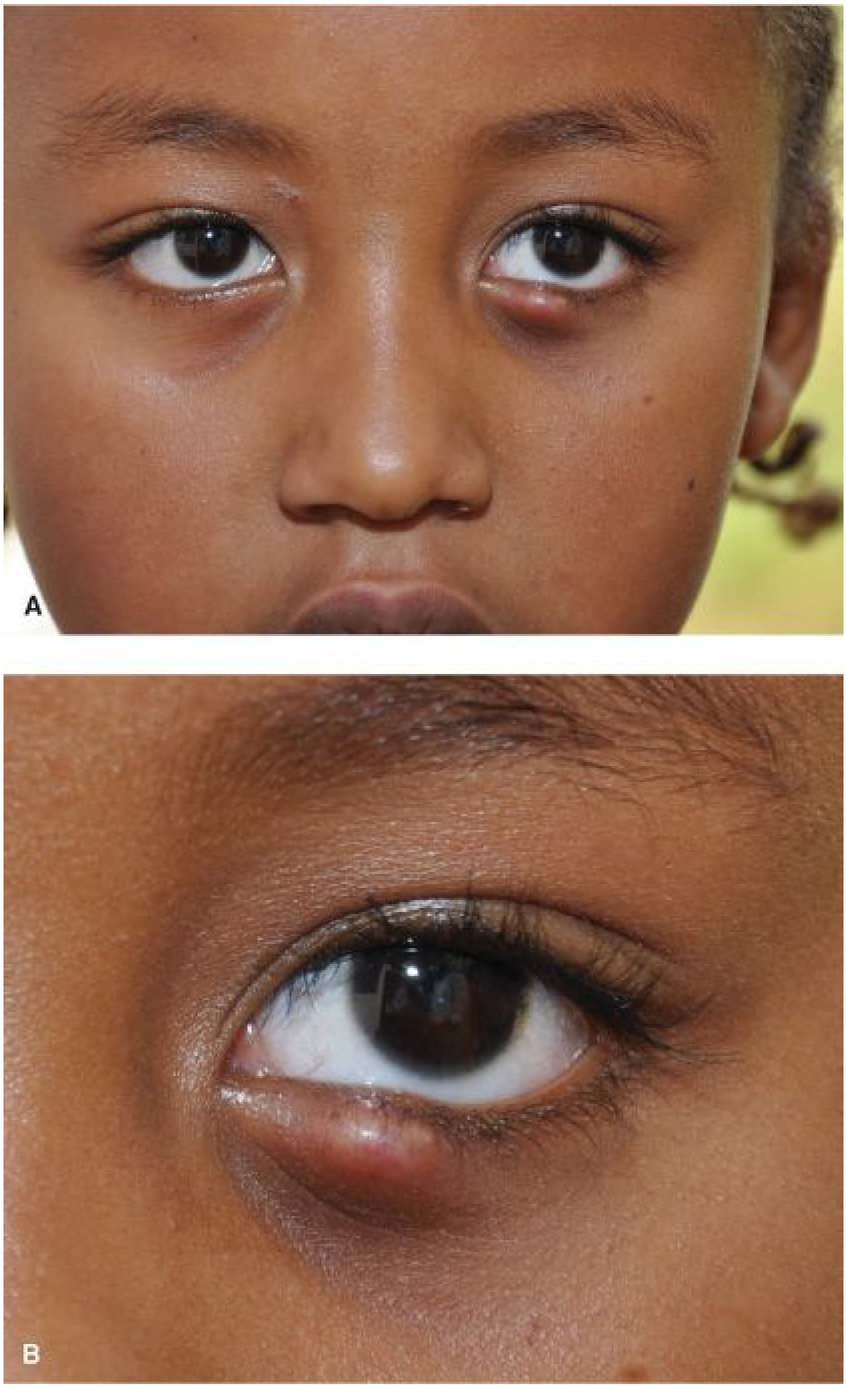


Figure 10-1 **A.** External hordeolum on the lower eyelid of a 5-year-old girl. **B.** Close-up showing eyelid swelling. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

A hordeolum is an acute painful infection of the glands of the eyelid, usually caused by bacteria. Hordeola can be located on the internal or external eyelid. Internal hordeola that do not completely resolve become cysts called chalazia. External hordeola are commonly known as styes.

SYNONYMS

Stye (external hordeolum).

EPIDEMIOLOGY

- Unclear incidence or prevalence in the US, but often stated to be more common in school-age children.
- In one study of school-age children in Brazil, the prevalence of chalazion was found to be 0.2 percent and that of hordeolum was 0.3 percent.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

HORDEOLUM (ACUTELY TENDER NODULE IN THE EYE)

- Infection in the meibomian gland (internal hordeolum), often resolves into a chalazion (**Figure 10-1**).
- Infection in the Zeiss or Moll gland (external hordeolum) (**Figures 10-2** and **10-3**).

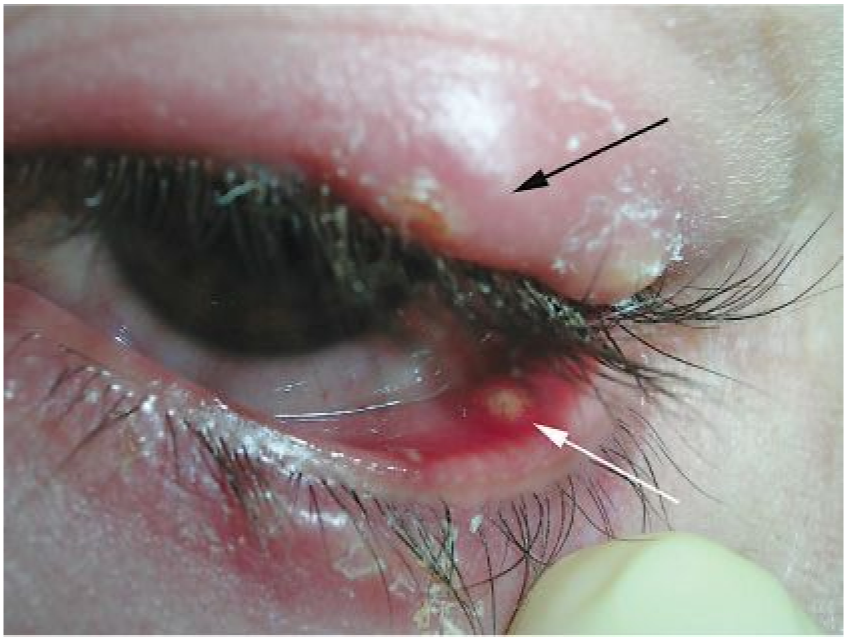

Figure 10-2 External hordeolum (*black arrow*) and an internal hordeolum (*white arrow*). (*Used with permission from Richard P. Usatine, MD*.)

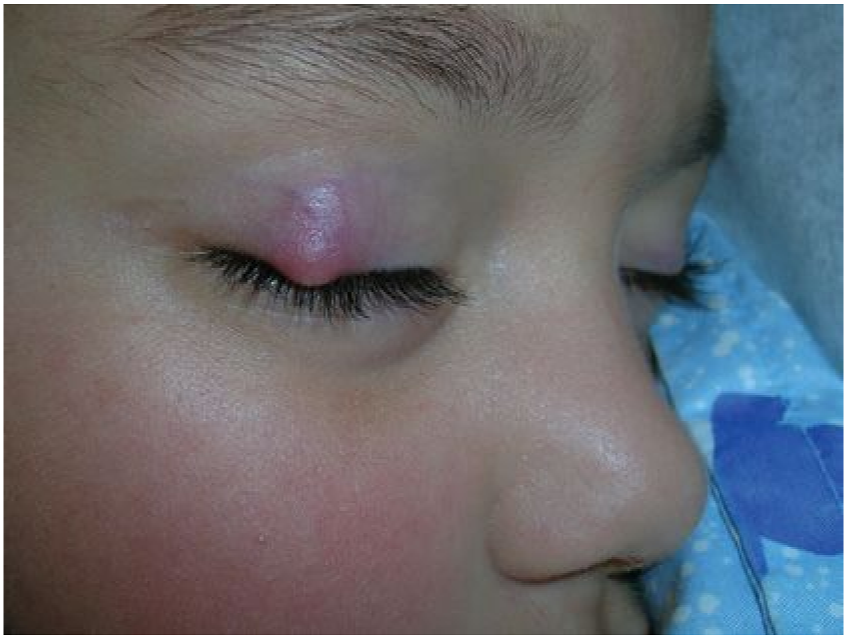

Figure 10-3 External hordeolum with disruption of the normal contour of the eyelid. (*Used with permission from Richard P. Usatine, MD*.)

- *Staphylococcus aureus* is the causative agent in most cases.

CHALAZION

- Meibomian gland becomes blocked, often in a patient with blepharitis.
- Blocked meibomian gland's duct releases gland contents into the soft tissue of eyelid.
- Gland contents cause a lipogranulomatous reaction (**Figure 10-4**).

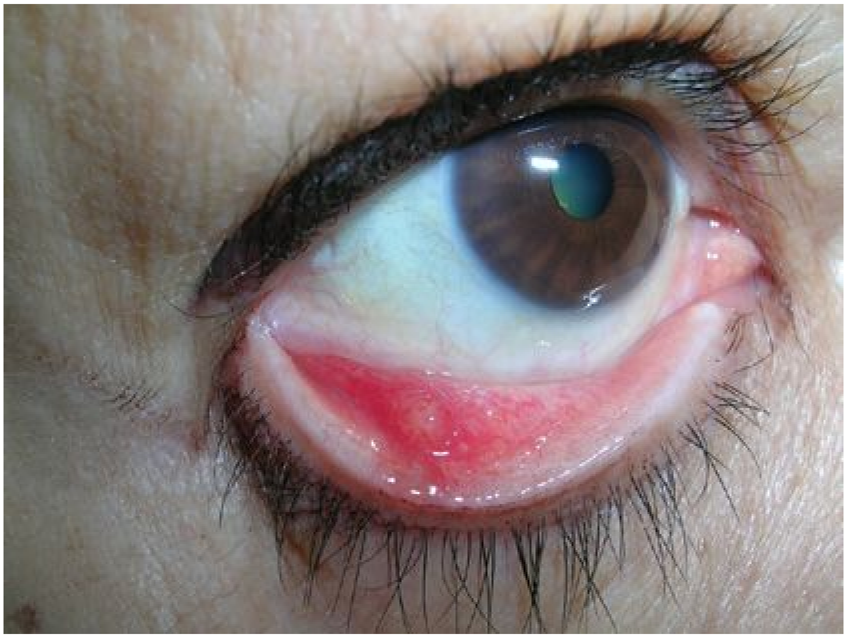

Figure 10-4 Chalazion viewed from internal eyelid showing the yellow lipogranulomatous material. (*Used with permission from Richard P. Usatine, MD.*)

- Reaction can cause acute tenderness and erythema, which then resolves into a chronic nodule (**Figure 10-5**).

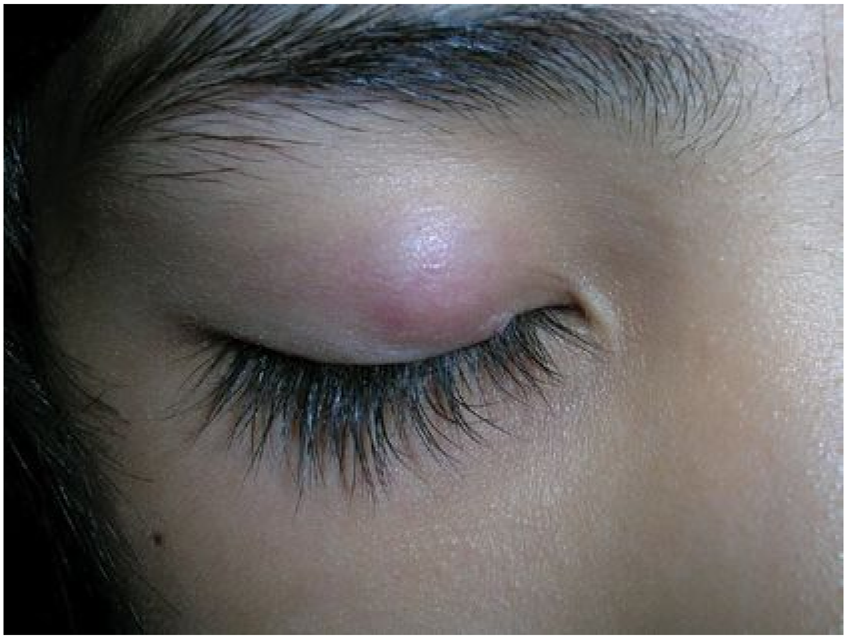

Figure 10-5 Chalazion present for 4 months on the upper eyelid of a young girl with minimal symptoms but cosmetically unappealing. (*Used with permission from Richard P. Usatine, MD*.)

RISK FACTORS

- Hordeolum: *S. aureus* blepharitis, previous hordeolum.
- Chalazion: Seborrheic blepharitis and rosacea.

DIAGNOSIS

- Chalazion and hordeolum are clinical diagnoses.
- Chalazion is a nontender nodule on the eyelid.
- Hordeolum.
    - Tenderness and erythema localized to a point on the eyelid (**Figures 10-1** to **10-3**).

  - Conjunctival injection may be present.
  - Fever, preauricular nodes, and vision changes should be absent.
  - Laboratory tests are generally not indicated.

DIFFERENTIAL DIAGNOSIS

- Xanthelasma—Yellowish plaques, generally near medial canthus (see Chapter 193, Hyperlipidemia).
- Molluscum contagiosum—Waxy nodules with central umbilication; generally multiple (see Chapter 115, Molluscum Contagiosum).

MANAGEMENT

- Hordeolum (internal):
  - No studies of nonsurgical interventions (compresses, lid scrubs, antibiotics, or steroids) met criteria for inclusion in a Cochrane study. No evidence for or against nonsurgical interventions for acute internal hordeolum.[1] SOR Ⓐ
  - Treat as described in the following section for external hordeolum.
- Hordeolum (external):
  - Warm soaks, 3 to 4 times a day for 15 minutes, will elicit drainage in most cases. SOR Ⓒ
  - Topical antibiotics (e.g., bacitracin ophthalmic ointment) may be beneficial for recurrent or spontaneously draining hordeolum. SOR Ⓒ
  - Cases that do not respond to warm soaks or that are extremely painful and swollen may be incised and drained with a small incision using a #11 blade. Make the incision on either the internal or external eyelid depending on where the hordeolum is pointing. A chalazion clamp can be used to protect the globe from damage. SOR Ⓑ
  - Antibiotics do not provide benefit after incision and drainage.[3] SOR Ⓑ

  - Systemic antibiotics are usually not needed unless patient has preseptal cellulitis. SOR C

- Chalazion
  - Can be treated conservatively with lid hygiene and warm compresses. Warm compresses can be applied 2 to 3 times daily but may take weeks to months to work. SOR C
  - One study demonstrated a 58 percent response rate of 1 percent topical chloramphenicol with warm compresses.[3] SOR B
  - Higher percentages of resolution can be achieved with either incision and curettage or injection with steroid (e.g., 0.3 mL triamcinolone acetonide) (80% to 92%).[4–6] SOR B The chalazion is usually drained from the internal eyelid using a chalazion clamp to protect the globe. After anesthetizing the area, a #11 blade is carefully used to open the chalazion. A chalazion curette helps to scoop out the lipogranulomatous material. No suturing is needed.
  - A study of 106 patients compared triamcinolone injection, incision and curettage, and warm compresses, and found resolution rates of 84 percent, 87 percent, and 46 percent, respectively.[6] SOR B
  - One study demonstrated a better response to incision and curettage in the following situations: patients 35.1 years of age or older, with lesion duration equal to or greater than 8.5 months and size equal to or greater than 11.4 mm.[5] SOR B

REFERRAL

Refer to an ophthalmologist if the hordeolum or chalazion is interfering with vision and not responding to therapy. If a surgical intervention is needed and you lack experience doing such a procedure, refer to ophthalmology. Recurrent chalazia due to underlying blepharitis raises a concern for ocular rosacea and should prompt a referral to ophthalmology (see Chapter 97, Rosacea).

PREVENTION

Eyelid hygiene (keeping the area around the eyelid clean) may prevent hordeola.

PROGNOSIS

Chalazia can persist for years if untreated (**Figure 10-6**). Some patients are prone to recurrence of hordeola and chalazia.

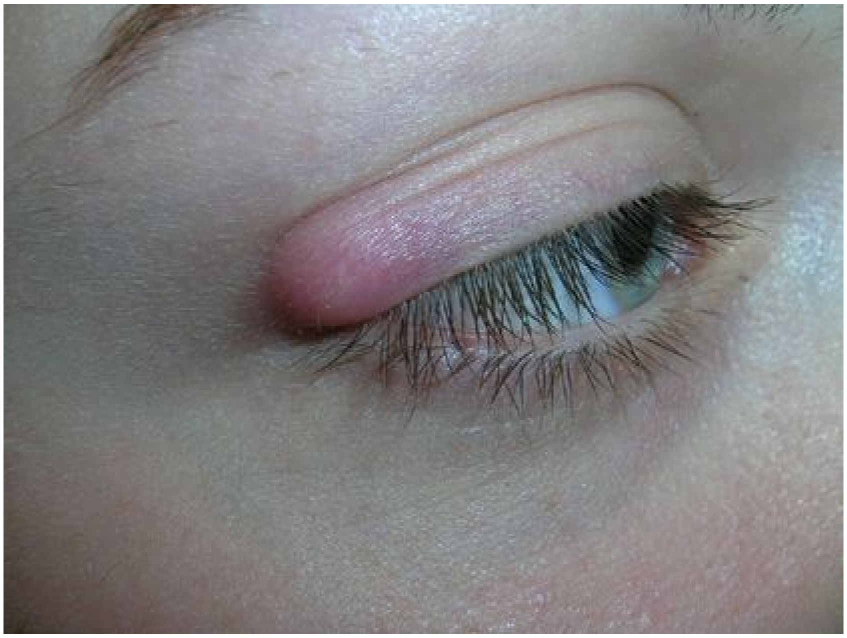

Figure 10-6 Chalazion in a 14-year-old girl. This eyelid swelling had been there for one year at the time of presentation. She had no pain but was unhappy with the appearance. (*Used with permission from Richard P. Usatine, MD.*)

FOLLOW-UP

A hordeolum with significant purulence and swelling should be reevaluated in 2 to 3 days or referred to an ophthalmologist. Warm compresses are slow to work for a chalazion, so follow-up should be no sooner than 1 month if nonsurgical treatment is prescribed.

PATIENT EDUCATION

Hordeolum commonly responds to warm soaks and topical antibiotics. It often recurs and can develop into a chronic chalazion, which may need to be treated with surgical removal or a steroid injection.

11 CORNEAL FOREIGN BODY AND CORNEAL ABRASION

Heidi Chumley, MD
Kelly Green, MD

PATIENT STORY

An 8-year-old boy was poked in the eye with a small branch while hiking with his cub scout pack. He presented with pain, tearing, photophobia, and a foreign body sensation. Fluorescein application demonstrated a green area under cobalt-blue filtered light (**Figure 11-1**). Careful inspection with magnification, including eversion of the upper eyelid, revealed no foreign body. He was treated with antibiotic eye drops. He showed improvement the next day and over time had complete resolution.

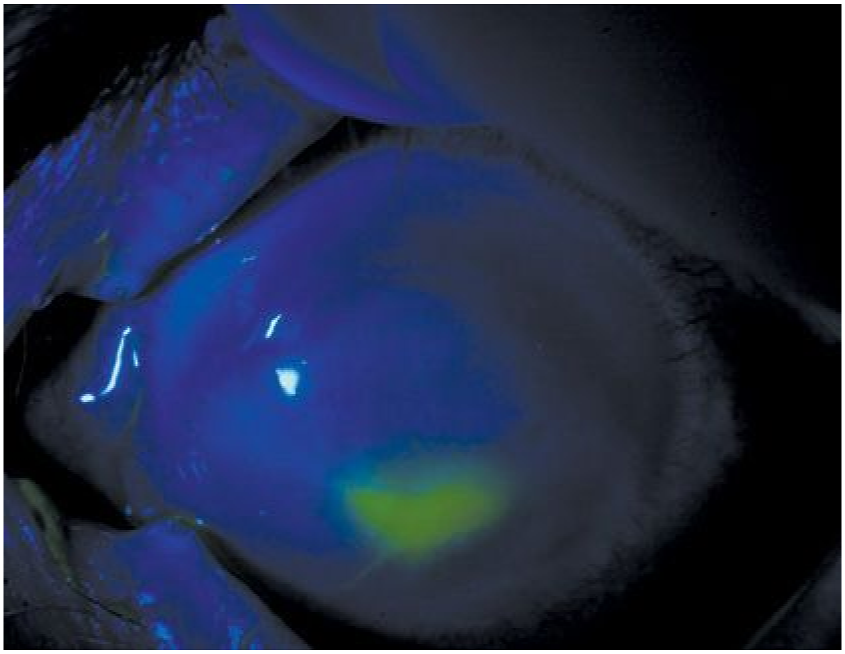

Figure 11-1 Fluorescein stains green, indicating corneal abrasion. (*Used with permission from Paul D. Comeau*.)

INTRODUCTION

Corneal abrasions are often the result of eye trauma and can cause an inflammatory response and significant pain. Corneal abrasions are detected using fluorescein and a UV light. A corneal foreign body can be seen during a careful physical examination with a good light source or slit lamp. Nonpenetrating foreign bodies can be removed by an experienced physician in the office using topical anesthesia. Refer all penetrating foreign bodies to an ophthalmologist.

SYNONYMS

Corneal abrasion is sometimes referred to as a corneal epithelial defect.

EPIDEMIOLOGY

- Corneal abrasion with or without foreign body is common; however, the prevalence or incidence of corneal abrasion in the general pediatric population is unknown.
- Corneal abrasion is the most common eye injury for children presenting to an emergency room.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- The cornea overlies the anterior chamber and iris and provides barrier protection, filters UV light, and refracts light onto the retina.
- Abrasions in the cornea are typically caused by direct injury from a foreign body, resulting in an inflammatory reaction.
- The inflammatory reaction causes the symptoms and can persist for several days after the foreign object is out. Typically in children, the corneal abrasion heals more rapidly than in adults.

RISK FACTORS

- Participation in sports such as hockey, lacrosse, or racquetball raises the risk of corneal abrasions from ocular trauma.[2]
- Ventilated neonates (as a result of mask pressure on the orbit) or sedated patients (as a result of disruption of the blink reflex, and subsequent corneal exposure) are at increased risk for corneal abrasions.[2]

Contact lenses, especially soft extended wear, increase the risk of developing an infected abrasion that ulcerates.[2] Any contact lens wearer with a corneal abrasion should see an ophthalmologist, due to the high risk of permanent vision loss due to infection.

DIAGNOSIS

CLINICAL FEATURES

▶ History and physical

- History of ocular trauma or eye rubbing (although corneal abrasions can occur with no trauma history and young children may not accurately report trauma).

- Symptoms of pain, eye redness, photophobia, and a foreign-body sensation.
- Foreign body seen with direct visualization or a slit lamp (**Figures 11-2** and **11-3**).

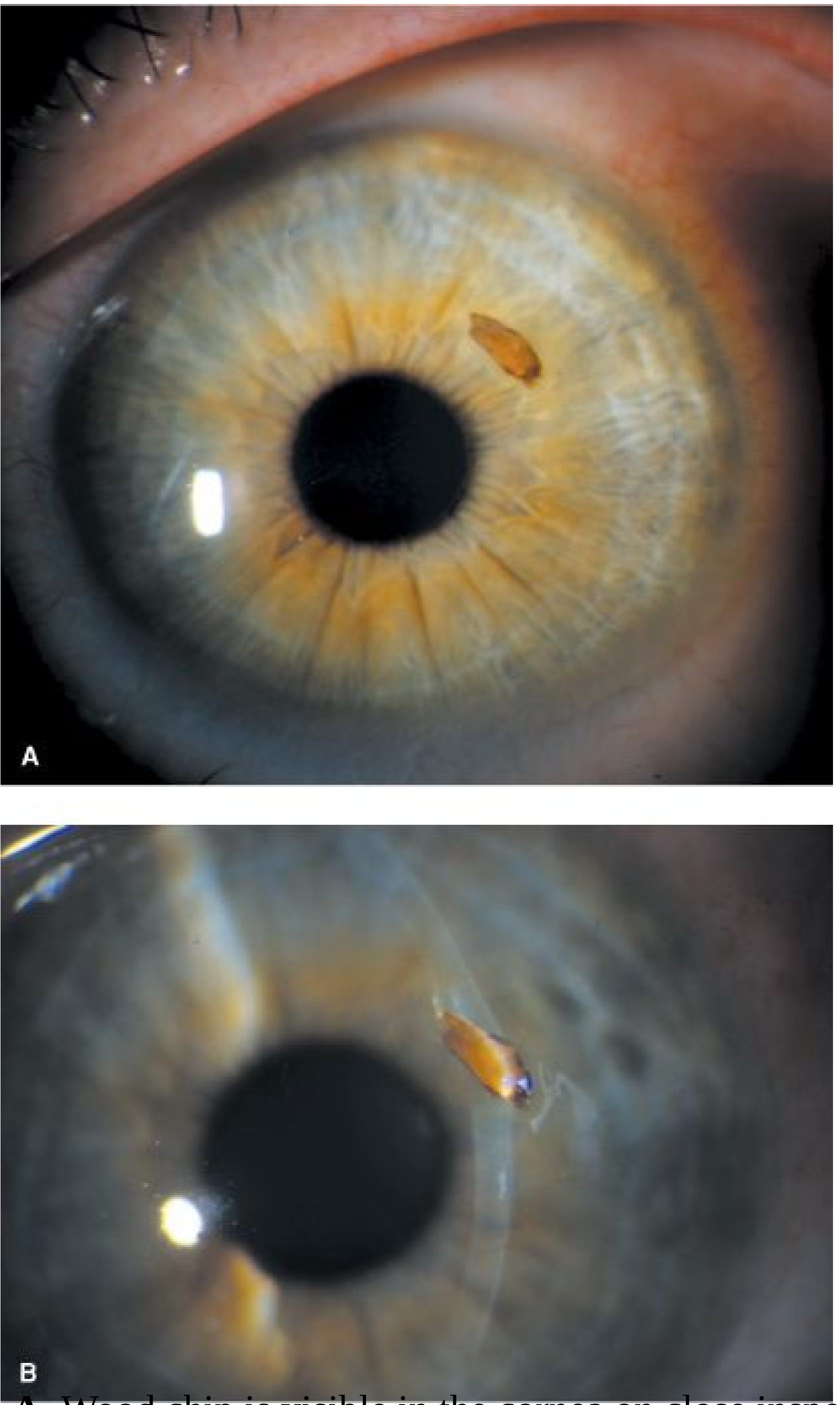

Figure 11-2 **A.** Wood chip is visible in the cornea on close inspection of the eye. **B.** Slit-lamp examination reveals this wood chip has penetrated the

cornea. (*Used with permission from Paul D. Comeau*.)

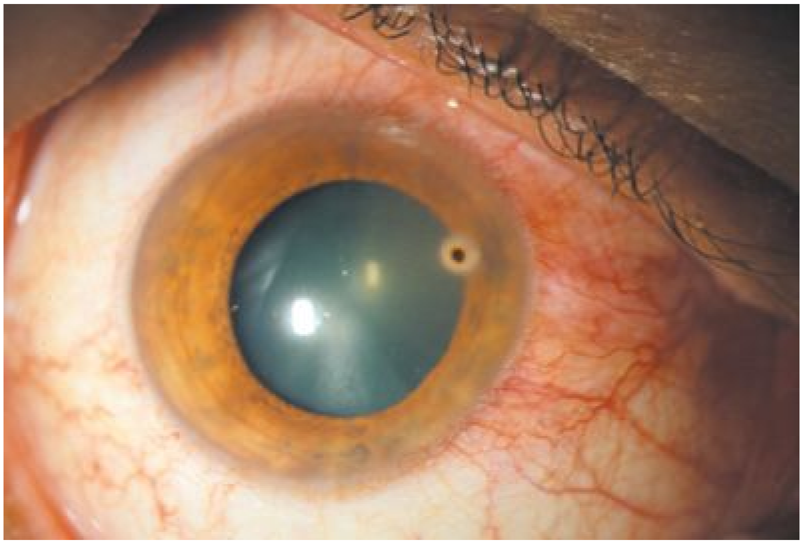

Figure 11-3 Metallic foreign body with rust ring within the corneal stroma and conjunctival injection. (*Used with permission from Paul D. Comeau*.)

- Fluorescein application demonstrates green area (which represents the disruption in the corneal epithelium) under cobalt-blue filtered light (**Figure 11-1**).
- History of contact lens wear.
- History of ocular or perioral herpes virus infection.

LABORATORY TESTING

- Culture by an ophthalmologist if an abrasion with infection (corneal ulcer) is suspected.

IMAGING

- If physical examination is equivocal, imaging may be useful to determine if a foreign body has perforated the cornea. An object that has fully perforated the cornea has passed through the cornea and will be located in the anterior segment or posterior segment of the eye, making it difficult to see without imaging technology. The most important question to answer is the following: what is the mechanism of injury? If there is a chance of an intraocular foreign body, proceed with imaging. On exam, it is important to note apparent disruption of other ocular structures, such as the iris. If there is gross blood in the anterior chamber with history of mechanism of injury which could lead to intraocular foreign body, consider imaging.

- CT or spiral CT can detect nonmetallic and metallic foreign bodies.
  - A metallic foreign body can be seen on an orbital radiograph. Avoid MRI if the history suggests the foreign body may be metallic. Ultrasound and ultrasound biomicroscopy can also aid in visualization of intraocular foreign bodies and may be useful in some cases.

DIFFERENTIAL DIAGNOSIS

- Uveitis or iritis—Usually no history of trauma, with unilateral 360-degree perilimbal injection, eye pain, photophobia, and vision loss (see Chapter 13, Uveitis and Iritis).
- Keratitis or corneal ulcerations—Diffuse erythema with ciliary injection often with miosis; eye discharge; pain, photophobia, and vision loss depending on the location of ulceration (**Figures 11-4** and **11-5**). There is often a history of trauma, herpes simplex virus (HSV), or contact lens wear. Patients should see an ophthalmologist urgently.

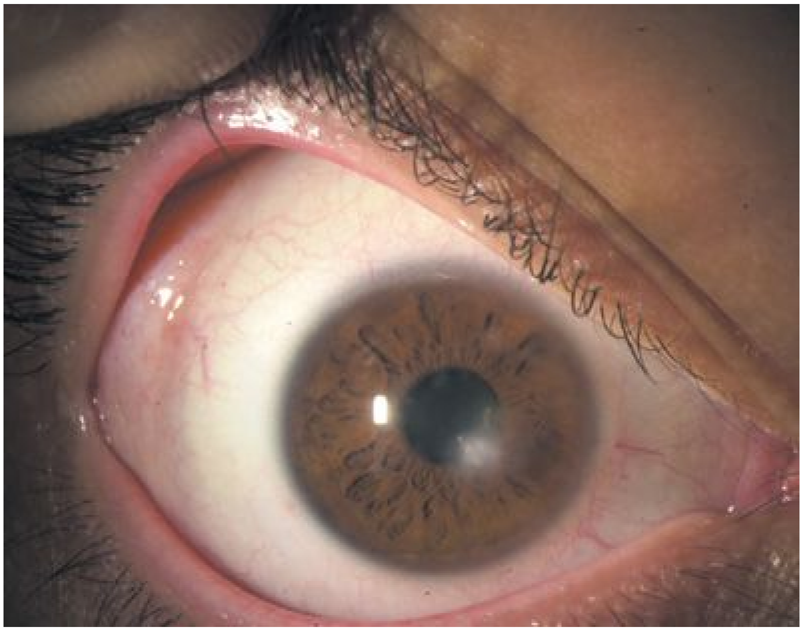

Figure 11-4 Small corneal ulcer in the visual axis. (*Used with permission from Paul D. Comeau*.)

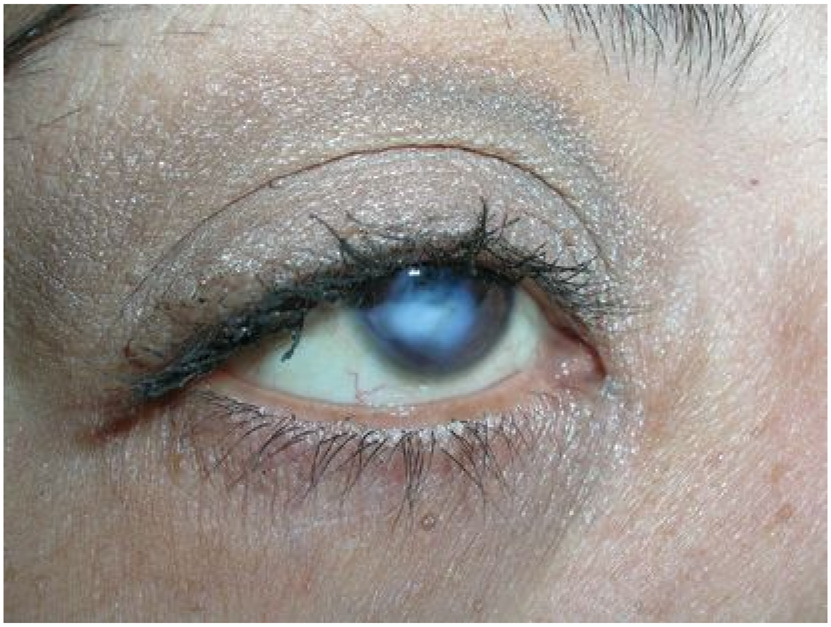

Figure 11-5 Large corneal scar from previous ulcerations secondary to contact lens use. The scar obscures the visual axis and this young patient is awaiting a corneal transplant. (*Used with permission from Richard P. Usatine, MD*.)

- Conjunctivitis—Conjunctival injection; eye discharge; gritty or uncomfortable feeling; no vision loss, history of respiratory infection, or contacts with others who have red eyes (see Chapter 12, Conjunctivitis).

MANAGEMENT

NONPHARMACOLOGIC

- Confirm diagnosis with fluorescein and a UV light (for abrasion) if no foreign body is readily visible (see **Figure 11-4**).
- Carefully inspect for a foreign body. Evert the upper eyelid for full visualization. Slit-lamp visualization may be needed to determine if the cornea has been penetrated (see **Figure 11-2**). Note that foreign bodies can frequently lodge in the superior tarsal conjunctiva and must be removed, lest they continue to abrade the cornea.
- Remove (or refer for removal) nonpenetrating foreign bodies. Apply a topical anesthetic, such as proparacaine or tetracaine. Remove with irrigation, a wet cotton-tipped applicator, or a fine-gauge needle at the slit lamp.
- Remove contact lenses until cornea is healed.[3] SOR Ⓒ
- Avoid patching in corneal abrasions smaller than 10 mm; it does not help.[4] SOR Ⓐ

MEDICATIONS

- Consider topical ophthalmic NSAIDs for pain if needed.[5,6] SOR Ⓐ While the evidence for this intervention of pain relief is relatively good, there are some risks to their use and these medications can be costly. They do not speed healing and oral analgesics can be used for pain.
- Consider topical antibiotics. SOR Ⓒ Chloramphenicol ointment reduced the risk of recurrent ulcer in a prospective, non-placebo, controlled trial.[7]

Although chloramphenicol is rarely used in the US, other ophthalmic antibiotics, such as erythromycin ointment, are used for corneal abrasions. SOR Ⓒ While there is an epithelial defect, there is risk for infection/ulceration. The choice of whether or not to use antibiotics can be based upon the mechanism of injury. Small abrasions can be treated with lubrication with artificial tears and over-the-counter ophthalmic ointments until the abrasion heals.

REFERRAL

- Refer penetrating foreign bodies to an experienced eye surgeon.

PREVENTION

Eye protection should be worn for high-risk occupational and recreational activities.

PROGNOSIS

Prognosis is generally good. Development of infection or a rust ring worsens prognosis.

FOLLOW-UP

See all patients in 24 hours for reassessment. If there is no improvement, look for an initially overlooked foreign body or a full-thickness injury. Do not hesitate to refer to ophthalmology if the patient is not improving.

PATIENT EDUCATION

- Advise children (and their parents) who play sports, such as racquetball or hockey, to wear eye protection for primary prevention.
- Advise patients with corneal abrasions that healing usually occurs within 2 to 3 days, and they should report persistent pain, redness, and photophobia.
- Patients should be advised not to sleep in contact lenses, even if labeled “extended wear.”

12 CONJUNCTIVITIS

Heidi Chumley, MD
Richard P. Usatine, MD
Kelly Green, MD

PATIENT STORY

A 4-year-old boy woke up with one eye matted shut. The child's parents cleared the matted material with a warm washcloth and brought the child into the doctor's office. The child indicates discomfort but not pain. The child and the parents believe the child's vision is fine. On examination, the child is afebrile with conjunctival injection, lid swelling and purulent discharge in the left eye (**Figure 12-1**). Vision testing is normal. Based on the age of the child and the purulence of the discharge, bacterial conjunctivitis was diagnosed and antibiotic drops were prescribed.

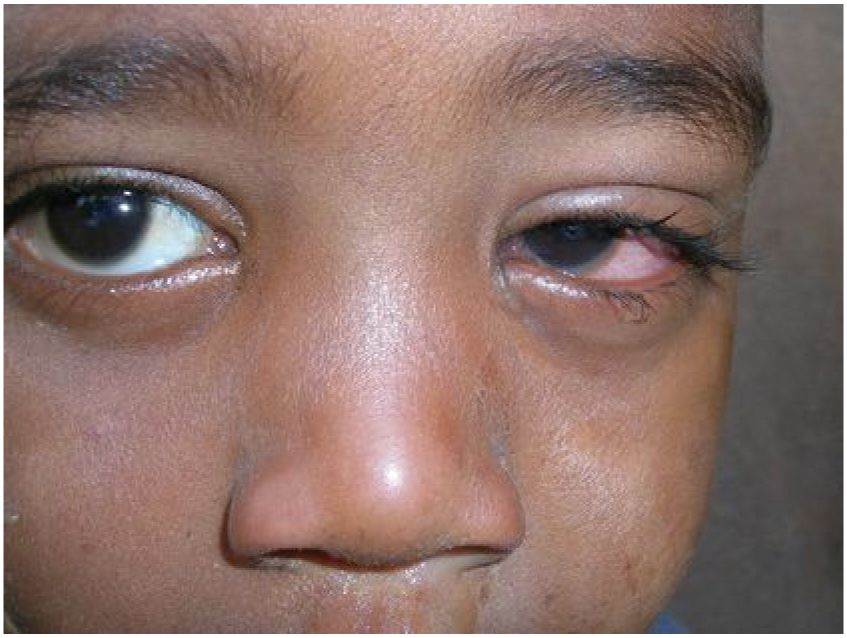

FIGURE 12-1 Unilateral conjunctivitis in a 4-year-old child. The child's age and purulent discharge are consistent with a bacterial etiology. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Conjunctivitis, inflammation of the membrane lining the eyelids and globe, presents with injected pink or red eye(s), eye discharge ranging from mild to purulent, eye discomfort or gritty sensation, and no vision loss. Conjunctivitis is most commonly infectious (viral or bacterial) or allergic, but can be caused by irritants. Diagnosis is clinical, based on differences in symptoms and signs.

SYNONYMS

Pink eye.

EPIDEMIOLOGY

- Infectious conjunctivitis is common and often occurs in outbreaks, making the prevalence difficult to estimate.
- In the US, the estimated annual incidence rate for bacterial conjunctivitis is 135 per 10,000 people, with 23 percent, 28 percent and 13 percent of cases occurring in children ages 0 to 2, 3 to 9, and 10 to 19, respectively.[1]
- Viral conjunctivitis is far more common than bacterial conjunctivitis.
- Allergic conjunctivitis in children and adults had a point prevalence of 6.4 percent and a lifetime prevalence of 40 percent in a large population study in the US from 1988 to 1994.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

Conjunctivitis is predominately infectious (bacterial or viral) or allergic, and the most common etiologies vary by age.

- Neonatal conjunctivitis is often caused by *Chlamydia trachomatis* and *Neisseria gonorrhoeae*.[3]
- Children younger than 6 years are more likely to have a bacterial than viral conjunctivitis. In the US, the most common bacterial causes are *Haemophilus* species and *Streptococcus pneumoniae* accounting for almost 90 percent of cases in children.[4,5]
- Children age 6 years or older are more likely to have viral or allergic causes for conjunctivitis.[4] Adenovirus is the most common viral cause.

DIAGNOSIS

- To distinguish conjunctivitis from other causes of a red eye, ask about pain and check for vision loss. Patients with a red eye and intense pain or vision loss that does not clear with blinking are unlikely to have conjunctivitis and should undergo further evaluation.
- Always ask about contact lens use as this can be a risk factor for all types of conjunctivitis, including bacterial conjunctivitis. Any patient who uses contact lenses should remove the lenses from both eyes in the event of any sort of red eye complaint. The patient should see an ophthalmologist.
- Typical clinical features of any type of conjunctivitis may include eye discharge, gritty or uncomfortable feeling, one or both pink eyes, and no vision loss. The infection usually starts in one eye, and progresses to involve the other eye days later.
- Viral conjunctivitis often presents with two pink eyes and minimal discharge (**Figure 12-2**).

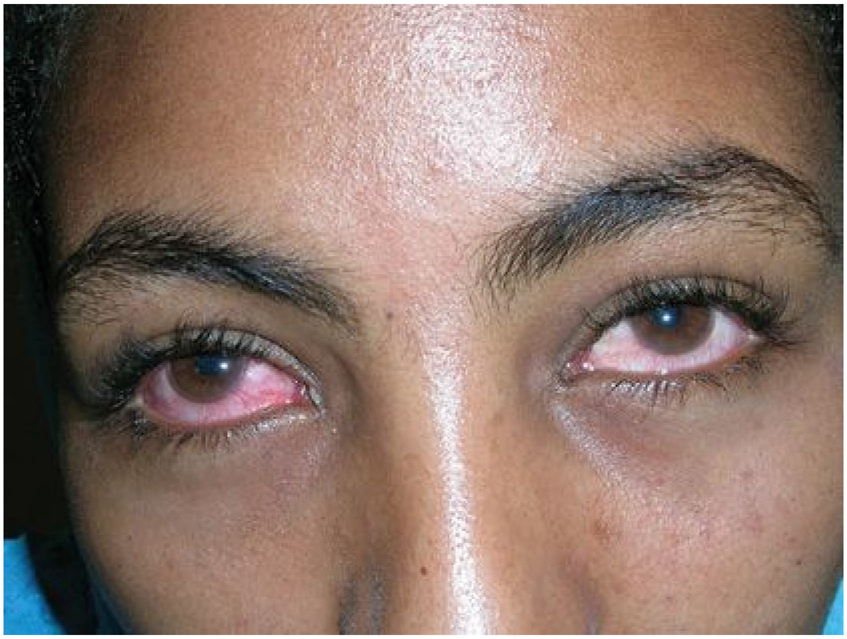

FIGURE 12-2 Viral conjunctivitis demonstrating bilateral conjunctival injection with little discharge. (*Used with permission from Richard P. Usatine, MD.*)

- Bacterial conjunctivitis (**Figures 12-1**, **12-3**, and **12-4**) has a more purulent discharge than viral or allergic conjunctivitis.

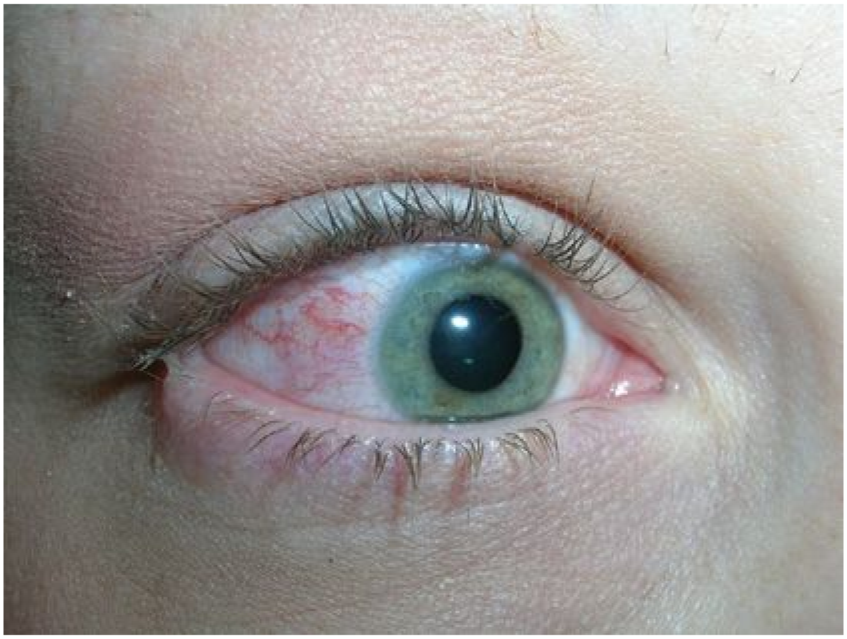

FIGURE 12-3 Bacterial conjunctivitis with visible discharge on the lateral eyelids. The conjunctivitis was bilateral. (*Used with permission from Richard P. Usatine, MD*.)

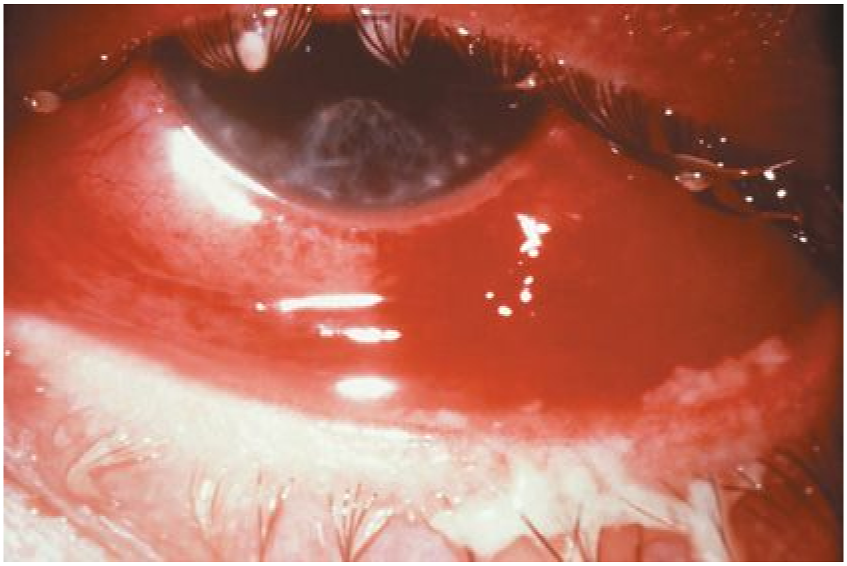

FIGURE 12-4 Gonococcus conjunctivitis has a copious discharge. This severe case resulted in partial blindness. (*Used with permission from Disease Control and Prevention [CDC]*.)

- In one study, 96 percent of children, presenting to an emergency room, with a history of gluey or sticky eyelids and a purulent discharge noted on physical examination had bacterial conjunctivitis.[5]
- Allergic conjunctivitis is typically bilateral and accompanied by eye itching. Giant papillary conjunctivitis is a type of allergic reaction, most commonly seen in patients who wear soft contact lenses (**Figure 12-5**).

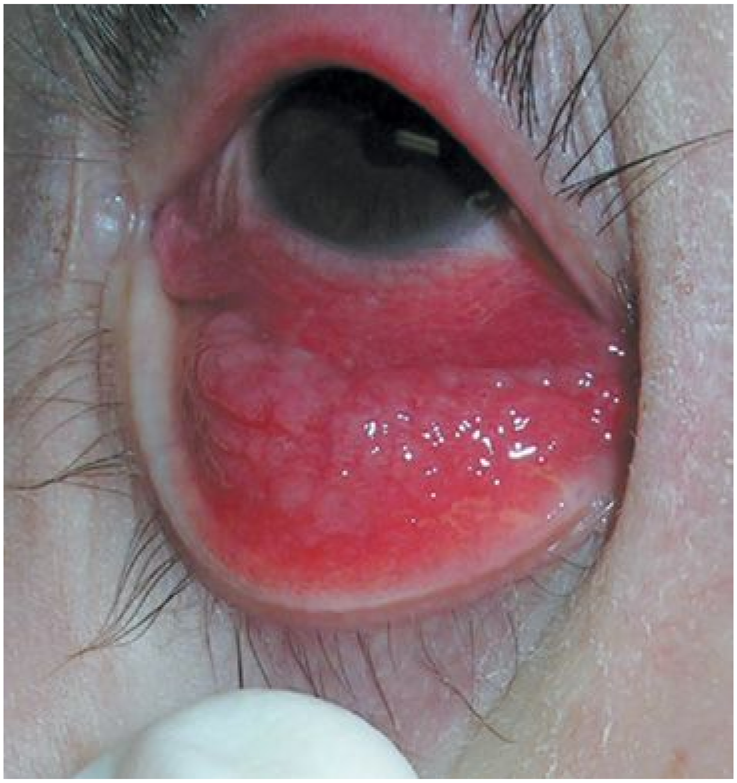

FIGURE 12-5 Giant papillary conjunctivitis in a contact lens wearer. (*Used with permission from Mike Johnson, MD.*)

LABORATORY TESTING

- An in-office rapid test for adenoviral conjunctivitis (RPS Adeno Detector) has a sensitivity of 88 percent and a specificity of 91 percent compared to viral cell culture with confirmatory immunofluorescence staining.[6] Since adenoviral conjunctivitis is self-limited, and is usually diagnosed based on history and physical examination, the test is rarely performed.

DIFFERENTIAL DIAGNOSIS

- Nasolacrimal duct obstruction in newborns typically presents with excess tearing. Erythema and inflammation may be present at the nasal and inferior lid. The obstruction may occasionally lead to the development of infectious conjunctivitis (see also Chapter 14, Nasolactrimal Duct Obstruction).

- Keratitis or corneal ulcerations—Diffuse conjunctival injection, often with miosis (constriction of pupil), eye discharge, pain, photophobia, and vision loss depending on the location of ulceration. Herpes keratitis is a diagnosis that should not be missed (**Figures 12-6** and **12-7**). The use of fluorescein and a UV light can help identify dendritic ulcers or other corneal damage and prompt an emergent referral to an ophthalmologist (**Figure 12-7**). Contact lens wearers should urgently see an ophthalmologist for keratitis.

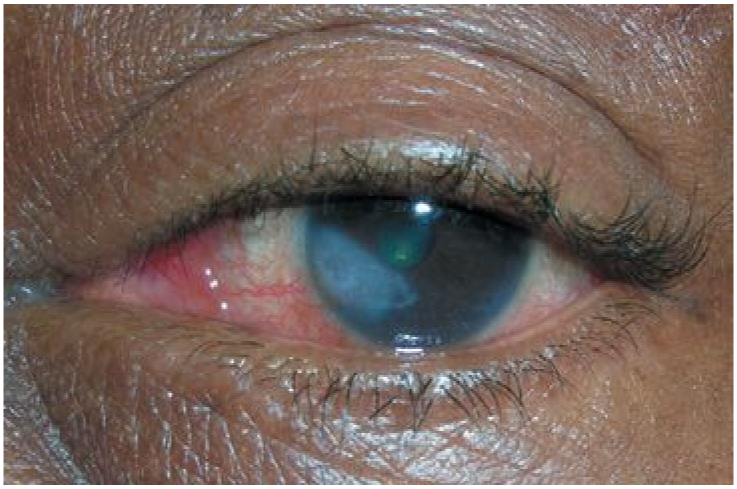

FIGURE 12-6 Herpetic keratitis in a woman staying in a shelter after Hurricane Katrina. (*Used with permission from Richard P. Usatine, MD.*)

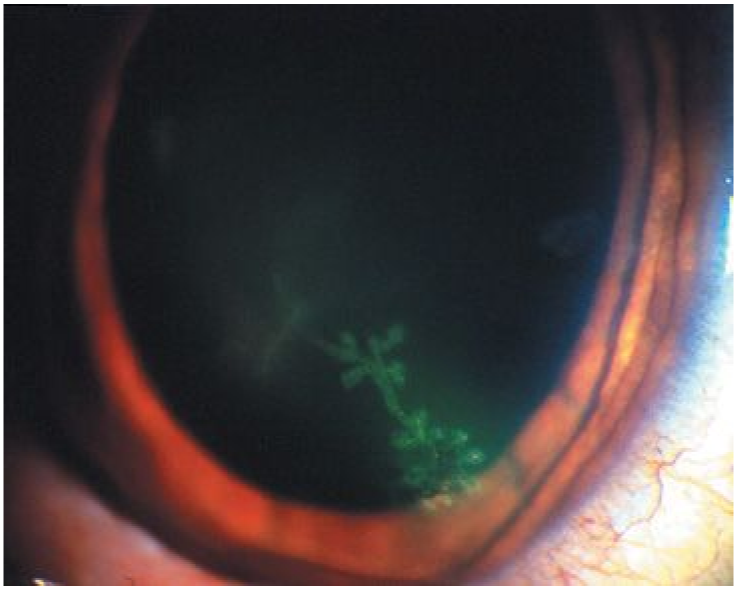

FIGURE 12-7 Slit-lamp view of a dendritic ulcer with fluorescein uptake from herpetic keratitis. (*Used with permission from Paul D. Comeau*.)

- A foreign body in the eye can cause conjunctival injection and lead to a bacterial superinfection. If the foreign body is not easily dislodged with conservative measures, or appears to be superinfected with ulceration or leukocyte infiltrate, prompt referral to an ophthalmologist is required (**Figure 12-8**).

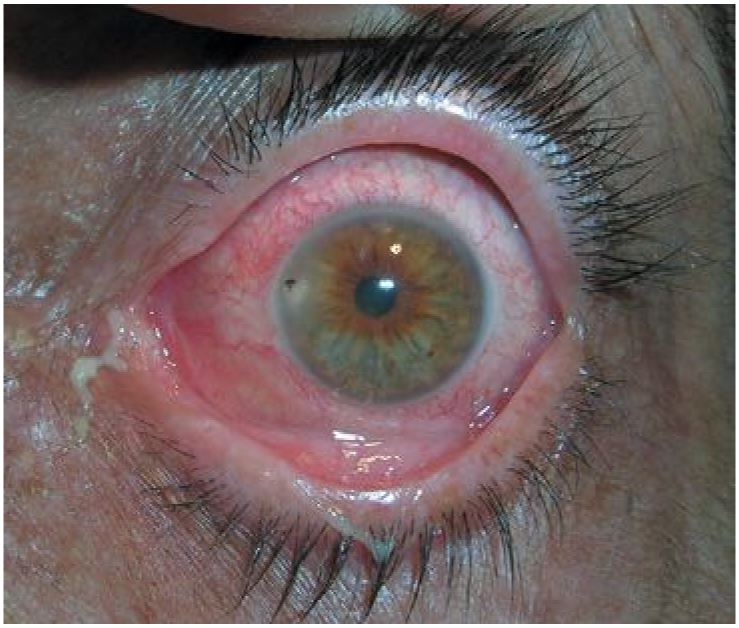

FIGURE 12-8 Conjunctivitis caused by a foreign body in the eye. The ground metal speck is seen on the cornea, and the corneal infiltrate, along with a purulent discharge, indicate a bacterial superinfection. (*Used with permission from Richard P. Usatine, MD*.)

- Uveitis or iritis—360-degree perilimbal injection, eye pain, photophobia, and vision loss. Frequently treated initially as conjunctivitis without resolution (see also Chapter 13, Uveitis and Iritis).
- Trachoma is an eye infection caused by *C. trachomatis* that is rare in the US but common in the rural areas of some developing countries. It is a leading cause of blindness in the developing world. Poverty and poor hygiene are major risk factors. Once the eye is infected, follicles can be seen on the upper tarsal conjunctiva upon eyelid eversion (**Figure 12-9**). Superior tarsal conjunctival scarring leads to entropion, which causes corneal scarring and ultimately blindness.

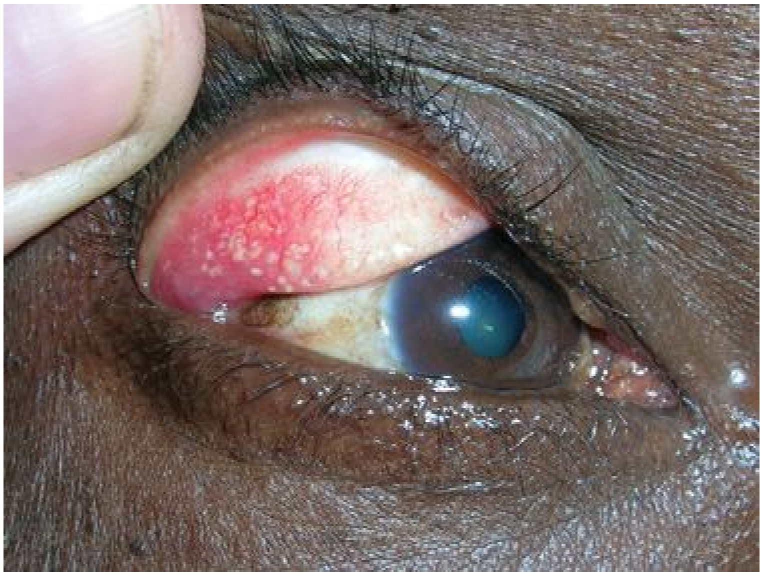

FIGURE 12-9 Trachoma showing many white follicles on the underside of the upper eyelid. (*Used with permission from Richard P. Usatine, MD*.)

- Vernal conjunctivitis is a severe recurrent form of allergic conjunctivitis that is more common in the summer (not the spring). The term *vernal* refers to the spring time, and therefore it is now referred to as “warm weather conjunctivitis” rather than “spring catarrh.” Giant papillae that look like a cobblestone pattern may be seen in this condition. It occurs primarily in young boys, and typically ceases to recur seasonally with age.

MANAGEMENT

- Hand hygiene can control the spread of infectious conjunctivitis.
- Children younger than age 6 years.[4]
    - Azithromycin 1.5 percent ophthalmic solution twice daily for 3 days resulted in a clinical and microbiologic cure in more than 80 percent of children.[7,8] SOR Ⓐ This dosing regimen provides equivalent efficacy to 4 times a day dosing of tobramycin.[7,8] SOR Ⓑ
    - A combination of polymixin B and trimethoprim (Polytrim) is effective and widely used for the treatment of bacterial conjunctivitis.
    - Erythromycin can also be used for bacterial conjunctivitis although its utility may be limited by resistance of *Haemophilus* and *Moraxella* species.
- Any patient with significant purulent ocular discharge should be treated for bacterial conjunctivitis.
- Many agents can be used to treat bacterial conjunctivitis. Studies show that more than 80 percent of patients show improvements with 0.3 percent ciprofloxacin, tobramycin, norfloxacin, or gentamicin, and 0.6 percent besifloxacin.[9–12]
- Moxifloxacin (Vigamox 0.5% solution) is a new generation fluoroquinolone that has been shown to be effective for the treatment of bacterial conjunctivitis.[13–15] It has a near neutral pH (6.8), so is well tolerated by children.[15] It is FDA approved for use in children over age 1 year. The dosing is 1 drop in the affected eye(s) three times daily for one week. SOR Ⓑ
- Aminoglycosides, such as tobramycin and gentamicin, are very effective against gram negative infections but not generally effective against streptococci.

- Allergic conjunctivitis can be treated with antihistamines, mast-cell stabilizers, nonsteroidal antiinflammatory agents, corticosteroids (only if under the care of an ophthalmologist), and immunomodulatory agents.[16]

REFERRAL

- Refer patients who have vision loss, copious purulent discharge (this could represent gonococcal disease, which must be cultured, and which can cause vision loss), severe pain, lack of response to therapy, or a history of herpes simplex or zoster eye disease to an ophthalmologist. In the case of any child who has copious purulent discharge, one should consider the possibility of sexual abuse. Obtain cultures immediately.
- Any patient who may need ocular steroid should be seen by an ophthalmologist. There is a severe risk for complications (elevated eye pressure, cataract, and corneal perforation) with the use of ocular steroids.

PREVENTION

Good hygiene practices with washing of the hands and face with soap and water.

FOLLOW-UP/RETURN TO SCHOOL

- Routine follow-up is generally not needed if symptoms resolve in 3 to 5 days.
- State health departments have no consensus on when children with conjunctivitis can return to school. A literature-based review suggests the best strategy is excluding children from school until they are asymptomatic.[17]

PATIENT EDUCATION

- Most children older than age 6 years have a nonbacterial cause of conjunctivitis, except those with a history of gluey eyes and a purulent discharge seen on physical examination.
- Remove contact lenses until conjunctivitis has resolved.
- Avoid touching the face or rubbing the eyes and wash hands immediately afterwards.
- Do not share face towels, eye makeup, or contact lens cases.
- Inform your physician immediately if your child experiences eye pain or vision loss.

13 UVEITIS AND IRITIS

Heidi Chumley, MD

PATIENT STORY

A 16-year-old boy presents with sudden onset of a red right eye, severe eye pain, tearing, photophobia, and decreased vision. He denies eye trauma. His review of systems is positive for knee and ankle pain over the previous 6 months. On examination, he has a ciliary flush (**Figure 13-1**) and decreased vision. He is referred to an ophthalmologist who confirms the diagnosis of acute anterior uveitis. He is also referred to a pediatric rheumatologist who makes the diagnosis of juvenile onset spondyloarthritis. His uveitis is treated with topical steroids.

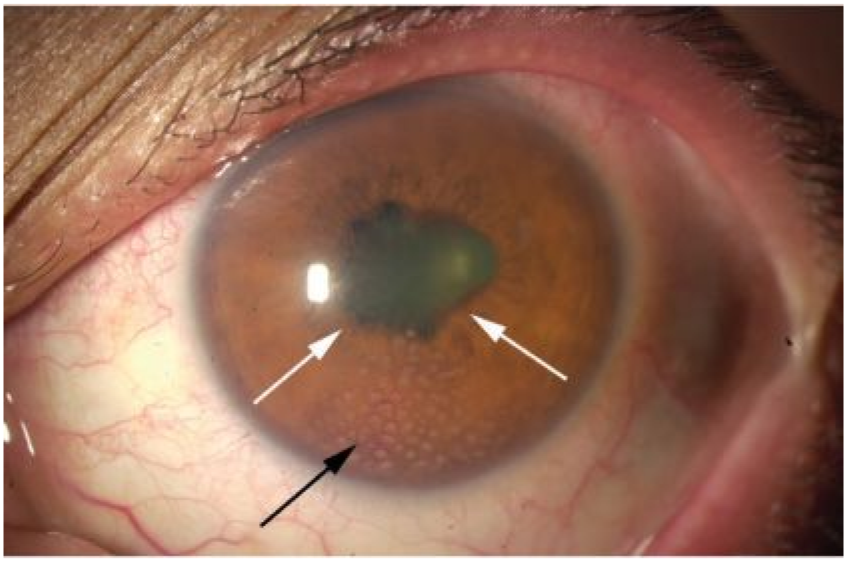

FIGURE 13-1 Acute anterior uveitis with corneal endothelial white cell aggregates (*black arrow*) and posterior synechiae formation (iris adhesions to the lens, *white arrows*). (*Used with permission from Paul D. Comeau*.)

INTRODUCTION

Uveitis is inflammation of any component of the uveal tract: iris (anterior), ciliary body (intermediate), or choroid (posterior). Most uveitis is anterior and is also called iritis. Uveitis is caused by trauma, inflammation, or infection and the most common etiologies vary by location in the uveal tract. Patients present with vision changes and, if uveitis is anterior, eye pain, redness, tearing, and photophobia. All patients with uveitis should be referred to an ophthalmologist.

SYNONYMS

Anterior uveitis includes iritis and iridocyclitis. *Iritis* is when the inflammation is limited to the iris. If the ciliary body is involved too, then it is called *iridocyclitis*. Posterior uveitis includes choroiditis and chorioretinitis.

EPIDEMIOLOGY

- Annual incidence of uveitis is 17 to 52 per 100,000 population and prevalence is 38 to 714 per 100,000 population.[1]
- Occurs at any age, but most commonly between 20 and 59 years.[1]
- Anterior uveitis (iritis) accounts for approximately 90 percent of uveitis as seen in primary care settings.[1]
- Eighty percent of uveitis cases seen in children are caused by juvenile idiopathic arthritis.[2]
- In the US, noninfectious uveitis accounts for 10 percent of legal blindness.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- Uveitis in children is predominantly associated with juvenile idiopathic arthritis, but can also be caused by trauma, infections, inflammation, or, rarely, neoplasms. Most likely causes differ by location.[4]
- Iritis—Autoimmune disorders, especially juvenile idiopathic arthritis, and trauma are more common (**Figure 13-2**). Infection, malignancy and idiopathic causes are less common. Infections include herpes, syphilis, and tuberculosis.[4]

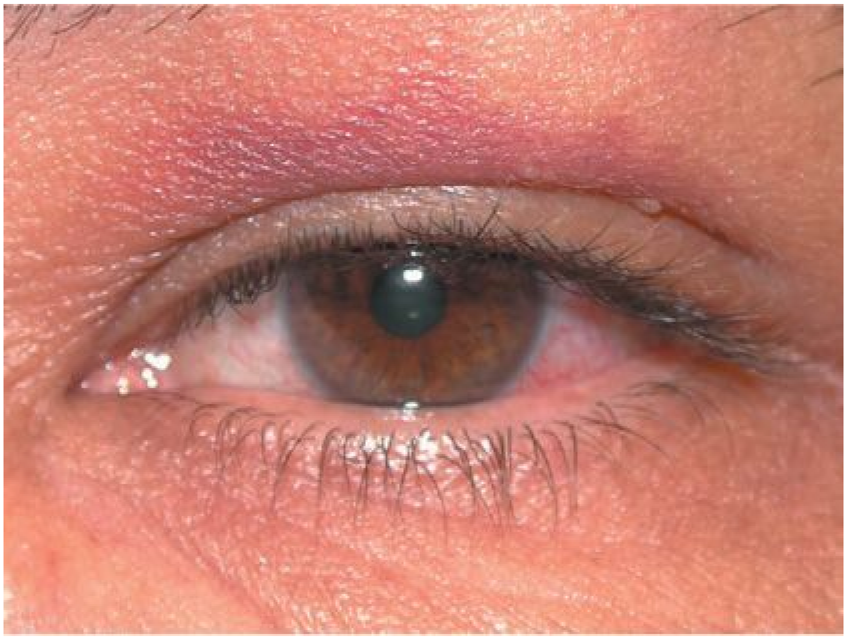

FIGURE 13-2 Traumatic iritis (anterior uveitis) after being hit in the eye with a baseball. He has photophobia and eye pain. (*Used with permission from Richard P. Usatine, MD*.)

- Intermediate—Most are idiopathic[4] (**Figure 13-3**).

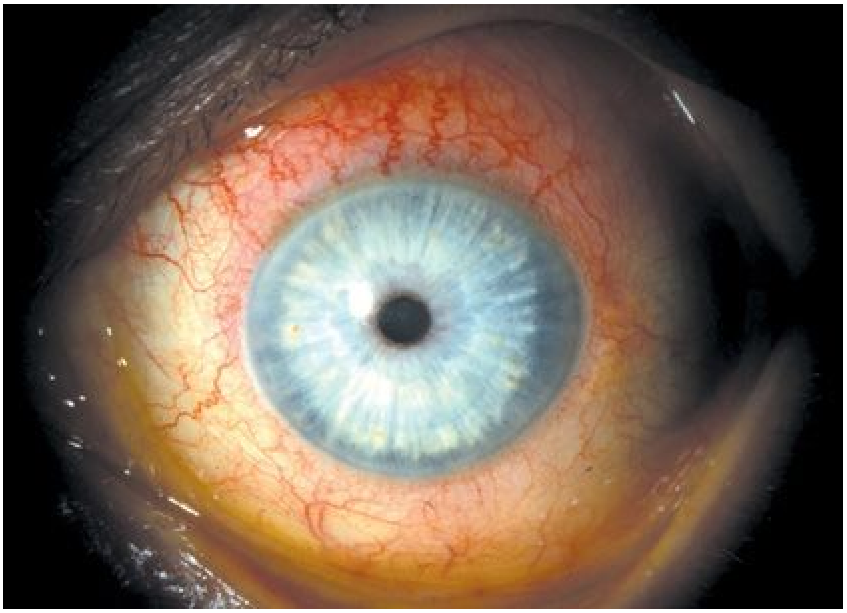

FIGURE 13-3 Idiopathic intermediate uveitis. The ciliary flush is perilimbal injection from dilation of blood vessels adjacent to the cornea, extending 3 mm into the sclera. Perilimbal injection may appear as a violet hue around the limbus with blurring of individual vessels. (*Used with permission from Paul D. Comeau*.)

- Posterior—In infants, congenital infections (toxoplasmosis, rubella, cytomegalovirus, herpes simplex virus, and syphilis) are common causes. In toddlers, Toxocara canis or Toxocara cati acquired from ingestion of contaminated soil can cause a unilateral posterior uveitis. Cytomegalovirus is the most common in immunocompromised children. It may also be autoimmune, trauma, malignancy or idiopathic.
- Panuveitis (affecting all layers)—Idiopathic (22% to 45%) and sarcoidosis (14% to 28%).[4] Unilateral panuveitis is often endophthalmitis (endogenous or related to trauma or surgery). Bilateral panuveitis can be caused by sarcoidosis or syphilis.

RISK FACTORS

Patients with Behçet disease and ankylosing spondylitis have uveitis more commonly than the general population (relative risk of 4 to 20) because of human leukocyte antigen (HLA) associations.[5] Congenital infections and immunodeficiency raise the risk of infectious uveitis.

DIAGNOSIS

CLINICAL FEATURES

Anterior acute uveitis presents with:

- Usually unilateral eye pain, redness, tearing, photophobia, and decreased vision.
- 360-Degree perilimbal injection, which is most intense at the limbus (**Figures 13-1**, **13-2**, and **13-4**).

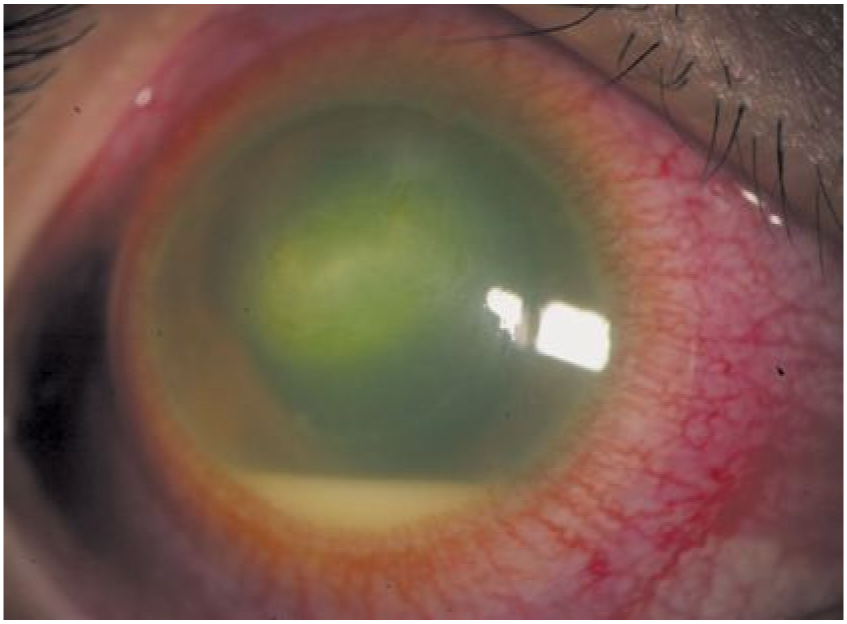

FIGURE 13-4 Hypopyon with severe anterior uveitis, showing layering of leukocytes and fibrinous debris in the anterior chamber. May be sterile or infectious. An intense ciliary flush is seen. Most commonly seen in HLA-B27-positive patients with uveitis. Hypopyon may also be a presenting sign

of malignancy (retinoblastoma and lymphoma). (*Used with permission from Paul D. Comeau.*)

- History of eye trauma, an associated systemic disease, or risk factors for infection.
- Severe anterior uveitis may cause a hypopyon from layering of leukocytes and fibrous debris in the anterior chamber (**Figure 13-4**). Behçet syndrome and HLA-B27 disease are the only two common noninfectious causes of hypopyon.

Intermediate and posterior uveitis:

- Presents with altered vision or floaters.
- Often, there is no pain, redness, tearing, or photophobia.

Sarcoid uveitis presents with:

- Panuveitis (anterior, intermediate, and posterior).
- Gradual and usually a bilateral onset.
- Few vision complaints unless cataracts or glaucoma develops.
- Characteristic findings on slit-lamp examination (i.e., mutton-fat keratic precipitates, posterior iris synechiae).[6]

Typical distribution

- Anterior uveitis is typically unilateral and sarcoid uveitis is typically bilateral.

DIFFERENTIAL DIAGNOSIS

Causes of red eye, other than uveitis:

- Scleritis—Segmental or diffuse inflammation of sclera (dark red, purple, or blue color); severe, boring eye pain often radiating to head and neck;

and photophobia and vision loss.

- Episcleritis—Segmental or diffuse inflammation of episclera (pink color), mild or no discomfort but can be tender to palpation, and no vision disturbance.
- Keratitis or corneal ulcerations—Diffuse erythema with ciliary injection often with constricted pupil; eye discharge; and pain, photophobia, and vision loss depending on the location of ulceration. Frequently associated with trauma, a history of herpes simplex virus (HSV) infection, or contact lens wear. Needs urgent evaluation by an ophthalmologist. There will be staining of the cornea with fluorescein.
- Conjunctivitis—Conjunctival injection, eye discharge, gritty or uncomfortable feeling, and no vision loss (see Chapter 12, Conjunctivitis). Recent history of red eye contacts or URI symptoms.

MANAGEMENT

Refer patients for any red eye along with loss of vision to an ophthalmologist. Patients with uveitis warrant additional examinations by the ophthalmologist.

- Traumatic uveitis—Dilated funduscopy for other ocular trauma, measurement of intraocular pressure, gonioscopy to evaluate for angle recession and risk for future glaucoma, and treatment may include steroid and/or cycloplegics for comfort.
- Nontraumatic uveitis—Slit-lamp examination and laboratory tests to assist with diagnosis of underlying cause; treatment is based on underlying cause but is usually topical steroid drops with or without cycloplegia.
- Therapeutic dilation is used to break the posterior synechiae that can occur (**Figure 13-5**).

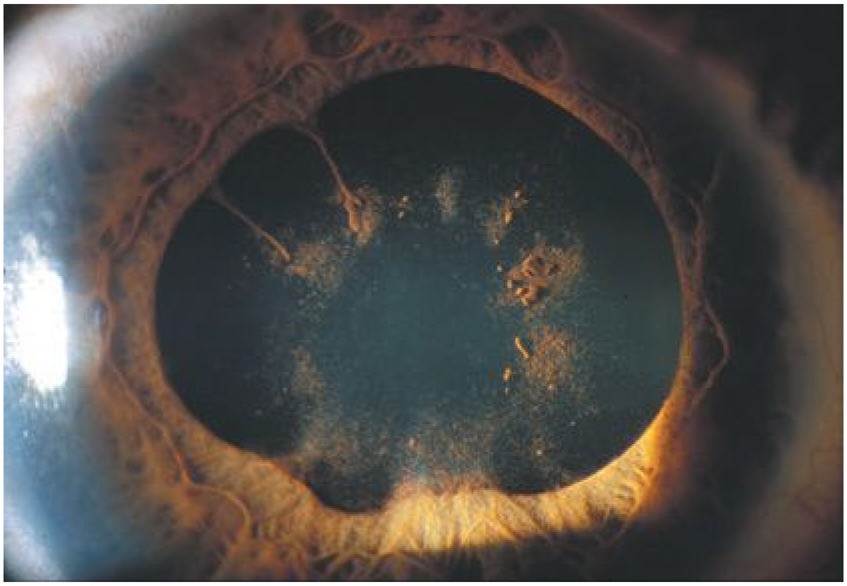

FIGURE 13-5 This patient with uveitis had posterior synechiae that are attachments of the iris to the anterior capsule of the lens. Therapeutic dilation broke the synechiae, but left residual pigment on the anterior capsule. (*Used with permission from Paul D. Comeau*.)

PROGNOSIS

Uveitis causes vision loss, cataract, and often glaucoma if treatment is delayed or not provided. HLA-B27 disease is the most common etiology for anterior uveitis, and is associated with recurrent, bilateral anterior uveitis.

FOLLOW-UP

Appropriate follow-up is based on the underlying cause.

PATIENT EDUCATION

- See a physician immediately for a red eye with loss of vision.
- A series of tests may be performed to determine the cause of the uveitis; however, the underlying cause is often elusive.

14 NEONATAL NASOLACRIMAL DUCT OBSTRUCTION

Andreas Marcotty, MD

PATIENT STORY

A 6-month-old child is brought to the pediatrician with a history of tearing, drainage, crusting of the eyelashes and lids, perhaps of both eyes and most notably upon awakening. The tearing occurs without distress and is worse with outside air exposure, especially if it is cold and windy. There is no associated fever or discomfort. Despite the increase in tearing, there is no light sensitivity.[1] Most notable is the chronically increased tear film meniscus (**Figure 14-1**). The baby has a chronic problem since shortly after birth with constant tearing, mucoid debris and a couple of episodes of increased debris, suggestive of conjunctivitis.

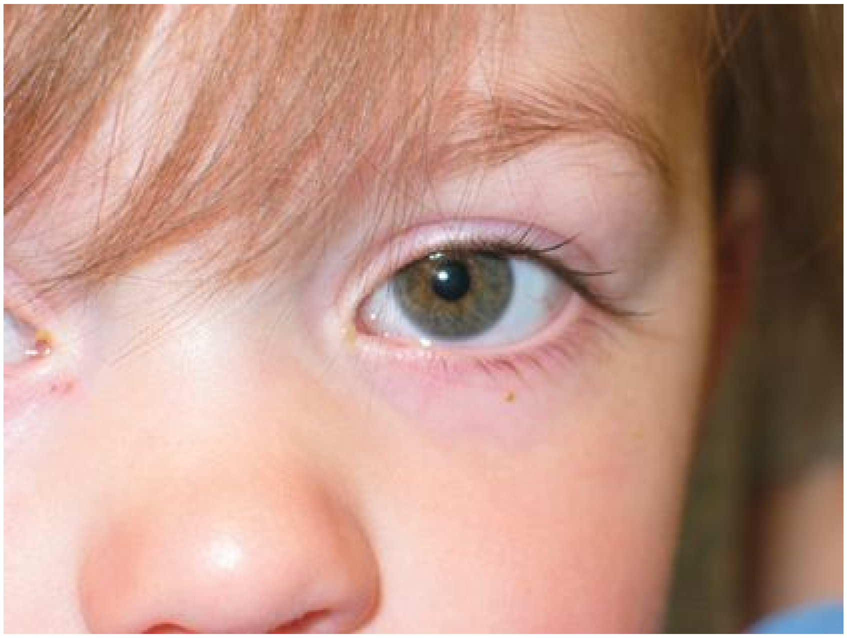

FIGURE 14-1 Nasolacrimal Duct Obstruction with an increased tear film and no evidence of infection (conjunctival injection, purulent debris). (*Used with permission from Andreas Marcotty, MD.*)

Examination demonstrates no photophobia by penlight or indication of pain. There is mild erythema to the lower lids. Notable is the increased tear lake bilaterally, dried mucous on the skin and mucoid debris in the tear film. The eyes show no conjunctival injection or inflammation. There is a normal and symmetrical red reflex by ophthalmoscopy. Fluorescein dye disappearance test demonstrates prolonged retention of the dye in the tear film of each eye longer than 5 minutes.[2,3] Massage of the tear sac can result in expression of copious amount of mucopurulent material but did not in this case. The child was diagnosed with neonatal nasolacrimal duct obstruction (NLDO).

INTRODUCTION

Neonatal nasolacrimal duct obstruction (NLDO) presents with the parents stating that the eye is always crying. The eye remains wet leading to debris and crusting. NLDO may look like infectious conjunctivitis and occasionally leads to the development of true conjunctivitis.

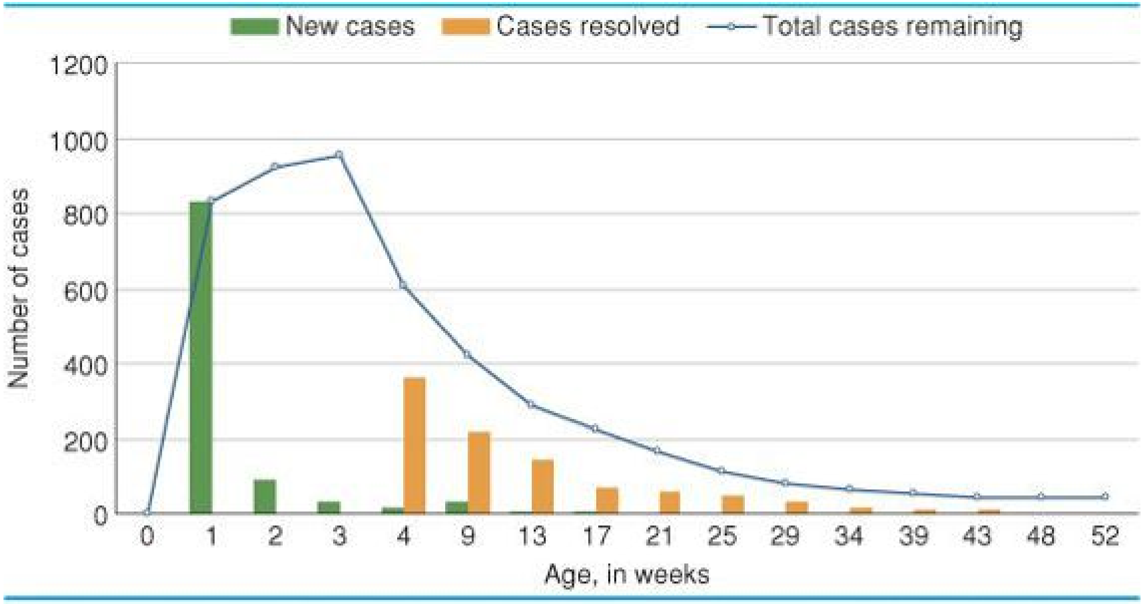
SYNONYMS

Dacrocystitis is when the NLDO is infected. Epiphora is the overflow of tears.

EPIDEMIOLOGY

- In a large cohort by Peterson and Robb published in 1978, 50 percent had resolution by the age of 4 months and 89 percent resolved without surgical therapy.[4]
- There is no sex predilection and no genetic predisposition. The blockage can be unilateral or bilateral.
- Range of spontaneous resolution (including the use of massage) is from 65 percent to 95 percent by the age of 10 months.[5–7]
- The natural history of resolution helps to determine the optimal age of surgical intervention (**Table 14-1**).

TABLE 14-1 Natural Progression of Nasolacrimal Duct Obstruction.



Data adapted from: MacEwen CJ and Young DH: Epiphora During the First Year of Life. *Eye*. 1991;5:596-600.

ETIOLOGY

- NLDO can result from Congenital Impatency of Nasolacrimal System. Canalization of the nasolacrimal duct (NLD) is usually complete by 8 months of gestation.[8]

- Most frequent location for impatency is the distal end of NLD at the valve of Hasner beneath the inferior turbinate of the nose.
- Both upper and lower system obstructions can occur.
- May present as an amniocele or dacryocystocele and be associated with the infection Dacryocystitis (**Figure 14-2**).

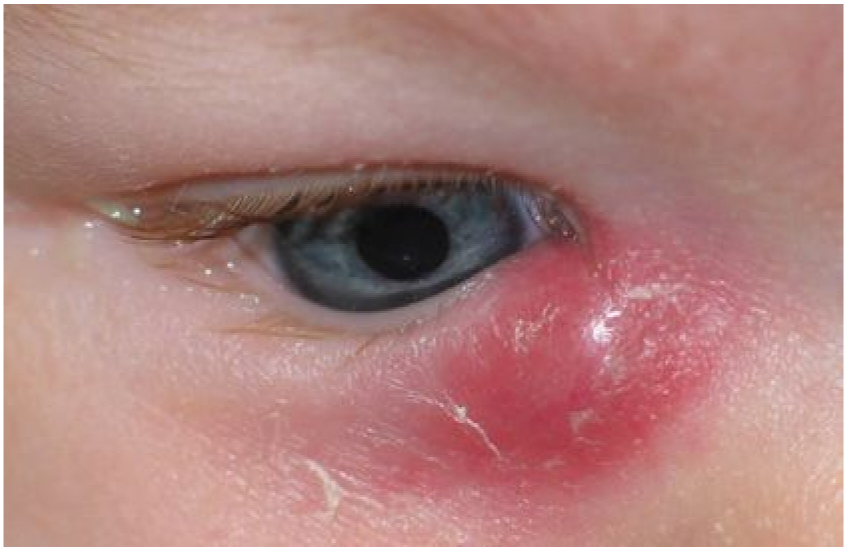


FIGURE 14-2 Dacryocystitis with probable dacryocystocele. There is erythema of skin, fullness to lower lid and an increased tear film. (*Used with permission from Andreas Marcotty, MD.*)

- May have fluid filled cyst within the nasal cavity.
- NLDO can be acquired as a consequence of conjunctivitis.
- Less common presentations include:
  - Generalized ductal stenosis.
  - Imperforate nasolacrimal puncta.
  - Canalicular abnormalities.

RISK FACTORS

NLDO is associated with craniofacial abnormalities and syndromes such as:

- Trisomy 21, Crouzon, Treacher-Collins, ectodermal dysplasia, Hay-Wells syndrome, Saethre-Chotzen syndrome, Kallmann syndrome, Nager syndrome, frontonasal dysplasia, branchio-oculofacial syndrome, CHARGE syndrome, and velocardiofacial syndrome (**Figure 14-3**).[9–11]

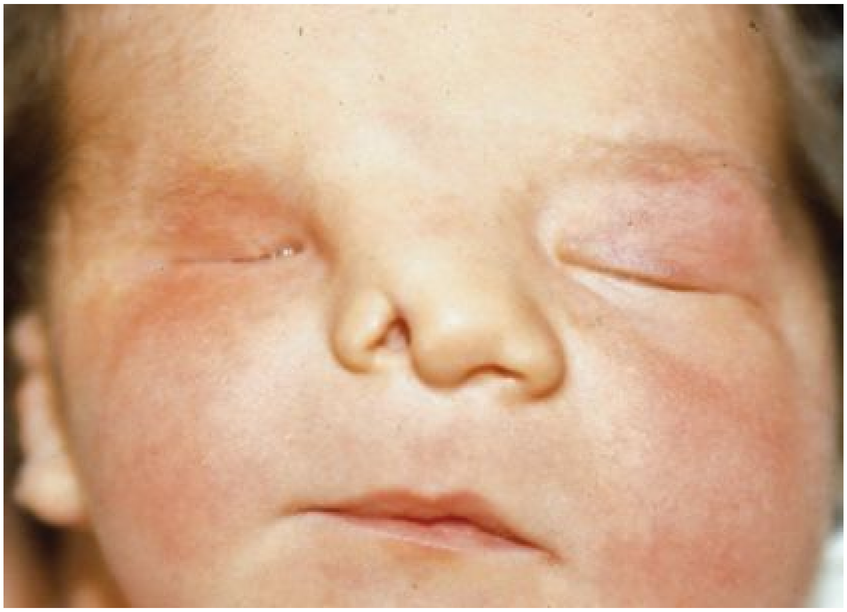

FIGURE 14-3 Midline craniofacial abnormality with secondary tear duct abnormalities. There is an abnormal medial canthus of the right eye and a cleft involving the nasal bone to the right nares. (*Used with permission from Andreas Marcotty, MD.*)

DIAGNOSIS

HISTORY

- Parents state that the eye is “always crying.”
- The eye remains wet leading to debris and crusting.

PHYSICAL EXAMINATION

Presentation can range from simple tearing to an acute dacryocystitis. Key findings include:

- Erythema of surrounding skin with the primary location of inflammation at the nasal and inferior lid.
- An increased tear film meniscus with tears frequently resting on the skin temporally (**Figure 14-4**).

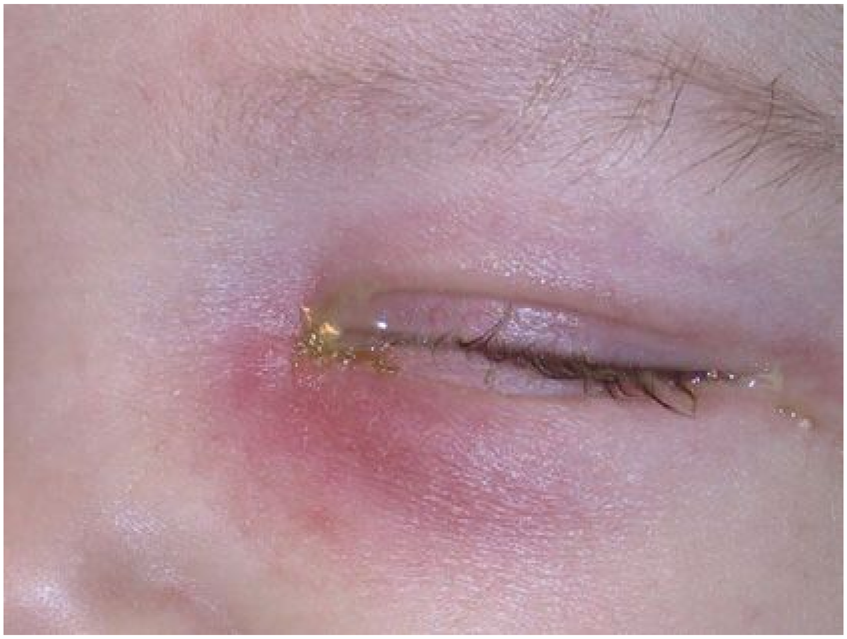

FIGURE 14-4 Acute dacryocystitis. Note the erythema of the skin that is not localized, tearing and mucopurulent debris. (*Used with permission from Andreas Marcotty, MD*.)

- Occasionally a fluctuant or a cystic mass at the inner lower lid (**Figure 14-5**).

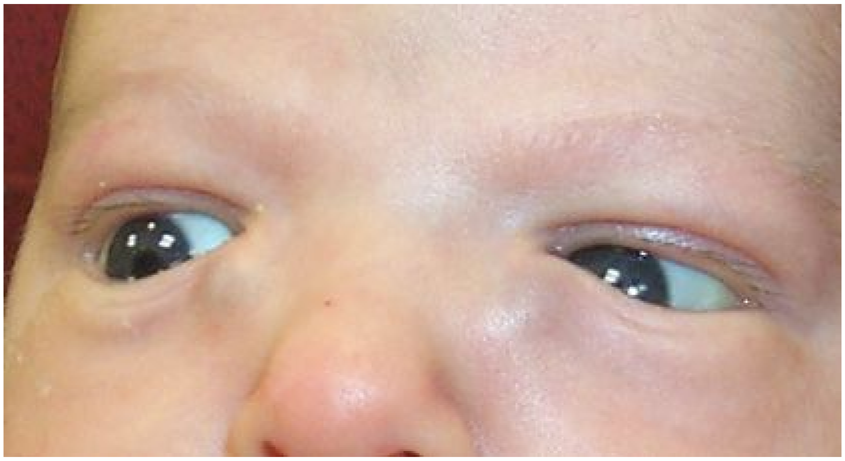

FIGURE 14-5 Bilateral dacryocystoceles demonstrating blueish discoloration of the skin at the medial canthus, as well as cystic swelling of the nasal aspect to both lower lids. (*Used with permission from Elias Traboulsi, MD.*)

  - May also have a cystic lesion present upon nasal endoscopy (**Figure 14-6**).

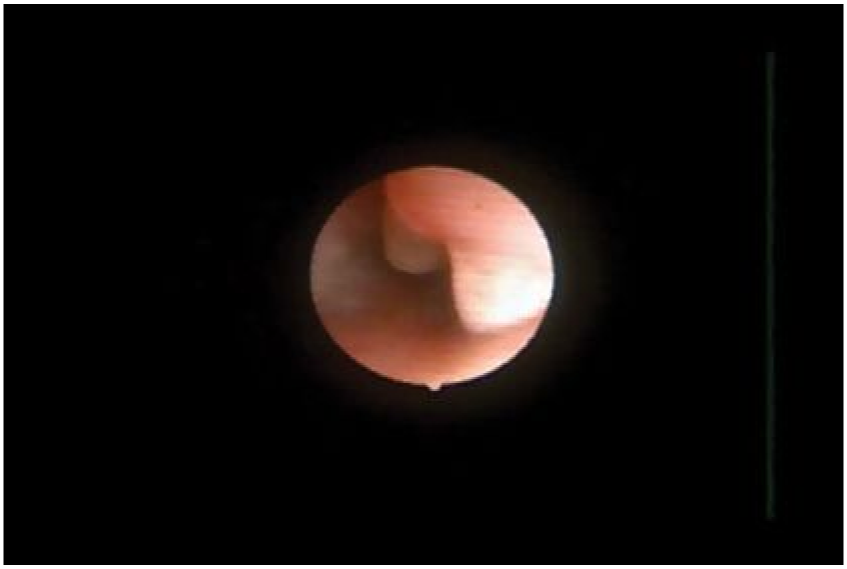

FIGURE 14-6 Intranasal cyst found with a dacryocystocele using endoscopy. (*Used with permission from Paul Krakovitz, MD.*)

- Tenderness of the localized mass.
- Expression of mucopurulent debris with compression of the sac.

TESTING

- Compression of the sac with regurgitation of tears and debris.
- Fluorescein dye retention test.[3,4] Using a fluorescein strip, stain the tears (in the cul-de-sac of the eyelid) with a small amount of fluorescein, dab the excess, and wait 5 minutes. Using a Woods lamp or ultraviolet light, illuminate the eyes and lids, looking for the green fluorescence.
    - A negative test will reveal little to no residual dye fluorescence.
    - A positive test will show an increased tear lake with green fluorescence.

IMAGING

- While imaging is usually not needed, a CT or MRI scan could show an enlarged tear sac/duct on the orbital views and additional structural changes involving the nasal bone.

DIFFERENTIAL DIAGNOSIS

- Epiblepharon is a developmental anomaly caused by an abnormal insertion of muscle fibers of the lower or upper lid resulting in a fold of skin which presses against the lashes, rolling them inward, causing them to rub on the cornea and conjunctiva. This creates a foreign body sensation and secondary tearing (**Figure 14-7**).

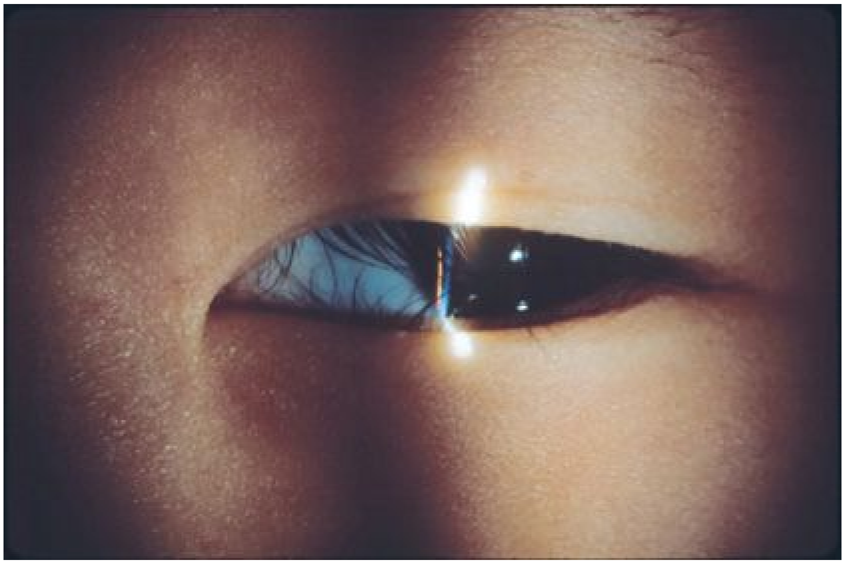

FIGURE 14-7 Congenital epiblepharon typified by in-turned upper and lower lid lashes, with corneal and conjunctival touch. Photograph taken during slit-lamp exam. (*Used with permission from Andreas Marcotty, MD*.)

- Congenital Glaucoma is a structural abnormality involving Schlemm's canal and the trabecular meshwork resulting in decreased outflow from the anterior chamber and the secondary increase of the intraocular pressure. It occurs in approximately 1/10000 births (**Figure 14-8**). The presentation of congenital glaucoma includes: epiphora, photophobia (**Figure 14-9**), corneal opacification/haze, and buphthalmos also known as enlarged eye.

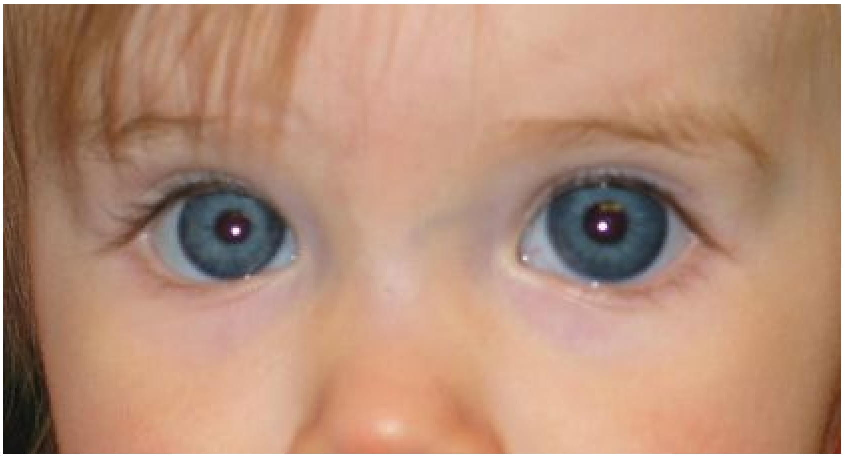

FIGURE 14-8 Congenital glaucoma with epiphora. Note the asymmetrically enlarged corneas, epiphora, and absence of corneal edema.

(*Used with permission from Andreas Marcotty, MD*.)

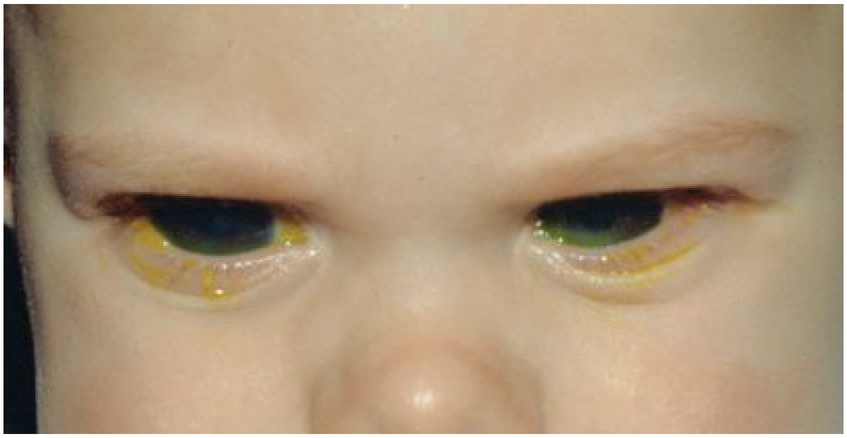

FIGURE 14-9 Congenital Glaucoma with epiphora and photophobia. Note the head down posture, epiphora and enlarged corneas with fluorescein staining of tears. (*Used with permission from Andreas Marcotty, MD*.)

  - Primary occurs when there are no other abnormalities causing the outflow to be obstructed. Associated with autosomal recessive genetic abnormalities, approximately 10 percent are inherited.
  - Secondary is when there are other anterior segment abnormalities such as aniridia (absence of the iris) or systemic disorders leading to the congenital glaucoma.

- One anterior segment dysgenesis syndrome is Axenfeld-Rieger Syndrome/Peter’s anomaly (**Figure 14-10**).

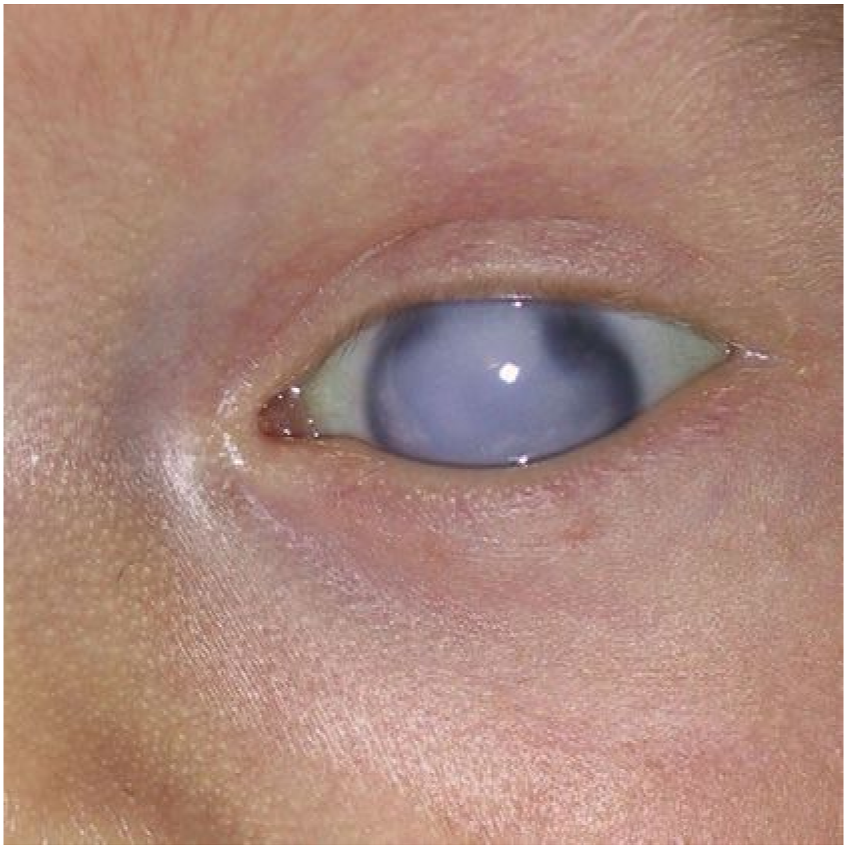

FIGURE 14-10 Peter’s Anomaly showing opacification of the cornea. This may be associated with glaucoma. (*Used with permission from Andreas Marcotty, MD*.)

- Congenital infections (TORCH) and neurocutaneous disorders can cause congenital glaucoma. One neurocutaneous disorder is known as Sturge-Weber disease (**Figure 14-11**).

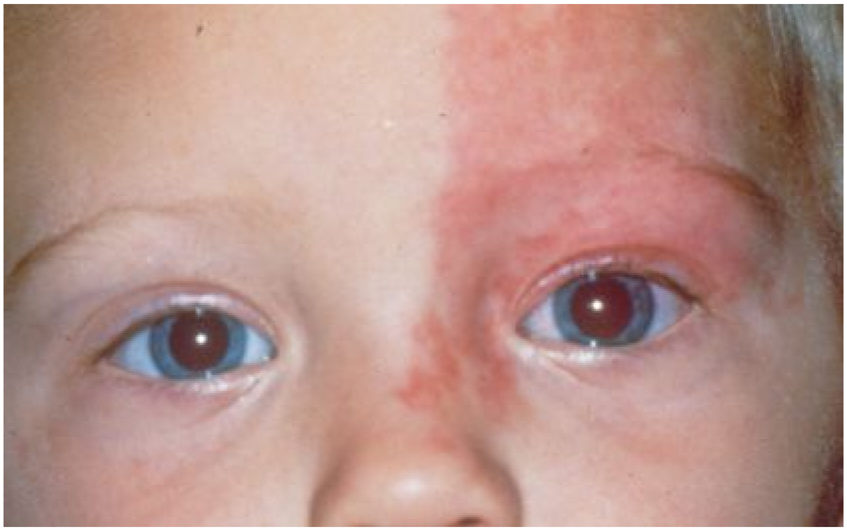

FIGURE 14-11 Encephalotrigeminal hemangiomatosis is also called Sturge-Weber disease when there are neurological abnormalities accompanying the vascular malformation. Note the “Port Wine stain” on the face with lid involvement and scleral injection, but no glaucomatous changes. Glaucoma can occur at birth with this disease. (*Used with permission from Andreas Marcotty, MD.*)

- External infections include: Conjunctivitis (viral or bacterial; see Chapter 12, Conjunctivitis).
- Internal infections include: Congenital Viral Infection, Toxocara, Congenital Syphilis, or TORCH infections.
- Corneal ulcer, which could be secondary to an infection or trauma (**Figure 14-12**).

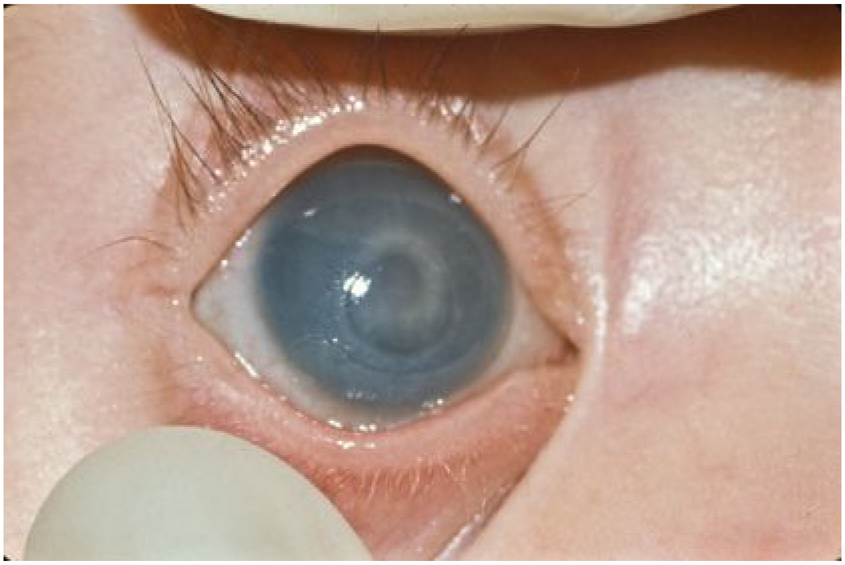

FIGURE 14-12 Sterile corneal ulcer in Familial Dysautonomia with a central epithelial defect and raised edges. (*Used with permission from Andreas Marcotty, MD*.)

- Corneal abrasion (**Figure 14-13**; see Chapter 11, Corneal Foreign Body and Corneal Abrasion).

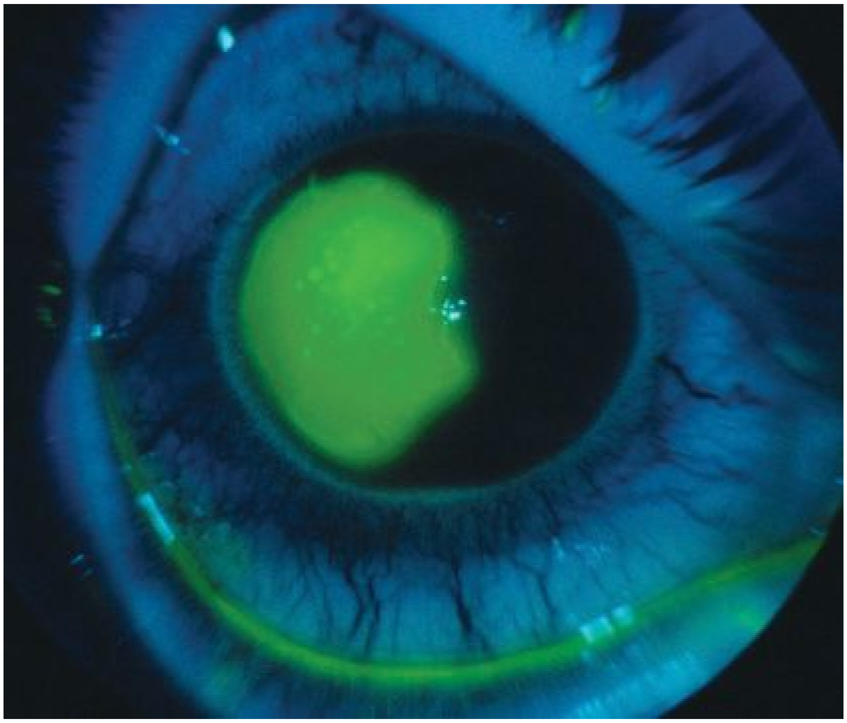

FIGURE 14-13 Corneal abrasion stained with fluorescein and illuminated with a Wood’s lamp (ultraviolet light). (*Used with permission from Andreas Marcotty, MD*.)

MANAGEMENT

ANTIBIOTICS ONLY WHEN NEEDED

- Initially, the distinction between tearing as a consequence of an obstruction of the outflow system versus an insult to the eye with secondary tearing must be made. This differentiation is critical in the successful management of tearing and to the health of the visual system and child. Occasionally, there may an infectious component in NLDO.
- If cultures are taken when there is a NLDO, there was a 25 percent chance of infection with *Haemophilus influenzae*, *Staphylococcus aureus*, or *Moraxella catarrhalis*. If there is an associated dacryocystitis, the organisms isolated have been reported to be coagulase-negative Staphylococcus and non-pneumococcal a-Streptococcus.[12]
- Conjunctival culture is not indicated unless there are signs of significant infection.
- If there is an infection, an antibiotic ophthalmic preparation should be prescribed. Antibiotics that have the appropriate therapeutic antibacterial spectrum include: Erythromycin, Polymyxin-trimethoprim sulfate, Azithromycin, Quinolones (Gatifloxacin, Ciprofloxacin, Ofloxacin, Levofloxacin), and Gentamicin.

MASSAGE

- Traditionally, the management of tear duct obstruction without complication is primarily one of observation, with massage.
- The massage technique is described in an article by Crigler[13] and restated by Kushner.[14]

- Anatomically, the nasolacrimal sac and duct sit very nasal and begin in the superior nasal corner of the orbit. The lacrimal sac and duct then travel straight downward alongside the posterior and nasal edge of the caruncle of the medial canthus and into the lacrimal bone, where it can no longer be massaged.

MASSAGE TECHNIQUE

Compression begins at the superior, nasal site with a steady pressure, squeezing the lacrimal sac between the fingertip and the nasal bone. The finger is then rolled downward and posteriorly against the frontal and lacrimal bones, finishing the massage, when the lower edge of the orbit is felt.

SURGERY

- In infants without spontaneous resolution, surgical treatment with Probe and Irrigation (P&I) can result in a cure rate of 78 percent to 96 percent with the variability reflecting the age of probing and the selection bias of the surgeon or the complexity of the case.[7,14–16] SOR A
- The younger the age of the infant in the series, the more successful the procedure. Some studies show a dramatic decrease in surgical success after 13 months of age and others only after 36 months of age.[15,16] SOR B
- Given the success that early treatment can achieve, some advocate in-office P&I under local anesthesia, with general anesthesia necessary for older children (older than 6 months).
- If primary treatment with P&I fails, the secondary procedure may be repeat probing, placing a stent, or performing a balloon catheter dilation. Early stenting was performed using a silicone tube looped through both the upper and lower canalicular systems with the ends knotted and secured in the nasal cavity.

- Stenting is currently done through one canaliculus using a Monoka™ stent, decreasing the risk of trauma to both punta and canaliculi if the tube becomes dislodged.
- Balloon catheter dilation is another procedure, which combines dilation and a stent. An inflatable stent is passed into the nasolacrimal duct and filled with a saline solution, enlarging the canal with rupture of the obstruction as well as dilation of the canal. Balloon catheter dilation has also been performed as a primary treatment with an 82 percent success rate in children under four years age.[18] SOR B Notably, it has a higher cost due to the material and equipment as well as a requirement of general anesthesia. As a secondary procedure, following a primary treatment of P&I, balloon catheter dilation is as successful as the placement of any type of temporary indwelling tube, into the lacrimal system to create permanent patency.[19]
- Finally, the last procedure to consider would be lacrimal duct bypass surgery, also called a dacryocystorhinostomy (DCR), which is destructive to the natural anatomy of the system and therefore the final option.

PROGNOSIS

The natural history of resolution and the success of surgery by age vary according to the series. Spontaneous resolution with massage occurs in 54 percent to 89 percent of infants.[5,7,15,17] SOR A

FOLLOW-UP

Simple NLDO without a dacrycystitis or dacryocystocele can be followed less closely as it is common and has a minor risk of complication. Dacryocystitis is a more serious problem and close management with appropriate antibiotics oral or intravenous therapy is needed. Dacryocystocele is important to recognize early, as it may require very early surgery with P&I and possible ENT endoscopic assistance to look for and manage an intranasal cyst.

PATIENT EDUCATION

The most important educational information to provide to parents is that of appropriate massage technique and the need to persist in this treatment, as time generally will allow for resolution. If the family is concerned, early therapy with in-office surgery can be undertaken, although not to the exclusion of tear duct massage.

15 STRABISMUS AND PSEUDOSTRABISMUS

Paul J. Rychwalski, MD

PATIENT STORY

A 5-month-old infant is brought to your office by her mother. The mother reports that the child has a “lazy eye.” On further inquiry, the mother describes a 1-month history of the child’s eyes turning inward toward the nose. This occurs intermittently and is not noticed by the child’s father. The mother shows several photographs that are inconclusive. The infant’s maternal uncle had strabismus surgery as a child. On examination, the infant protests when either eye is covered, and seems to have an inward deviation of the right eye, more pronounced when looking to the left (**Figures 15-1A,B,C**). The patient is able to move the eyes easily in all directions.

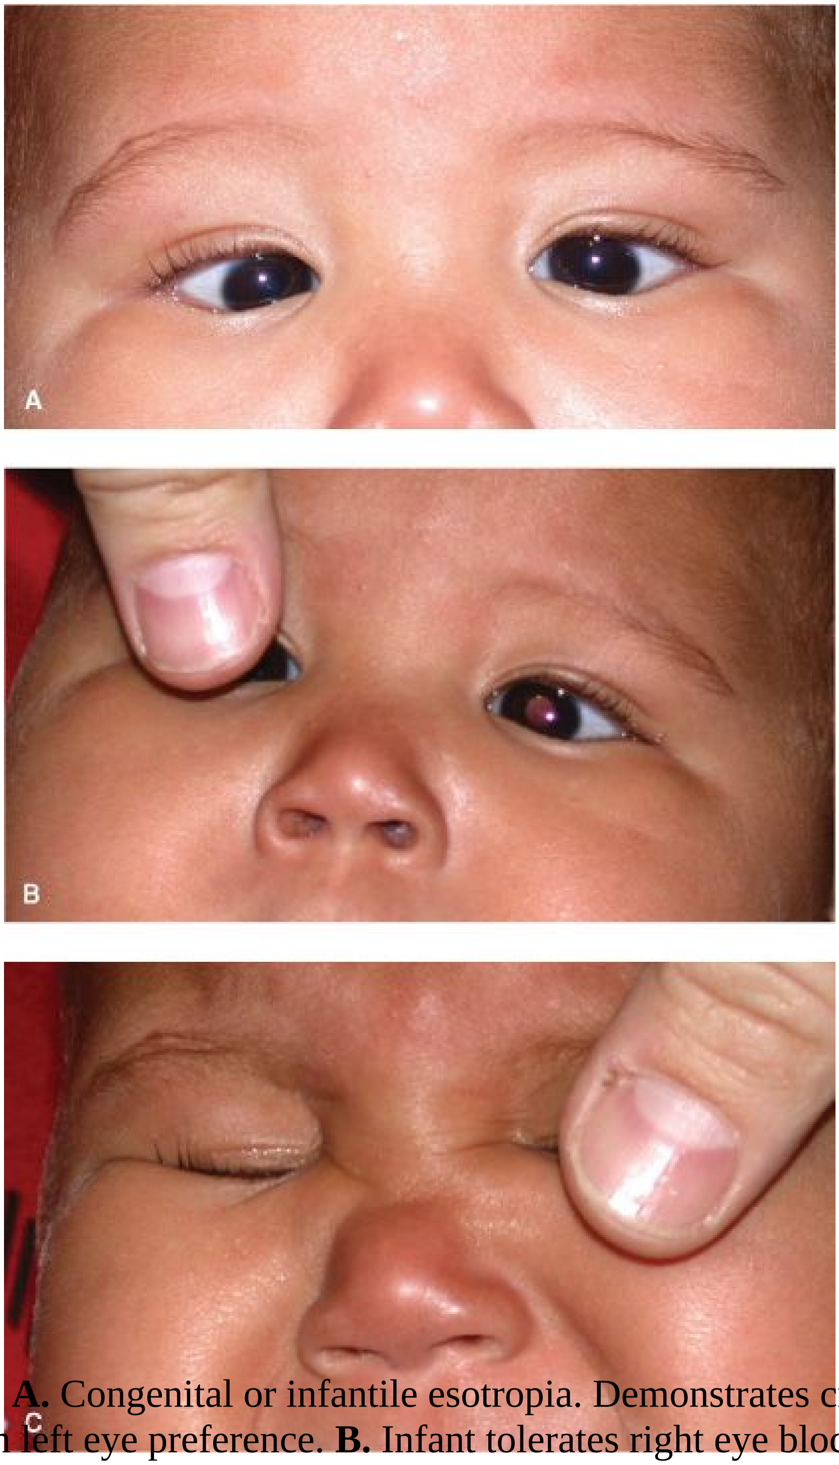

Figure 15-1 **A.** Congenital or infantile esotropia. Demonstrates cross-fixation with left eye preference. **B.** Infant tolerates right eye blockage. **C.** Infant upset to have left eye covered. (*Used with permission from Paul J. Rychwalski, MD*.)

INTRODUCTION

Strabismus refers to any misalignment of the eyes. It can be further categorized based on the direction of the deviating eye(s): 1) esotropia—the eye turns inward; 2) exotropia—the eye turns outward; 3) hyper- and hypotropia—the eye turns upward or downward respectively; and 4) cyclotropia or torsional—the eye is rotated clockwise or counterclockwise. Further, the terms used to describe strabismus also depend upon the conditions under which it is present (constant or intermittent) and whether it changes with the position of gaze (comitant or incomitant).

SYNONYMS

Squint, lazy-eye, cross-eye, walleye, or crooked eye.

EPIDEMIOLOGY

- There is geographical variation in the prevalence of strabismus.
- Esotropia is more common in Western populations whereas exotropia is more common in Eastern populations.
- US population-based studies have found an annual incidence per 100,000 population of 64 in exotropia (corresponding to a prevalence of 1 percent of children aged <11 years), 111 in esotropia (corresponding to a prevalence of 2 percent of children aged <6 years), and 12.9 in hypertropia (corresponding to a prevalence of 0.26 percent of children aged <19 years).
- In the US, the incidence of esotropia is highest in children younger than 7 years, whereas the incidence of exotropia is highest in children aged 6 to 9 years, and is also high in adolescents and adults with sensory strabismus.
- The prevalence of strabismus is higher in those with intellectual disabilities (44.1%) compared with the general population. The prevalence

in white people is 2 percent to 4 percent, but may be lower in Asian populations.[1–3] Among Hispanic and Latino children, prevalence is:
  - 2 percent at ages six to 11 months.
  - 2.6 percent at ages 36 to 47 months.
  - 2.8 percent at ages 60 to 72 months.

- Among African-American children, prevalence:
  - 1.1 percent at ages six to 11 months.
  - 1.9 percent at ages 36 to 47 months.
  - 3.9 percent at ages 60 to 72 months.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

Proper alignment of the eyes is guaranteed by a normally functioning sensory and motor fusion mechanism. If either of these two systems is perturbed, strabismus may result.

- Sensory:
  - All the nervous impulses that reach the eyes. These factors include the movements of extraocular muscles, psycho-optical reflexes (poorly understood fusional impulses), external influences on muscle tone (endolymph, vestibular system, possible reflexes from neck muscles), and influences of the several nuclear and supranuclear areas that govern ocular motility.

- Motor:
  - Second, there are *anatomical factors*, which consist of orientation and shape of the orbits; size and shape of the globes; volume of the retrobulbar tissue; functioning of the eye muscles as determined by their insertion, length, elasticity, and structure; and anatomical arrangement of connective tissue, ligaments, and pulleys of the orbit.[5]

RISK FACTORS

- Positive family history.
- Prematurity.
- Developmental delay.
- Neurologic disease.
- Genetic abnormalities.
- Vision loss.

DIAGNOSIS

The diagnosis is made with a careful history and physical examination as outlined in the following sections.

- History
  - Age of onset, especially during perinatal period.
  - Birth history.
  - Family history.
  - Associated illness or trauma, especially neurologic.
  - Associated signs including nystagmus, headache, ptosis, anisocoria.
  - Constant vs. intermittent.
  - Change of deviation based on direction or distance of fixation.
- Physical examination.
  - General health and neurologic status.
  - Head position—ocular torticollis may be induced by ocular misalignment.
  - Vision, eyelid position, or pupils.
  - Corneal light reflex or Hirschburg test.
    - The projected light reflex will be centered on each eye if they are aligned. In esotropia, the light on the inwardly deviated eye will be displaced temporally and in exotropia it will be displaced nasally.
  - Cover and cover/uncover test.

        - Cover the apparently straight/fixating eye and observe the fellow eye for a refixation movement.
        - An esotropic eye will have a refixation movement from nasal to temporal in order to pick up fixation and vice versa.
    - Ductions and versions.
        - Check eyes separately and together for ability to move completely.
    - Penlight exam.
        - Look for ocular abnormalities of the cornea, iris or lens.
    - Red reflex test.
    - Complete ophthalmologic examination including cycloplegic refraction and dilated fundus examination.

CLINICAL FEATURES

It is important to distinguish between congenital or infantile and acquired strabismus, as some forms of acquired strabismus can be caused by a life-threatening or vision-threatening condition.

- Causes of primary strabismus include idiopathic infantile or congenital esotropia (**Figure 15-1**) and intermittent exotropia (**Figure 15-2**). These are usually comitant.

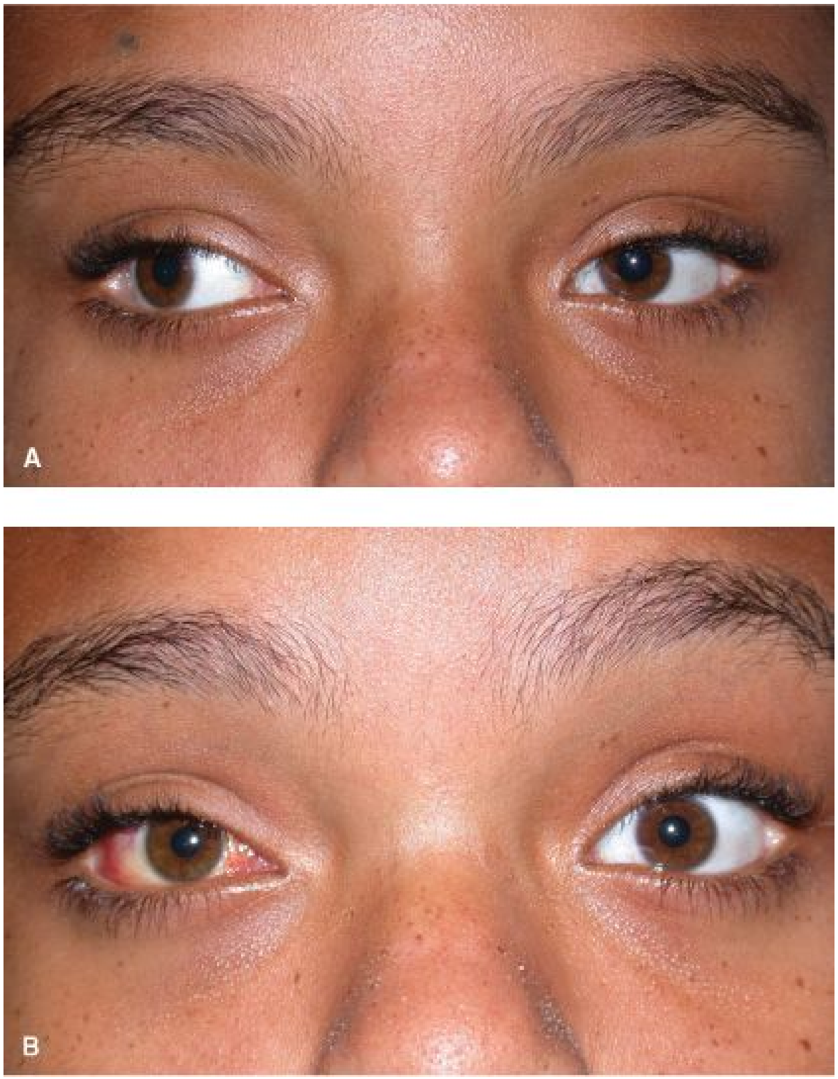

Figure 15-2 A. Constant exotropia of right eye. B. Exotropia surgically corrected with bilateral lateral rectus recession. (*Used with permission from Paul J. Rychwalski, MD*.)

- Secondary strabismus can be caused by retinoblastoma (sensory strabismus), head trauma with cranial nerve palsies or orbital fracture, myasthenia gravis, and Graves’ disease.
- Acute onset of acquired strabismus may occur with increased intracranial pressure due to intracranial hemorrhage, abscess, encephalitis, shunt failure, and tumors (intracranial, intraocular, or intraorbital).
- Forms of esodeviations include accommodative and refractive esotropia (**Figure 15-3**) due to high hyperopia or a high accommodative

convergence to accommodation (AC/A) ratio, idiopathic infantile esotropia, esotropic Duane (**Figure 15-4**), or dysinnervation syndrome Moebius syndrome, sensory esotropia, and abducens nerve palsy.

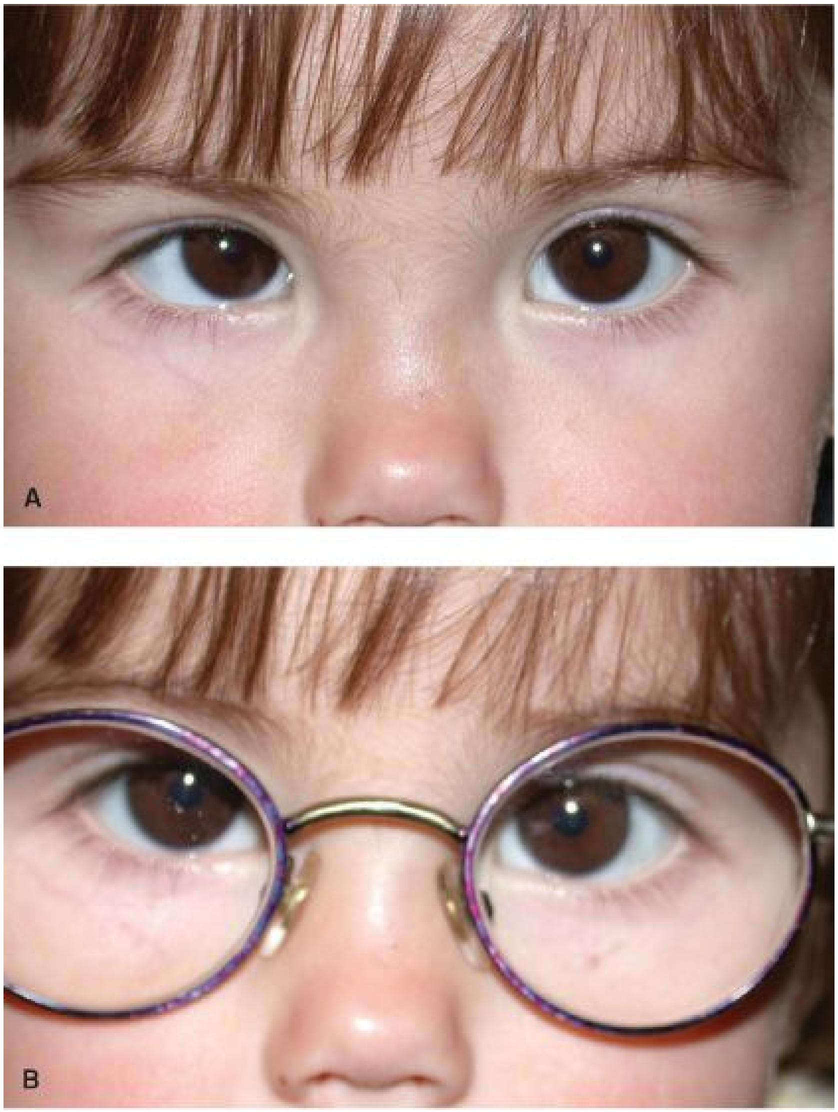

Figure 15-3 A. Accommodative esotropia. B. Corrected with glasses. (*Used with permission from Paul J. Rychwalski, MD*.)

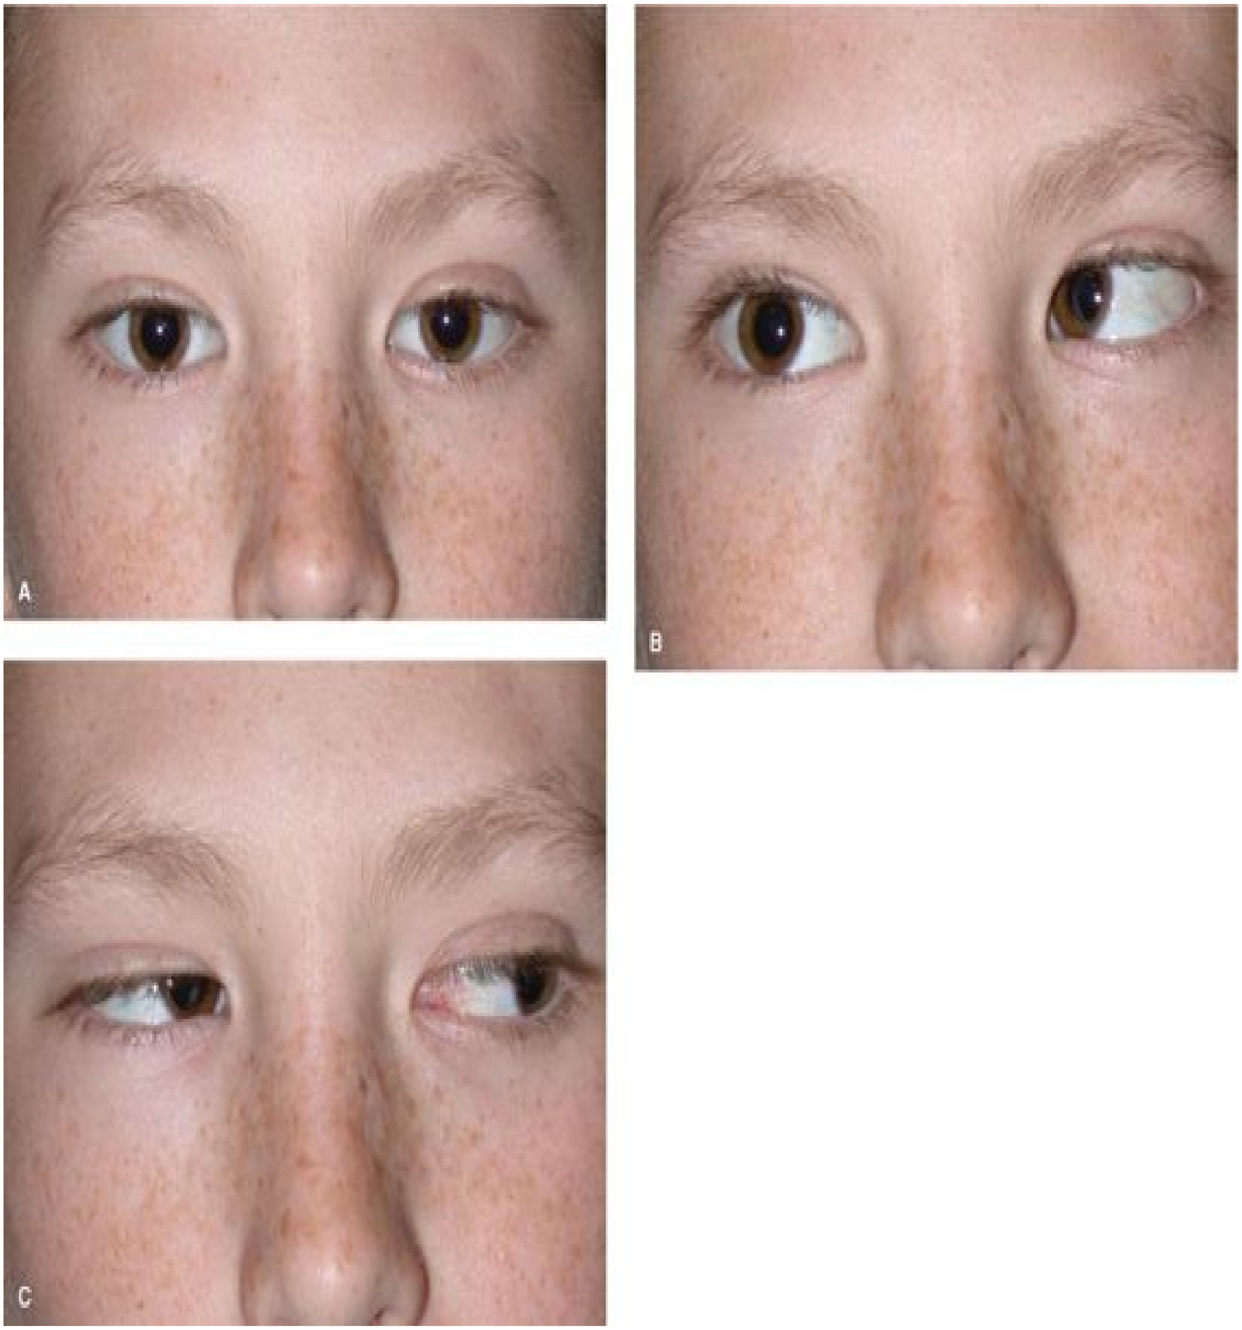

Figure 15-4 Duane syndrome. A. Eyes are straight in primary position. B. Reduced abduction of the right eye with a left esotropia. C. Normal adduction of the right eye but globe retraction and palpebral fissure narrowing of the right eye in adduction. (*Used with -permission from Paul J. Rychwalski, MD.*)

- Forms of exodeviations include intermittent exotropia, oculomotor nerve palsy (usually seen with ptosis and mydriasis on the ipsilateral side), and exotropic Duane syndrome.

- Causes of vertical deviations include trochlear nerve palsy, oculomotor nerve paresis, orbital fracture, thyroid-related ophthalmopathy, and Brown or superior oblique tendon syndrome (**Figure 15-5**).

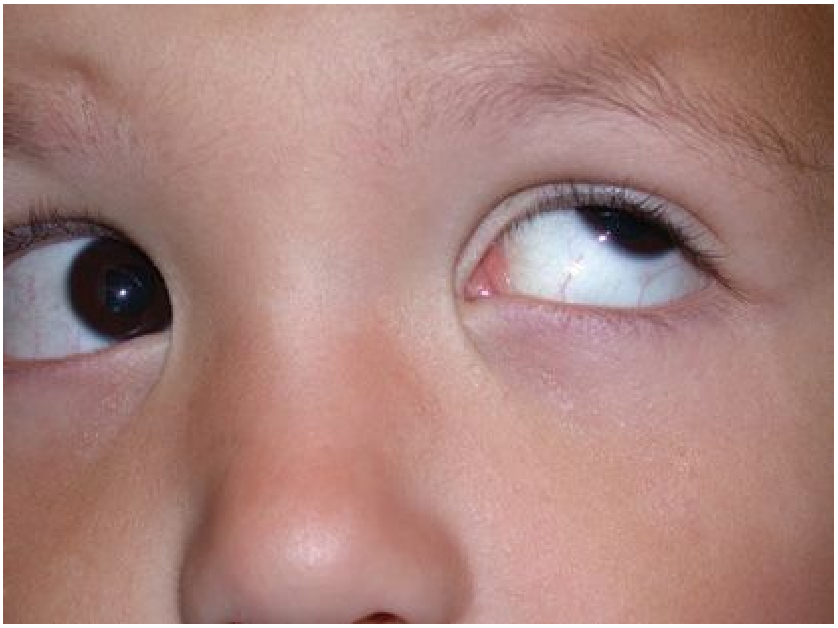

Figure 15-5 Right Brown syndrome (superior oblique tendon syndrome). Note restricted upgaze of right eye in adduction and apparent over-elevation of the left eye in abduction. (*Used with permission from Paul J. Rychwalski, MD*.)

IMAGING

- Neurologic imaging: In general, a fat-suppression MRI of the brain and orbits with and without contrast is indicated if the results of the history and physical examination point to a possible neurologic cause. Several features warrant investigation with imaging:
  - Abrupt onset.
  - History of trauma.
  - Associated neurologic signs such as anisocoria, ptosis, nystagmus, seizures, or headache.
  - Incomitance.

    - Craniofacial abnormalities.

DIFFERENTIAL DIAGNOSIS

- Pseudostrabismus (**Figure 15-6**).

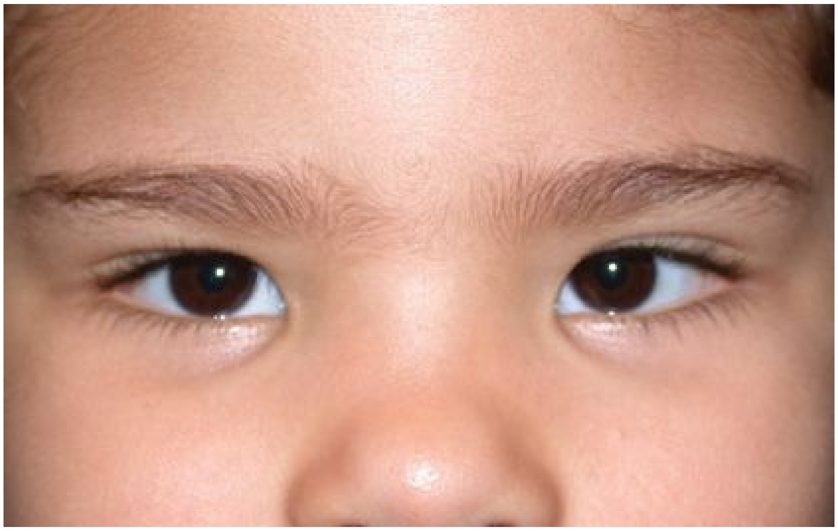

Figure 15-6 Pseudostrabismus. Note centered light reflexes, wide nasal bridge and prominent epicanthal folds. (*Used with permission from Paul J. Rychwalski, MD*.)

    - Prominent epicanthal folds.
    - Flat nasal bridge.
    - More apparent on lateral gaze.
    - Normal pupillary light reflex and cover tests.
    - Normal eye exam including refraction, anterior segment and retina.
- Infantile ocular instability.
    - Normal, variable deviation of the eyes seen in the first several weeks of life; usual exotropic.

MANAGEMENT

- Pseudostrabismus.
  - Complete visual and ocular examination.
  - Reassurance.
  - Repeat examination in 4 to 6 months looking for true strabismus. underlying the pseudostrabismus.
- Strabismus.
  - The treatment depends upon the etiology. The goal is to restore normal ocular alignment, preserve vision and binocular vision and stereopsis.

NONPHARMACOLOGIC

- Optical correction and amblyopia therapy (patching or other forms of occlusion) if indicated.[6–8] SOR A
- Prism glasses. SOR C

MEDICATIONS

- Miotic drops may induce accommodation (Phospholine iodide). SOR C
- Cycloplegics may be used in order to blur the stronger eye in amblyopia treatment (Atropine 1%).[6–9] SOR A

COMPLIMENTARY/ALTERNATIVE THERAPY

- Orthoptic exercises may be beneficial, especially in some smaller exodeviations. SOR C

SURGERY

- In sensory strabismus, surgery is indicated to correct conditions that cause obstruction of the visual axis (ptosis repair, cataract removal, or capillary hemangioma treatment).[10–13] SOR Ⓐ

- Strabismus surgery.
    - Recession: move the “over-working” muscle posteriorly in order to weaken it (**Figure 15-7**).

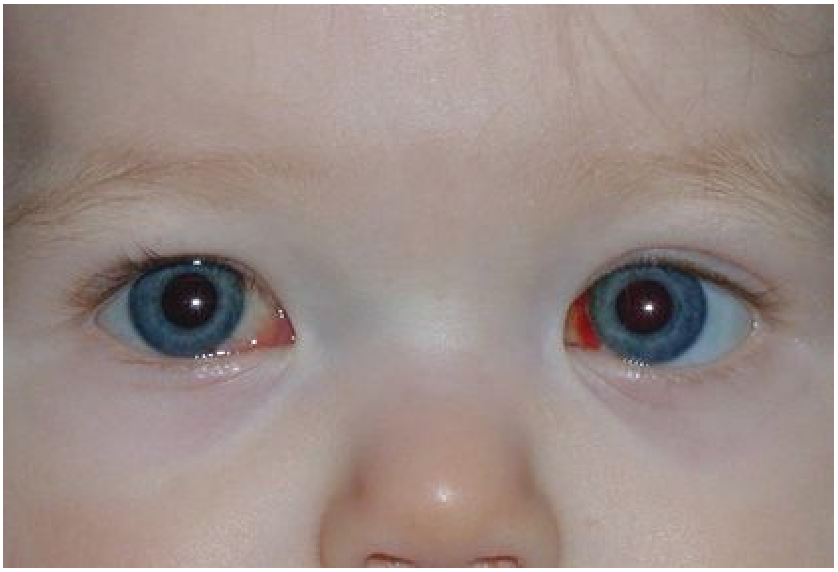

Figure 15-7 Eyes now in alignment one week after bilateral medial rectus recession for congenital esotropia. Note the remaining subconjunctival hemorrhages. (*Used with permission from Paul J. Rychwalski, MD*.)

-
    - Resection: remove a segment and reattach a relatively underacting muscle in order to strengthen it.

REFERRAL

Indications for referral to a pediatric ophthalmologist include:

- Constant esotropia at any age.
- The corneal light reflection test or cover test demonstrates deviation.
- Incomitant deviations (deviations that change depending upon the position of gaze). This could be a cranial nerve palsy, trauma or extraocular muscle syndrome.
- Torticollis that may be ocular.

- Parental concern exists about ocular alignment despite reassurance.
- Strong family history of strabismus or amblyopia.

PREVENTION AND SCREENING

- Vision screening is a very important way to identify vision problems.
- Children with a family history of childhood vision problems are more likely to have eye problems.
- The American Academy of Ophthalmology and the American Academy of Pediatrics recommend that children have their eyes checked by a pediatrician at the following ages:[14,15]
- Newborn.
    - All babies should have their eyes checked for infections, defects, cataracts, or glaucoma before leaving the hospital. This is especially true for premature babies, babies who were given oxygen for an extended period, and babies with multiple medical problems.
- By 6 months of age.
    - As part of each well-child visit, eye health, vision development, and alignment of the eyes should be checked.
- At 3 to 4 years of age.
    - Eyes and vision should be checked for any abnormalities that may cause problems with later development.
- At 5 years of age and older.
    - Vision in each eye should be checked separately every year. If a problem is found during routine eye exams, referral to a pediatric ophthalmologist may be required.
- Learning disabilities.
    - Learning disabilities are quite common in childhood years and have many causes. The eyes are often suspected but are almost never the cause of learning problems. Vision therapy will not improve a learning

disability. A referral for a thorough evaluation by an educational specialist may be indicated.[8]

PROGNOSIS

- Early identification is crucial for a good visual outcome. Adherence to amblyopia therapy remains a significant barrier to success even in cases of strabismus caught and treated early.

FOLLOW-UP

Follow-up is typically conducted every 2 to 3 months if the child is patching. In younger children, close follow-up is recommended, as the risk of amblyopia is higher during the critical period of visual development. Children otherwise at risk are seen at 6 and 12 month intervals.

PATIENT EDUCATION

- Early screening for problems and possible referral to a pediatric ophthalmologist is important.
- Adherence to the recommended therapies are critical to successful correction of any problem.

16 RETINOBLASTOMA AND THE DIFFERENTIAL DIAGNOSIS OF LEUKOCORIA

Abdul-Karim Sleiman
Arun Singh, MD
Elias I. Traboulsi, MD

PATIENT STORY

A 14-month-old boy was referred by his pediatrician because a whitish reflex from his left pupil (**Figure 16-1**) was noticed by his parents in certain directions of gaze. It was also noted on a few recent photographs. His pediatrician had checked the pupillary light reflex and indeed noted a dimmer and tan-colored reflex from the left pupil as opposed to a brighter and more reddish reflex in the left eye. She referred the child for further evaluation and management. Dilated fundus examination revealed a single large tumor in the left eye, occupying more than 50 percent of the globe. Ultrasonography showed a pattern consistent with calcifications within the tumor, and suggestive of retinoblastoma. A magnetic resonance imaging (MRI) scan showed no evidence of optic nerve or intracranial involvement. There were no other tumors in either eye. There was no family history of retinoblastoma. A decision was made to enucleate the eye because of the size of the tumor.

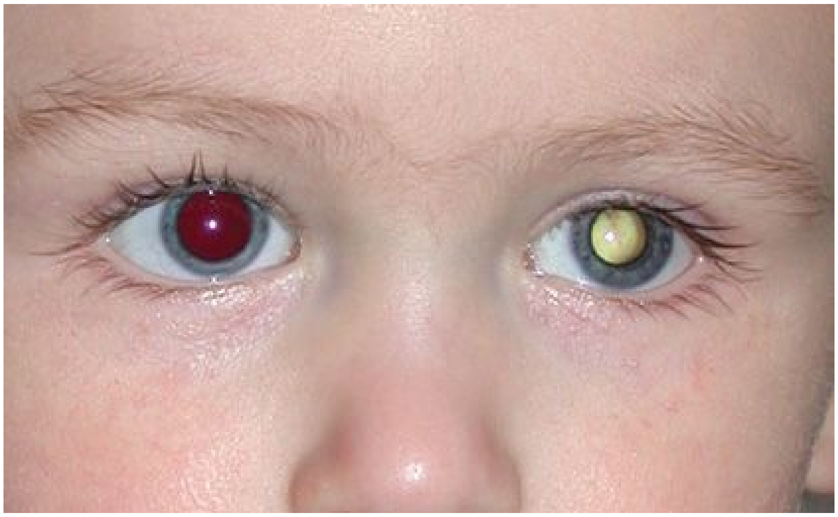

FIGURE 16-1 Leukocoria in the left eye of this infant with retinoblastoma. The tumor can actually be visualized behind the clear lens. (*Used with permission from Elias Traboulsi, MD*.)

INTRODUCTION

Leukocoria means a white (*leuko*) reflex from the pupil (*coria*). Leukocoria is a sign observed by the naked eye or with a scope, often detected incidentally on routine eye examination, or in photographs; it is not a diagnosis. The most feared cause of a white reflex in the pupil is retinoblastoma, the most common intraocular tumor of childhood. Other conditions can manifest themselves initially with leukocoria. Precise diagnosis ensures appropriate and early treatment to prevent irreversible blindness from primary pathology, secondary amblyopia, or life-threatening malignancies.

SYNONYMS

White pupillary reflex. White pupil.

EPIDEMIOLOGY

- Retinoblastoma is diagnosed in 47 percent of children who are referred with leukocoria to tertiary centers.[1]
- The majority (32 to 73%) of children with retinoblastoma present with leukocoria.[2,3]
- Retinoblastoma occurs as rarely as in 1:13,000 to 1:20,000 live births, with an annual incidence of 11.8 per million children between zero and four years of age in the US and similar statistics in Europe.[4]
- Other causes of leukocoria are slightly more common but exact estimates of their incidence are not available.

ETIOLOGY AND PATHOPHYSIOLOGY

- The direct cause underlying leukocoria that is common to the different conditions that cause it is an interference with the normal red reflex from opacities or abnormalities that occur strictly anywhere from the crystalline lens and posteriorly, hence excluding corneal opacities.
- Leukocoria from retinoblastoma is caused by the whitish well-circumscribed retinal mass.
- The tumor develops when a negative regulator of the cell cycle (pRB) is inactive or absent secondary to mutations in both alleles of the tumor suppressor gene *RB1* in a retinal progenitor cell.[5]
- The “two-hit” theory (first germline, second somatic; or both somatic) explains both heritable and non-heritable forms of retinoblastoma.
- Other conditions are listed in the differential diagnosis (see **Table 16-1**).

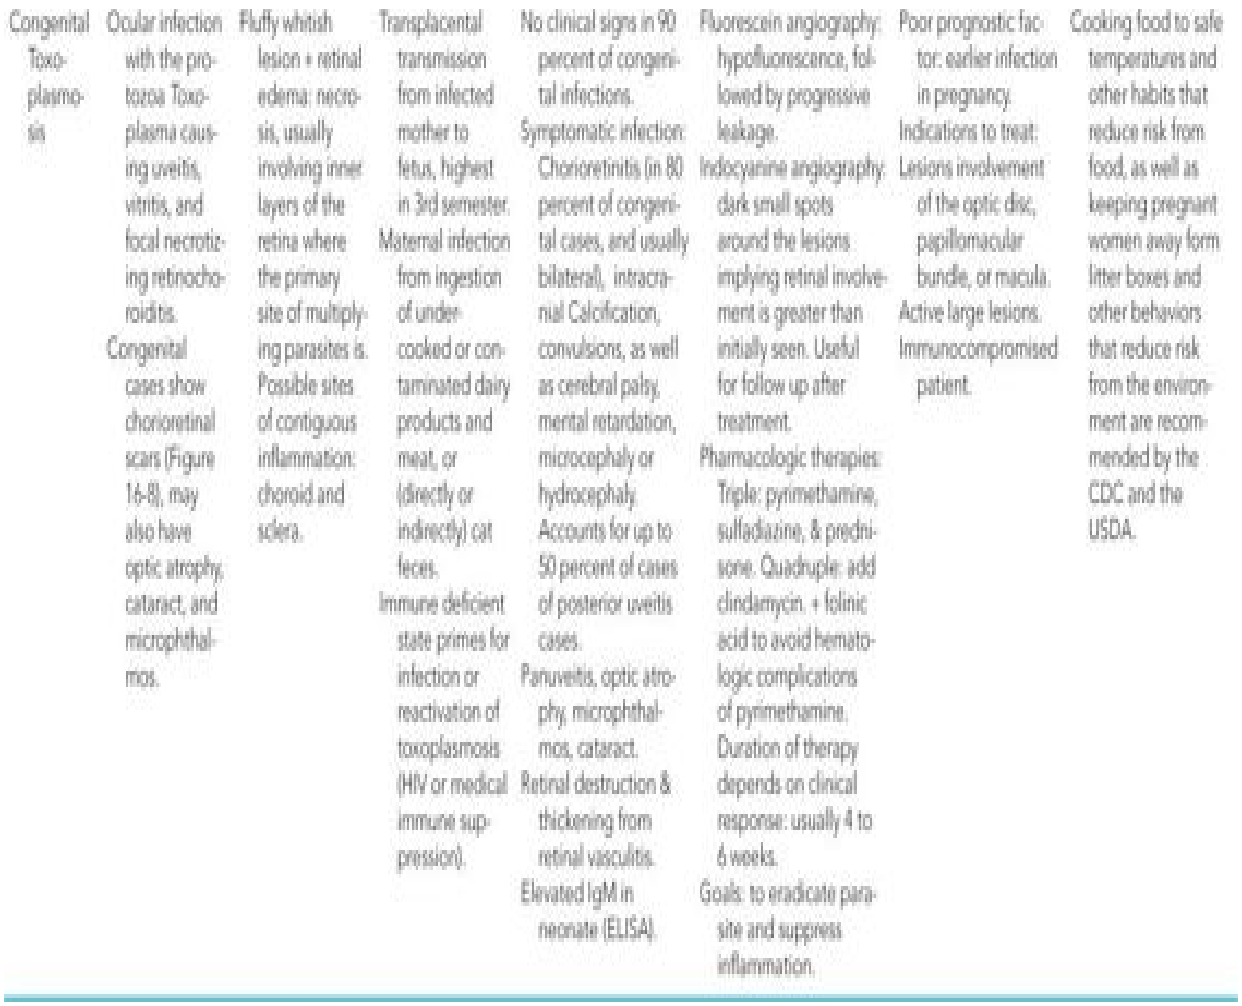
TABLE 16-1 Differential Diagnosis and Features of Entities that Can Simulate Retinoblastoma or Cause a Whitish Reflex from the Pupil

Entity	Definition & Epidemiology	Leukocoria	Causes and Risk Factors	Clinical Features	Management	Prognosis	Prevention, Screening, & Education
Cataract	Progressive opacification of the lens. Congenital: ~2 per 10,000. Infantile: 1 to 15 per 10,000.	Opacity in the lens. Noticed by primary carephysician or parents, by naked eye, on red reflex evaluation or in photos.	Genetically determined in 50 percent of cases; mostly autosomal dominant. Could be a sign of systemic or infectious process, or the result of an injury.	Decreased visual acuity. Nystagmus. Strabismus. Photophobia. Family history of hereditary cataract. Features of genetic disorders associated with cataract (galactosemia, Down's, etc). Labs for infections or metabolic causes. Genetic testing and/or karyotype.	If extra-axial or small & good vision, conservative: close follow up during age of visual development (until 8 to 9 years). Otherwise, prompt surgical extraction with optical rehabilitation (intraocular lens or postoperative contact lens) + near vision glasses + frequent adjustment of prescription with growth. Occlusion therapy (patching) if amblyopia ensues.	Untreated, amblyogenic and causing partial or total blindness. With early diagnosis and treatment, visual acuities of 20/40 to 20/20 can be achieved in many cases. Poor prognostic factors: nystagmus, strabismus, and unilateral infantile or congenital cataract.	Red reflex screening for all children in every exam. Regardless of leukocoria, all high risk children (positive family history, personal history of ionizing radiation exposure, long-term use of systemic steroids, or a systemic disorder associated with cataracts) require referral and yearly ophthamologic follow-up.
Persistent fetal vasculature (PFV) or Persistent hyperplastic vitreous (PHPV).	Congenital malformation resulting from failure of regression of the primary vitreous and hyaloid vascular system. Rare in the population. PFV is in up to 63 percent of children presenting with leukocoria.	Rudimentary vascular stalk in vitreous associated to plaque-like opacity retrolental fibrovascular tissue. Usually unilateral (Figure 16-4).	Arrest of normal involution of the embryonic vascular connective tissue that normally occurs after 4 months gestation. Non hereditary.	Microphthalmia. Strabismus. Cataract. Vascularized white retrolental tissue. Prominent iridial vessels. Elongated ciliary processes. Glaucoma. Other malformations (intralenticular hemorrhage, uveal coloboma, etc). Posterior features (retinal fold, hypoplastic macula &/or optic nerve, traction retinal detachment + stalk to optic disc)	Ocular ultrasound: persistent hyaloid remnants with hyaloid artery or canal from disc into vitreous towards lens + confirmation of other clinical findings. CT or MRI: same as ultrasound. With contrast: hypervascular vitreous. Treatment: Lens extraction and anterior vitrectomy; can be complex. Enucleation in severe cases with no vision and malformed small globe.	High risk of: glaucoma, cataract, intraocular hemorrhage, and retinal detachment. Visual prognosis limited by associated optic nerve or macular disease. Long term: enucleation for terminal glaucoma, intraocular hemorrhage, retinal detachment, phthisis bulbi.	Red reflex screening for all children in every exam. No preventive measures available due to sporadic nature of the abnormality. Has been diagnosed on fetal ultrasound.

Extensive myelination of the nerve fiber layer	Abnormal myelination of nerve fibers of the retina. Almost in 1 percent of the population.	Lesion follows distribution of nerve fibers, typically striated white or gray myelinated nerve fibers patches with feathery borders (Figure 16-5).	Most cases are sporadic. Can occur in the context of some syndromes such as Gorlin syndrome (basal cell nevus syndrome).	Mostly asymptomatic. Usually normal vision (scotomas or enlarged blind spots may occur). In extensive cases has been associated with a higher incidence of amblyopia, myopia, and strabismus. Optic nerve may also be hypoplastic.	Visual field test. Asymptomatic cases: no treatment required. Symptomatic cases: prompt treatment of coexisting conditions that are associated with negative prognosi such as high myopia and amblyopia.	Generally stable. Poor vision from amblyopia in some cases.	Typically stable and benign disease. No preventive measures available.
Retinopathy of prematurity (ROP)	Developmental vascular disorder with uncontrolled vasoproliferation of incompletely vascularized retinas of premature infants. Affects around 21 percent to 36 percent of preterm infants.	Opaque mass behind lens (retrolental fibroplasia) in advanced and untreated cases of ROP and retinal detachment.	Prematurity <32 weeks Decreasing gestational age and birth weight. Assisted ventilation (>1 week). Surfactant therapy. Blood transfusions. Severity of illness. Hyperglycemia and insulin therapy. Sepsis. Elevated arterial oxygen tension. Fluctuations in blood gas measurements. Intraventricular hemorrhage. Bronchopulmonary dysplasia.	Detected on screening by an experienced ophthalmologist: location and retinal changes noted. The AAP/AAO/AAPOS 2006 recommendations for screening: 1- all infants with a birth weight <1500 g or gestational age ≤32 weeks 2- selected infants weighing: 1500 to 2000 g or gestational age >32 weeks with an unstable clinical course 3- infants at high risk according to their attending pediatrician or neonatologist.	Prethreshold ROP: elective treatment for prevention of progression. Threshold ROP: ablation of peripheral abnormal retina with laser photocoagulation (better than cryotherapy). Severe ROP without retinal detachment + ocular opacities (photocoagulation not possible): Bevacizumab (anti-VEGF) off-label (optimal timing and dose unknown). Retinal detachment: urgent surgical treatment. Post-treatment follow-up exam: weekly or biweekly for 1 to 2 months then less frequently depending on clinical course.	Irregular progression. Spontaneous regression in vast majority in 4 months. Poor visual acuity or fundus structural abnormalities in 5.1 percent. Blindness in children <1000 g birth weight. Poor visual prognosis in untreated severe ROP. High risk for: vitreous hemorrhages, preretinal membrane, tractional retinal detachment, strabismus, anisometropia, future myopia.	First screening examination: sufficient if both retinas fully vascularized. Screening examinations should continue until ROP regresses and the vessels mature, or until treatment is needed. Prevention targeted at oxidant injury (vitamins, penicillamine, and limiting light exposure): tested but not supported by evidence. Recommendations avoiding episodes of physiologic instability.

Toxocariasis	Ocular infection caused by a zoonotic parasite: the dog or cat ascarid Toxocara (canis or catis). Most common in children aged 1 to 3 years. Leukocoria is the presenting sign in 15 percent of the cases. 98 percent of the cases have a history negative for visceral larva migrans syndrome.	Subretinal granuloma, whitish, 1 to 2 disc diameters, located anywhere in the retina. Nematode endophthalmitis: large inflammatory mass (with prominent vitreous inflammation). Both lesions may have calcification & be confused with retinoblastoma.	Ocular lesion: caused by inflammatory response to the second-stage larva. Human infection: due to accidental ingestion of infective eggs and tissue invasion of second stage larvae. Transmission: by con- taminated food or geophagia. Factors influencing onset of ocular disease are unknown, but the inflammatory reaction is mainly associated with larval death.	The only manifestation of the disease may be ocular. Unilateral. Subretinal granuloma (alone, in a quiet eye). Retinal damage: folds, elevation, detachment. Strabismus. Decreased vision. Chronic endophthalmitis. Uveitis (posterior). Macular and optic nerve diversion. Positive serum IgG (ELISA): confirmatory. Negative serum IgG: does not rule Toxocariasis out. Aqueous humor antibodies demonstrate intraocular production.	Peripheral granuloma (silent, minimal inflammation) does not require treatment. Anthelmintics (tiabendazole or diethylcarbamazepine) are controversial: larvae death may increase inflammation. Steroid umbrella (systemic or periocular) with anthelmintics to reduce inflammation, or alone to control vitreoretinal tractional membranes. Vitreoretinal surgery: for vitreous opacities, epiretinal membranes, and retinal detachment. Laser photocoagulation: to kill mobile visible larva, under "steroid umbrella." Other ophthalmologic procedures to improve vision.	56 percent suffer permanent vision loss. Poor visual prognostic factors are: Severe vitritis. Cystoid macular edema. Tractional retinal detachment.	No screening (no need for treatment if silent). Prevention by reducing oral transmission to humans: periodic deworming treatment of pets (especially lactating females), timely disposal of pet feces, and good hygiene practices. Education to patients at risk: to prevent infection in pets, and to avoid exposure to potentially contaminated soil.
Optic disc and uveal coloboma.	Cleft of the optic disc secondary to failure of the fetal fissure to close inferiorly. Rare.	White sharp decentered excavation in the optic disk. May extend inferiorly to retina and choroid (rarely affects the entire disc; **Figure 16-6**).	Sporadic or inherited. Isolated or part of a syndrome. Renal coloboma syndrome (autosomal dominant, PAX2 gene on 10q). CHARGE syndrome. Other syndromes (Walker-Warburg, Aicardi, Goldenhar, linear sebaceous nevus, Noonan, focal dermal hypoplasia)	Unilateral or bilateral. Thin neuroretinal rim. Iris & ciliary coloboma. Orbital cyst. Iris heterochromia. Retinal venous malformations. Renal coloboma findings (VU reflux, renal hypoplasia, renal failure, chronic nephritis). CHARGE syndrome (+PHPV, microphthalmos, facial palsy, facial dysmorphism, TE fistula, renal, cardiovascular and CNS abnormalities.)	Renal ultrasound to rule out significant renal disease. Rule out CHARGE syndrome (Colobomas, Heart defects, Choanal Atresia, Retarded growth, Genital abnormalities, Ear abnormalities) with echocardiography, nasal catheter (or CT sinuses) and hearing test.	Visual acuity ranges form normal to complete visual loss (not predictable by appearance of the lesion). Best visual prognostic factor: sparing of the fovea by associated chorioretinal coloboma.	Red reflex screening for all children in every exam. No preventive measures available due to nature of the abnormality.

Coats disease	Primary retinal telangiectasias, a rare exudative retinopathy usually affecting young males (80% are 5 to 10 years old).	Luminous leukocoria from massive yellow exudates on/in edematous retina (pseudotumor; **Figure 16-7**).	Idiopathic, congenital, and nonhereditary. Somatic mutation in NDP gene, causing deficiency of norrin (protein product) in the developing retina. No known associated systemic problems.	90 percent unilateral. Decreased visual acuity. Strabismus. Retinal telangiectasia: usually peripheral strings of fusiform aneurysmal dilatations of the retinal vessels (tiny light bulbs). Pseudo-tumoral exudates, predilection for macula. Exudative (partial or total) retinal detachment. Iridis rubeosis. Neovascular glaucoma. Cataract. Uveitis. Phthisis bulb.	Treatment goal: arresting vascular progression. Cryotherapy or laser photocoagulation: limited success. Avoided if lesions around optic nerve. Enucleation is an option for further complicated cases.	Variable evolution. Spontaneous stabilization or regression is occasional and may be temporary or permanent, but usually with loss of central vision (macular deposits). Retinal exudation can cause retinal detachment. Progressive retinal damage and eventual definitive blindness.	As precise origin is unknown, disease cannot be prevented.
Morning Glory syndrome	Congenital anomaly: funnel shaped excavation of the fundus and the optic nerve head with a ring of chorioretinal pigment around the disk. Uncommon, but more common in females.	Central white glialtuft of tissue at center of optic cup, surrounded by vessels radiating out like spikes from an enlarged optic nerve head.	Unknown. Sporadic occurrence in great majority of cases. Some underlying genetic defect must be present (see associated malformations).	Unilateral. Usually isolated. Retinal detachment up to 1/3 of cases. Association to midline cranial defects with symptoms of mouth-breathing, snoring, and rhinorrhea. Baasal cephaloceles Reported associations with capillary hemangiomas, carotid circulation abnormalities such as Moyamoya disease, and renal disease.	MRI: transphenoidal encephalocele may be seen affecting the nasopharynx. MRAs are essential to rule out associated Moyamoya disease that could be treatable.	Serous retinal detachment retinal folds, and subretinal neovascularization may contribute to a poor visual prognosis. Usually severely reduced visual acuity (20/200 to finger counting). But occasionally better.	No preventive measures available for malformation itself.



Congenital Toxoplasmosis	Ocular infection with the protozoa Toxoplasma causing uveitis, vitritis, and focal necrotizing retinochoroiditis. Congenital cases show chorioretinal scars (Figure 16-8), may also have optic atrophy, cataract, and microphthalmos.	Fluffy whitish lesion + retinal edema: necrosis, usually involving inner layers of the retina where the primary site of multiplying parasites is. Possible sites of contiguous inflammation: choroid and sclera.	Transplacental transmission from infected mother to fetus, highest in 3rd semester. Maternal infection from ingestion of undercooked or contaminated dairy products and meat, or (directly or indirectly) cat feces. Immune deficient state primes for infection or reactivation of toxoplasmosis (HIV or medical immune suppression).	No clinical signs in 90 percent of congenital infections. Symptomatic infection: Chorioretinitis (in 80 percent of congenital cases, and usually bilateral), intracranial Calcification, convulsions, as well as cerebral palsy, mental retardation, microcephaly or hydrocephaly. Accounts for up to 50 percent of cases of posterior uveitis cases. Panuveitis, optic atrophy, microphthalmos, cataract. Retinal destruction & thickening from retinal vasculitis. Elevated IgM in neonate (ELISA).	Fluorescein angiography: hypofluorescence, followed by progressive leakage. Indocyanine angiography: dark small spots around the lesions implying retinal involvement is greater than initially seen. Useful for follow up after treatment. Pharmacologic therapies: Triple: pyrimethamine, sulfadiazine, & prednisone. Quadruple: add clindamycin. + folinic acid to avoid hematologic complications of pyrimethamine. Duration of therapy depends on clinical response: usually 4 to 6 weeks. Goals: to eradicate parasite and suppress inflammation.	Poor prognostic factor: earlier infection in pregnancy. Indications to treat: Lesions involvement of the optic disc, papillomacular bundle, or macula. Active large lesions. Immunocompromised patient.	Cooking food to safe temperatures and other habits that reduce risk from food, as well as keeping pregnant women away form litter boxes and other behaviors that reduce risk from the environment are recommended by the CDC and the USDA.

RISK FACTORS

- The presence of a germinal mutation in the retinoblastoma gene confers up to 90 percent risk of developing retinoblastoma.
- A family history of retinoblastoma is a strong risk factor for offspring and siblings.
- Radiation exposure predisposes to second malignant neoplasms in hereditary retinoblastoma.
- The 13q deletion predisposes to bilateral disease with multiple other malformations including facial dysmorphism.

- The Children's Oncology Group (COG) trials for retinoblastoma are currently evaluating histopathologic risk factors, familial and environmental factors, multimodality treatments (including chemotherapies, stem cell therapy and viral oncolysis) for extraocular retinoblastoma and associated tumors, and late complications in survivors.[6–8]

DIAGNOSIS

Securing a firm diagnosis frequently necessitates examination under anesthesia with ocular, orbital and brain imaging as well as ocular photography.

CLINICAL FEATURES

- Common presenting signs of retinoblastoma include leukocoria, strabismus, poor vision, family history alone, and ocular inflammation.[2,3]
- The tumor may grow subretinally (exophytic) with later exudative retinal detachment, and/or towards the vitreous (endophytic) with possible intravitreal seeding.
- Patients with hereditary retinoblastoma are at risk of second malignant neoplasms.

DISTRIBUTION

- Unilateral unifocal retinoblastoma is usually non-hereditary.
- Hereditary retinoblastomas are in general either bilateral or unilateral and multifocal and occur early in infancy. They carry a high risk of second extraocular tumors.
- Extraocular disease consists of trilateral retinoblastoma (bilateral disease with pinealoblastoma), second malignancies (sarcomas), or metastasis.

- Based on its size, position in the globe, and dissemination, retinoblastoma is classified according to the International Intraocular Retinoblastoma Classification (ICRB), with the aim of accurate prognostication of globe salvage.[9]

LABORATORY TESTING

- Molecular genetic testing requires prior genetic counseling (see the following section).
- Histopathology of retinoblastoma (if enucleation is performed) is indispensable for detecting microscopic infiltration of the optic nerve or choroid, classification of the tumor, and subsequent decision regarding adjuvant chemotherapy.[10]
- Additional tests are individualized upon the planned mode of treatment; baseline blood chemistries and complete blood count before chemotherapy.

IMAGING

- Digital fundus photography is needed for documentation and classification (**Figure 16-2**).

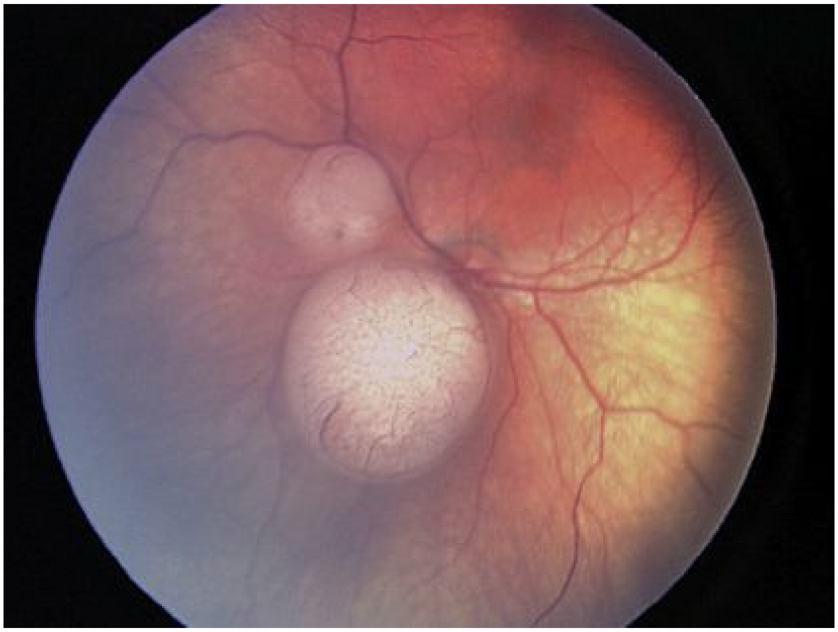


FIGURE 16-2 Wide-angle fundus photograph reveals two retinoblastoma tumors nasal to the optic nerve head. (*Used with permission from Elias Traboulsi, MD.*)

- Ocular ultrasonography demonstrates the solid intraocular mass, usually with calcifications, and evaluates the surrounding orbital tissues (**Figure 16-3**).

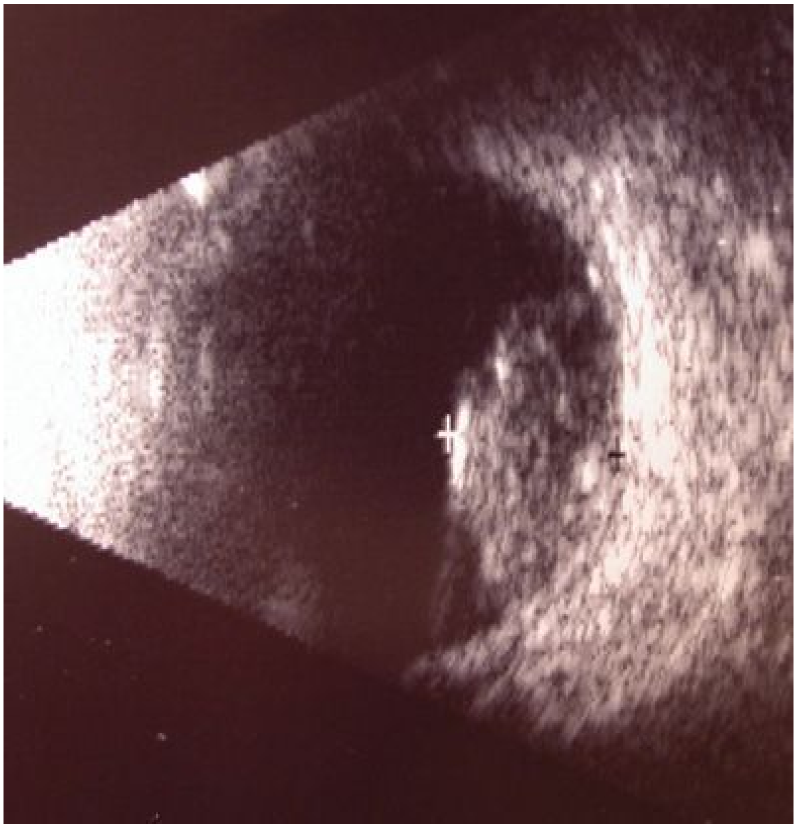

FIGURE 16-3 Ocular B-scan ultrasonogram of a single medium sized intraocular tumor. The areas of increased echodensity (white areas) within the mass correspond to foci of calcification. (*Used with permission from Elias Traboulsi, MD*.)

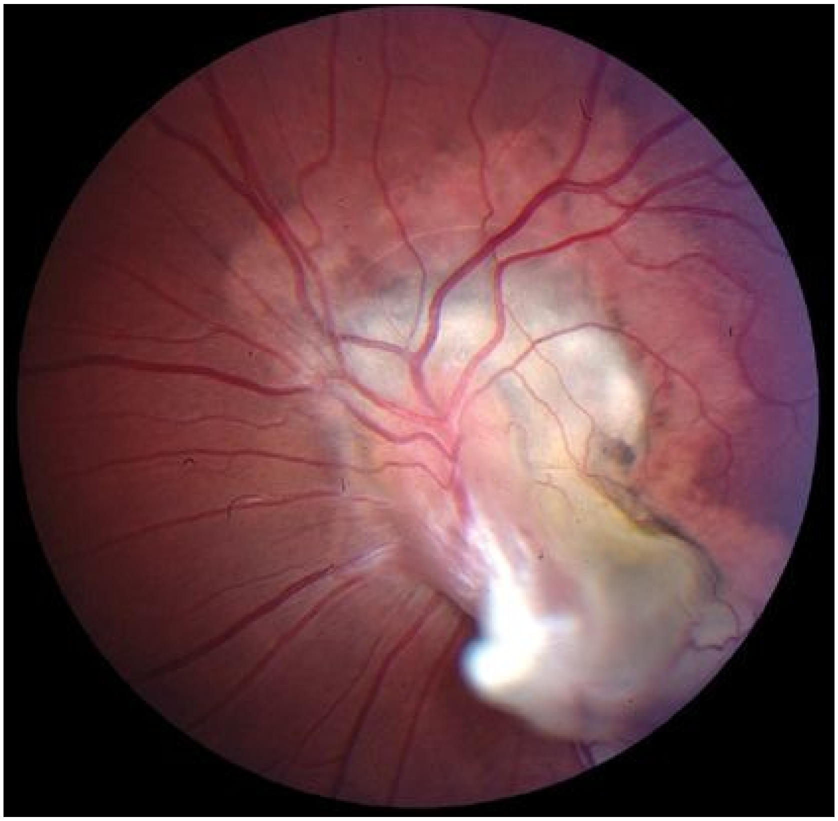

FIGURE 16-4 Persistent hyperplastic primary vitreous. The posterior portion of the retained and proliferated fetal vitreous is attached to the optic nerve head. Anteriorly these patients have a whitish mass occupying the posterior aspect of the lens and dragging the ciliary processes towards the lens. (*Used with permission from Elias Traboulsi, MD*.)

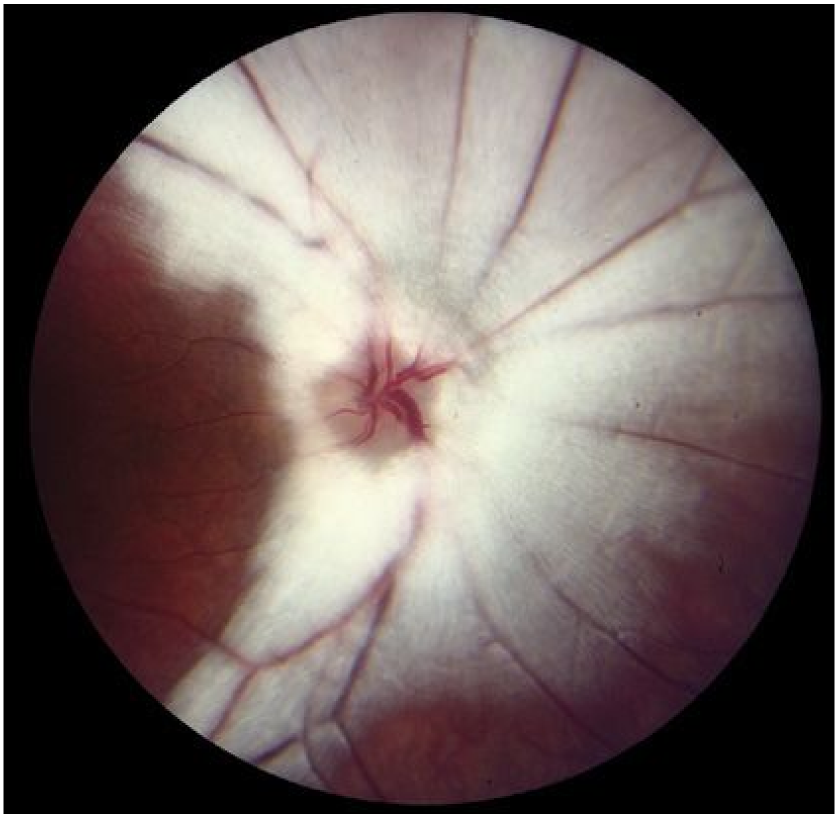

FIGURE 16-5 Extensive myelination of the optic nerve fibers in this right eye. Note fluffy edges and partial obstruction of the view of the optic nerve head by the white opaque myelinated axons. (*Used with permission from Elias Traboulsi, MD.*)

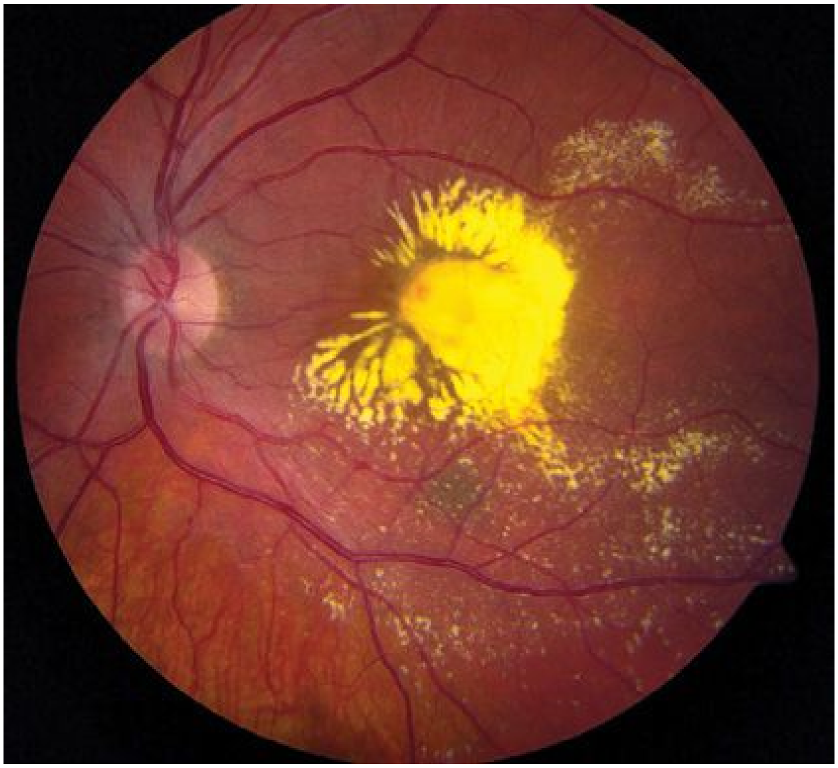

FIGURE 16-7 Yellowish macular elevated lesion made of cholesterol exudates from an abnormal leaky vascular aneurysm (not evident on this photo). The aneurysm can be in the peripheral part of the retina and the leakage will pool in the posterior pole. (*Used with permission from Elias Traboulsi, MD.*)

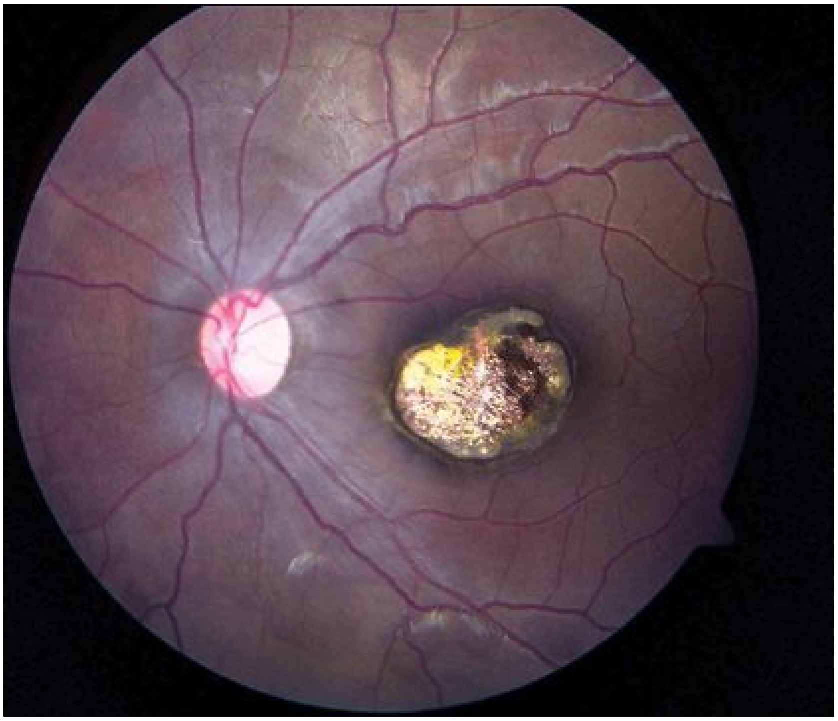

FIGURE 16-8 Macular chorioretinal scar from congenital toxoplasmosis. The white is sclera and the black is proliferated retinal pigment epithelium during the healing phase of the infections and inflammatory process. This is a typical location for congenital toxoplasmosis. (*Used with permission from Elias Traboulsi, MD.*)

- Computed tomography (CT) scanning also exhibits the characteristic intratumoral calcified foci, but it is avoided for the associated increased long-term risk for cancer. CT is reserved for diagnostically challenging cases.
- MRI differentiates retinoblastoma from Coats disease, in the presence of exudative retinal detachment.
- During workup and follow-up, MRI precisely ascertains tumor size, optic nerve and choroid involvement, and any associated brain tumors.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis of leukocoria in a child is the differential diagnosis of retinoblastoma (see **Table 16-1**).

MANAGEMENT

- The management includes (1) ruling out extraocular extension or other tumors, (2) treatment of the intraocular tumor, (3) long-term follow-up, and (4) genetic counseling.
- With modern treatment techniques, the ICRB proved to be the best predictor of treatment outcomes, especially first-line chemotherapy and adjuvant focal therapy.[9]
- The treatment plan is tailored to age, laterality, potential for vision, intraocular tumor burden, and tumor extent beyond the eye.
- Treatment aims at (1) saving the child’s life by eradicating the tumor, (2) maximizing preserved vision, and (3) decreasing the adverse effects of therapy.[6]

NONPHARMACOLOGIC

- Ablation of small tumors with local consolidative measures (cryotherapy, laser photocoagulation or transpupillary thermotherapy) can salvage the eye.
- In larger tumors, ablation may be used in conjunction with chemotherapy.[6] SOR Ⓐ
- Cryotherapy (through the sclera) is used for anteriorly located small tumors.
- Laser photocoagulation targets feeding vessels of small posterior tumors.
- Transpupillary thermotherapy directs infrared waves at the tumor mass, heats it up, and destroys it.
- Failures of the preceding therapies or recurrences are treated with episcleral radioactive plaques, external beam radiotherapy, or enucleation.

MEDICATIONS

- Chemotherapy is a safer alternative to radiation in retinoblastoma.
- Carboplatin alone can cause the tumor to shrink, however, most standard multi-agent regimens also include vincristine ± etoposide for 6 cycles.[6,11] SOR Ⓑ
- Success rates depend on regimen, tumor thickness, extent, and seeding.[12]
- Chemoreduction reduces tumor size to make it amenable to focal therapy.
- Local chemotherapy modalities, such as sub-Tenon (subconjunctival) carboplatin injection, are evolving as treatments for larger tumors. SOR Ⓒ

COMPLEMENTARY/ALTERNATIVE THERAPY

- External-beam radiation therapy (EBRT) aims at globe sparing, but it is avoided for major risk of inducing second neoplasms in hereditary disease.
- Brachytherapy (plaque radiotherapy) has excellent outcomes with minimal complications, especially for localized tumors.[13] SOR Ⓐ
- In extensive disease, combining chemoreduction with radiotherapy makes globe salvage more likely than when applying either modality alone.[13] SOR Ⓐ

SURGERY

- Enucleation is indicated for advanced unilateral intraocular tumors when the affected eye is unsalvageable, that is, hope of useful vision in it is very low to null, or when previous “globe-conserving” treatments have failed.[14] SOR Ⓐ

- Adjuvant chemotherapy should be considered after enucleation, if the pathology indicates high-risk features. SOR Ⓑ
- Approximately 6 weeks postoperatively, an ocular prosthesis can be placed.

REFERRAL

- All patients with suspected leukocoria need urgent referral to an ophthalmologist.
- Often, different specialists need to be involved in the work-up of leukocoria.
- Ophthalmologists and ocular oncologists evaluate the metastatic risk from the clinical features, the imaging, and the histopathology.
- Once the diagnosis of retinoblastoma is established, a pediatric oncologist needs to be involved in the management.
- The National Cancer Institute recommends referral of all pediatric and adolescent patients with malignancy to a medical center where the treatment plan can be developed under the care of a multidisciplinary team.[6]

PREVENTION AND SCREENING

- Newborns with a family history need prompt ophthalmologic evaluation with close follow up screening until age of 6 or until negative genetic test for *RB1*.[14]
- Risk prediction for patients and relatives is improved if genetic testing is used to distinguish asymptomatic children at risk from relatives without the mutation.[5,15]
- Relatives (parent, siblings, and offsprings) of individuals with documented germline mutations should undergo close surveillance.

PROGNOSIS

- Obvious external findings often predict enucleation and evidently poor visual prognosis.[16]
- Intraocular staging according to the ICRB predicts the ocular salvage rate (success of chemoreduction, no enucleation, no EBRT).[16–18]
- Relapse in the orbit is associated with systemic disease.[19]
- Metastatic risk is assessed from clinical features, imaging, and histopathology.
- Patients with extraocular involvement carry worse survival prognosis.
- The overall 5-year survival of retinoblastoma is around 94 percent in the US.[20]
- Survivors of the hereditary form have up to 35 percent risk for second malignancies in adulthood.[21]

FOLLOW-UP

- After diagnosis, periodic exams are performed to rule out asynchronous bilaterality.[6]
- Ophthalmologic follow-up consists of periodic careful examinations with or without MRI.
- After enucleation, a 2-year follow-up is needed to rule out orbital relapse.[19]
- In survivors, lumps or bone pain may indicate soft tissue or bone sarcomas.[5]

PATIENT EDUCATION

- Genetic testing requires counseling since it implies disclosure of critical information.
- A geneticist or genetic counselor provides information on the nature, inheritance, and consequences of a genetic disorder to individuals and families for better decision-making.
- Tumor laterality, family history, and molecular genetic diagnosis determines the risk to offsprings.
- Potential genetic risks, reproductive options, and prenatal testing are discussed with young adults who are affected or at risk, optimally prior to pregnancy.
- Survivors must avoid carcinogenic behaviors (smoking and DNA-damaging exposures).

17 PRESEPTAL (PERIORBITAL) CELLULITIS

Dawood Yusef, MD
Camille Sabella, MD

PATIENT STORY

A 1-year-old unimmunized boy is brought to the emergency department by his mother because of fever, eyelid swelling, and erythema for the past 24 hours. On examination, the child is febrile to 39°C and irritable. The right upper and lower eyelids are swollen and erythematous, with no proptosis (**Figure 17-1**). His extraocular movements are intact. A blood culture and complete blood count are drawn and the patient is admitted to the hospital for preseptal cellulitis and treated with intravenous antibiotics. Twenty-four hours later, the blood culture grows *Haemophilus influenzae* type b. He was treated with intravenous antibiotics and recovered completely.

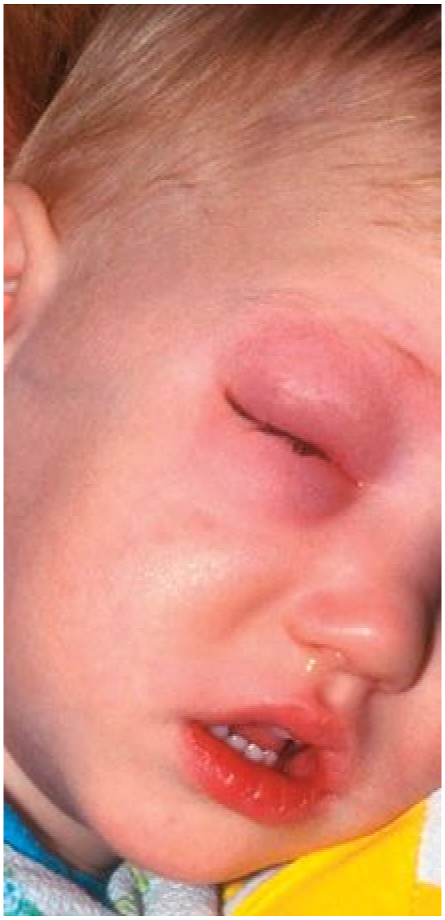

Figure 17-1 A 1-year-old boy with bacteremic periorbital cellulitis. (*Used with permission from Sabella C, Cunningham RJ III*. Intensive Review of Pediatrics, *4th edition. Lippincott Williams Wilkins, p 417, Figure 50.1*.)

INTRODUCTION

Preseptal (or periorbital) cellulitis is a bacterial infection of the eyelid anterior to the orbital septum that can result from bacteremia or from direct extension from the surrounding skin. It should always be distinguished from orbital cellulitis, which involves the tissue posterior to the septum (**Figure 17-2**).

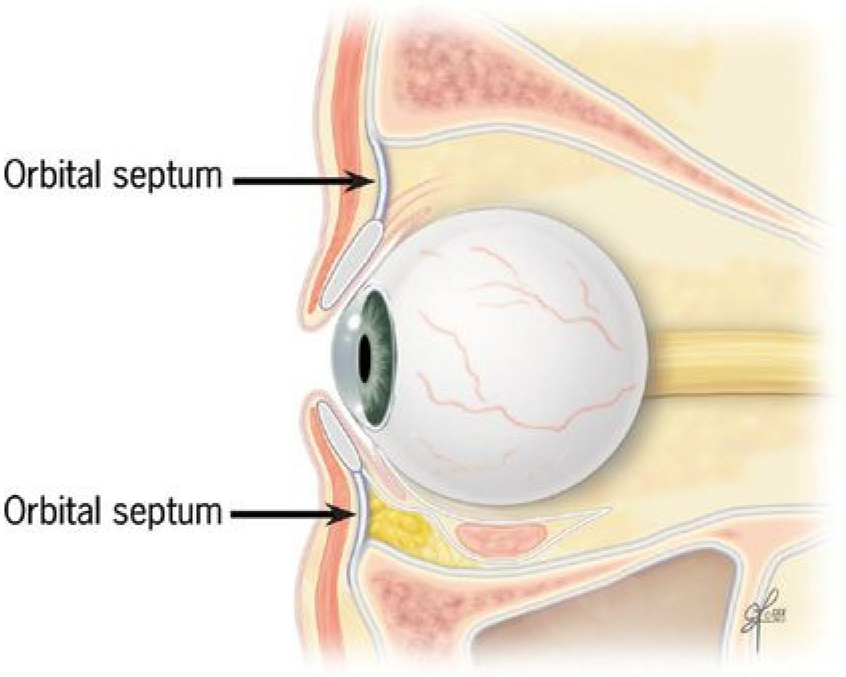

Figure 17-2 Illustration of a sagittal section of the orbit. Orbital septum is the anatomical landmark used to differentiate orbital (or postseptal) from preseptal cellulitis. (*Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2013. All Rights Reserved*.)

SYNONYMS

Periorbital cellulitis or preseptal cellulitis.

EPIDEMIOLOGY

- Preseptal cellulitis is most common in young children, occurring at a mean age of 21 months.[1,2]
- Because there are multiple modes of infection, periorbital cellulitis is more common than orbital cellulitis.[3,4]

ETIOLOGY AND PATHOPHYSIOLOGY

- The source of infection and mode of transmission can predict the bacteriology of the infection.
- The most common route of infection is from a breech in the skin overlying the eyelid or face, such as external trauma to the eye, an insect bite, or dacryocystitis (**Figure 17-3**).

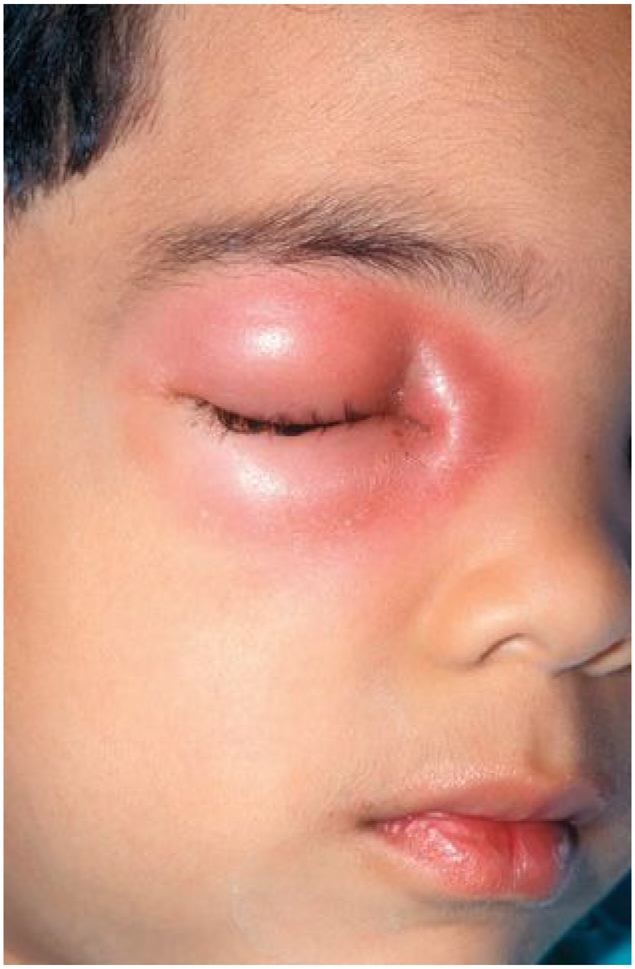

Figure 17-3 Dacryocystitis as a cause of periorbital cellulitis. (*Used with permission from Johanna Goldfarb, MD*.)

- *Staphylococcus aureus* (including community-associated methicillin-resistant *S aureus* [MRSA]) and *Streptococcus pyogenes* (Group A) are the most common pathogens when the route of infection is secondary to direct spread from the skin.[3]

- Community acquired-MRSA has become an emerging pathogen causing preseptal cellulitis.[5]
- Sinusitis can be associated with preseptal cellulitis, although orbital cellulitis is the more common complication of sinusitis. When sinusitis is the source of infection, the usually causative organisms are *Streptococcus pneumonia*e, *H influenzae*, and anaerobes.[2,4]
- Hematogenous spread (bacteremia) is another route of infection and mainly occurs in infants less than 2 years of age. In these cases, *H influenzae* type b (Hib), *S pneumoniae*, and *S pyogenes* are the most common pathogens.[6]
- The incidence of bacteremic preseptal cellulitis has decreased significantly because of widespread immunization with HIB vaccine. However, HIB infection should always be considered in unimmunized children (**Figure 17-1**).[4]

RISK FACTORS

- Nasolacrimal duct obstruction is a risk factor for acute dacryocystitis, which is inflammation and secondary infection of the nasolacrimal sac (**Figure 17-3**; see Chapter 14, Nasolacrimal Duct Obstruction).[7]
- Insect bite.
- Impetigo (see Chapter 99, Impetigo).
- Herpetic viral preseptal cellulitis (**Figure 17-4**; see Chapter 114, Herpes Simplex).

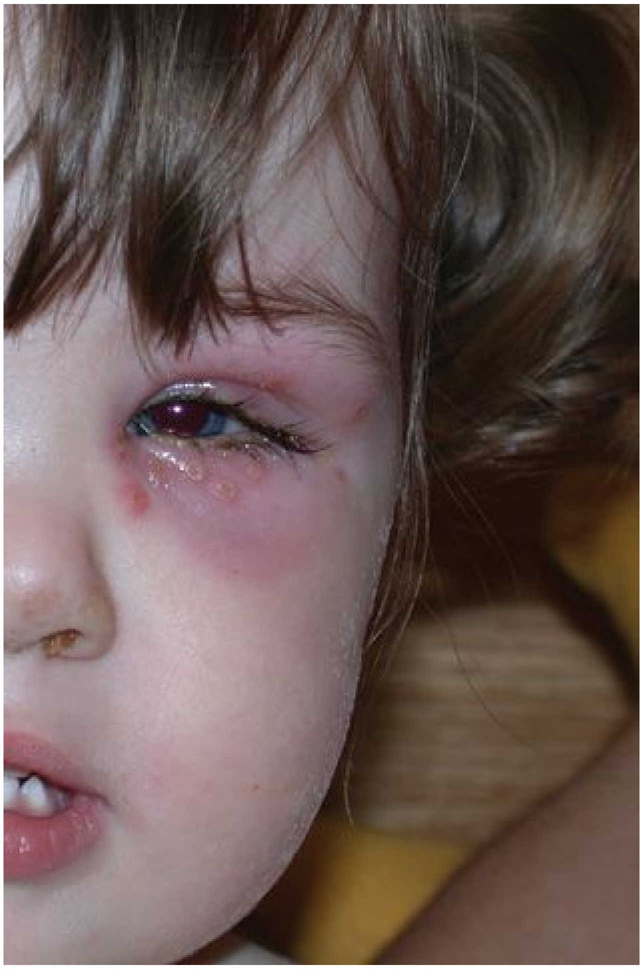

Figure 17-4 Periorbital cellulitis complicating herpes simplex virus infection of the face. (*Used with permission from Paul Rychwalski, MD.*)

- Varicella (see Chapter 108, Varicella).
- Trauma.
- Upper respiratory tract infection including sinusitis (see Chapter 26, Sinusitis).
- Recent eyelid surgery.
- Chalazion—Inflammation of the eyelid due to obstructed meibomian gland (see Chapter 10, Hordeolum and Chalazion).

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis can usually be made clinically.
- Unilateral eyelid swelling, pain, and erythema are the main features of preseptal cellulitis. Fever may or may not be present.
- In contrast to orbital cellulitis, visual impairment, ophthalmoplegia, and proptosis are usually absent in preseptal cellulitis.
- History and physical exam may reveal any of the risk factors previously mentioned and is helpful in making the diagnosis.
- Buccal cellulitis, like periorbital cellulitis, is a potential complication of bacteremia secondary to *H influenzae* type b or *S pneumoniae* (**Figure 17-5**).

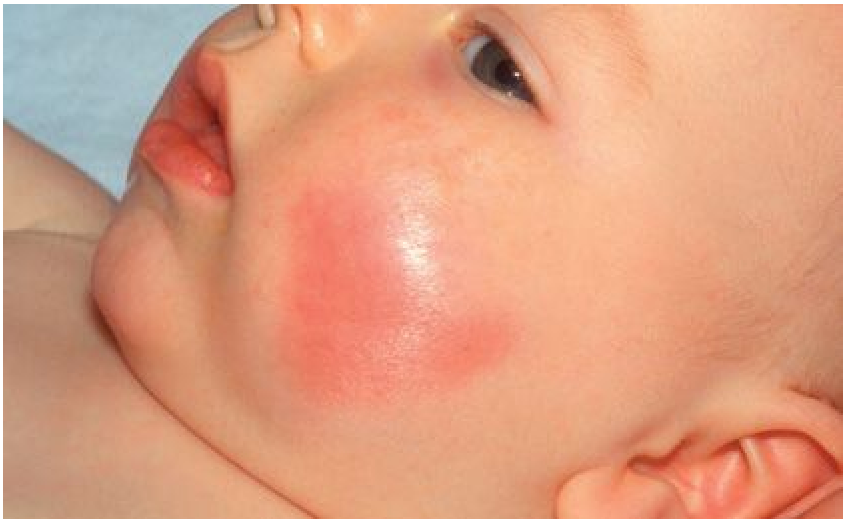

Figure 17-5 Buccal cellulitis in a 6-month-old infant with pneumococcal bacteremia. (*Used with permission from Sabella C, Cunningham RJ III.* Intensive Review of Pediatrics, *4th edition. Lippincott Williams Wilkins, p 417, Figure 50.2.*)

DISTRIBUTION

- Unilateral involvement is typical.

LABORATORY TESTING

- Laboratory testing is not usually required when the clinical presentation is mild and the route of spread is clear and benign.
- If the condition is difficult to differentiate from orbital cellulitis, a complete blood count with differential and a blood culture may be helpful.
- A blood culture should be obtained whenever systemic signs or symptoms are present, or if there is concern about hematogenous route of spread.[1,2]
- Gram stain and culture from fluid or purulent material from the periorbital area should be obtained whenever possible.
- Examination of the cerebrospinal fluid should be considered when bacteremic disease is confirmed or suspected. Infants with bacteremic preseptal cellulitis secondary to HIB have a high incidence of meningitis.[8]

IMAGING

- Imaging of the orbit may be required to distinguish preseptal from postseptal cellulitis (see Chapter 18, Orbital Cellulitis). In most cases, this distinction is made clinically so that imaging is not.
- Imaging should be considered when systemic signs and symptoms are present, when there is ophthalmoplegia or impaired vision, or in cases where clinical improvement is not achieved within 24 to 48 hours after initiation of appropriate antimicrobial therapy.
- Computed tomography is the most appropriate imaging study to differentiate preseptal from postseptal cellulitis.

DIFFERENTIAL DIAGNOSIS

- Orbital cellulitis can at times be difficult to differentiate from preseptal cellulitis (see Chapter 18, Orbital Cellulitis).
- Eye trauma with subsequent erythema and swelling in the periorbital area can usually be distinguished by the history (see Chapter 19, Eye Trauma—Hyphema).
- Allergic reaction may be difficult to distinguish from preseptal cellulitis. The presence of pruritis, bilateral involvement, and response to H2-blockers are suggestive of allergic reaction.
- Insect bite with local reaction—diagnosis can be made clinically and with a good history.
- Eyelid edema due to hypoproteinemia or end organ failure is usually bilateral.
- Hordeolum (stye) is a localized infection of the hair follicles of eye lashes or the eyelid glands—can be distinguished by the lack of significant eyelid erythema and edema, but may be complicated by cellulitis (see Chapter 10, Hordeolum and Chelazion).
- Chalazion is inflammation of the eyelid due to obstructed meibomian gland (see Chapter 10, Hordeolum and Chalazion).

MANAGEMENT

MEDICATIONS

- Because an organism is rarely isolated, treatment is usually empiric and targeted against the most common causative organisms, predicted by the suspected route and source of infection.
- The route of therapy should be based on the severity of infection and the likelihood of bacteremic infection.
- When the source of infection is from local trauma or from an adjacent infection like dacryocystitis, a first-generation cephalosporin an anti-

staphylococcal penicillin, or clindamycin may be used as initial empiric therapy. SOR Ⓒ

- The need for empiric coverage for MRSA depends on local prevalence and epidemiology.
- Intravenous therapy with ceftriaxone can be used when a bacteremic route of spread is suspected or proven, such as that seen with *H influenzae* type b infections.[9] SOR Ⓐ
- For uncomplicated preseptal cellulitis, the usual duration of therapy is 7 to 10 days, depending on clinical response. SOR Ⓒ
- If significant clinical improvement is not observed within 24 to 48 hours of initiating appropriate antimicrobial therapy, a CT scan of the orbit to rule out orbital cellulitis and initiation of IV antibiotics should be considered. SOR Ⓒ

REFERRAL

- If the diagnosis is in doubt, or if there is poor response to initial therapy, consultation with ophthalmology, infectious diseases, and/or otolaryngology should be considered.

PROGNOSIS

- Most patients how have preseptal cellulitis do well with appropriate therapy. Complications such as local abscess formation, retro-orbital, and intra-cranial extension are extremely rare.

FOLLOW-UP

- Adequate follow up is essential, especially in the first 24 to 48 hours after initiation of therapy.

PATIENT EDUCATION

- Redness and/or swelling around the eye should be considered a potential serious problem and warrants medical attention.
- Close follow-up is needed with the provider to assure that the infection is resolving in an expected manner.

18 ORBITAL CELLULITIS

Dawood Yusef, MD
Camille Sabella, MD

PATIENT STORY

A 12-year-old boy is brought to the emergency room with progressive eye lid swelling and redness associated with blurring of vision for the past 24 hours. Physical examination is significant for left eye lid swelling, erythema, ptosis, and painful eye movements. A computed tomography (CT) scan of the orbit shows opacification of the paranasal sinuses with retro-orbital extension and abscess formation (**Figure 18-1**). He is diagnosed with orbital cellulitis and orbital abscess and he is admitted to the hospital for intravenous antibiotics, and otolaryngology and ophthalmologic evaluation. His orbital abscess is surgically drained and he completes a 3-week course of antibiotic therapy and recovers completely.

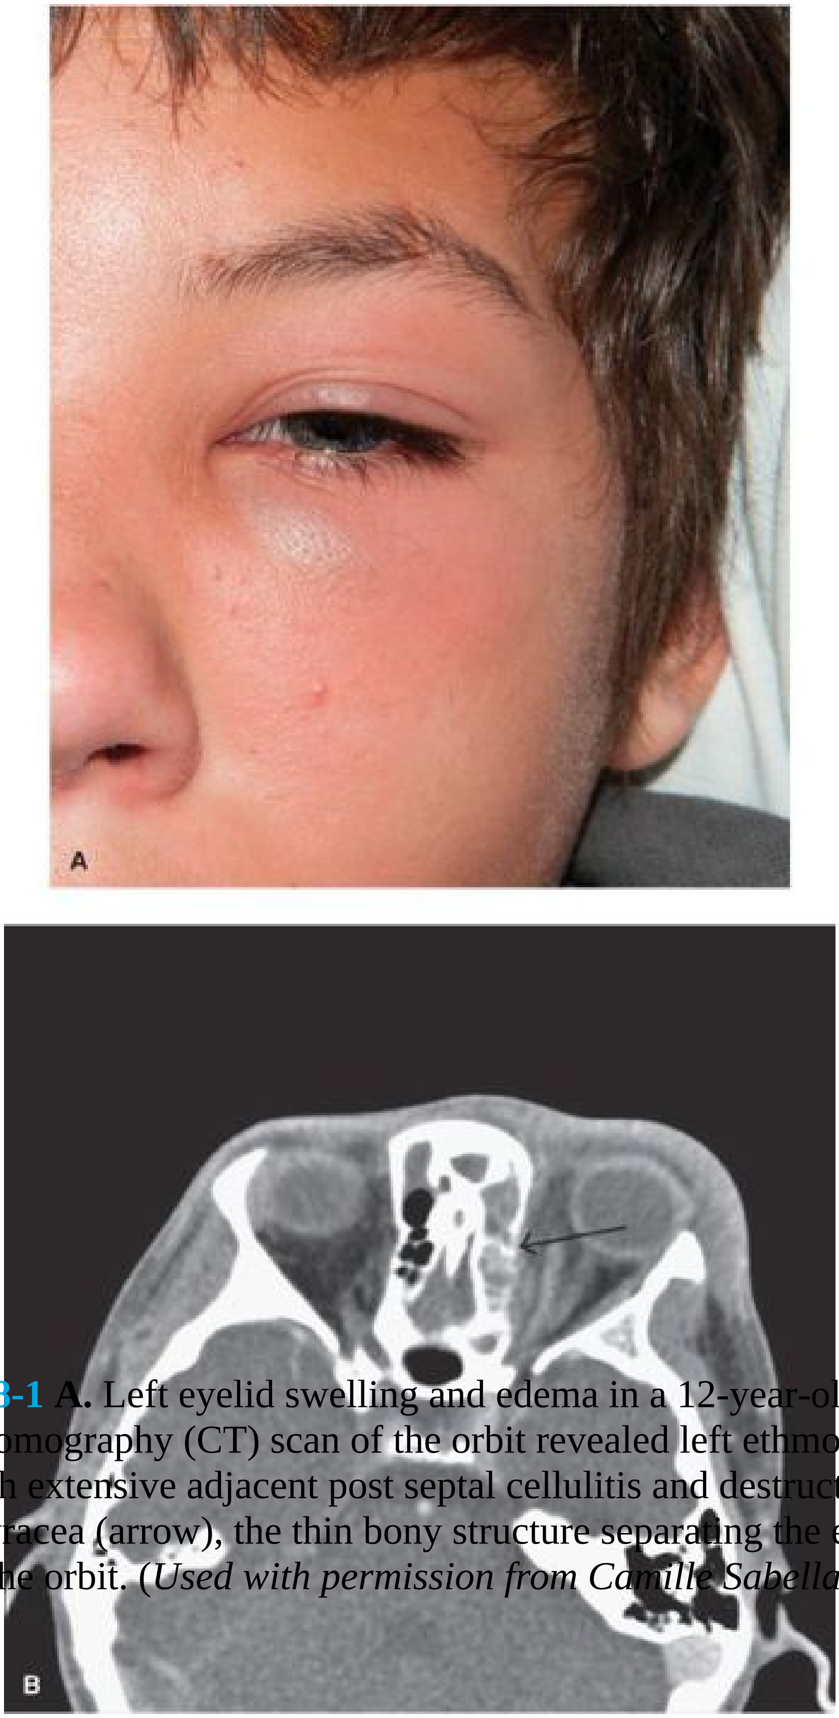

FIGURE 18-1 **A.** Left eyelid swelling and edema in a 12-year-old boy. **B.** Computed tomography (CT) scan of the orbit revealed left ethmoidal sinusitis with extensive adjacent post septal cellulitis and destruction of the lamina papyracea (arrow), the thin bony structure separating the ethmoid sinus from the orbit. (*Used with permission from Camille Sabella, MD*.)

INTRODUCTION

Orbital cellulitis is a serious infection of the orbit that involves the tissue located posterior to the orbital septum (postseptal cellulitis). Orbital cellulitis most commonly results as a complication of sinusitis, and should be distinguished from preseptal (periorbital) cellulitis, which involves the anterior portion of the septum (**Figure 18-2**).[1,2]

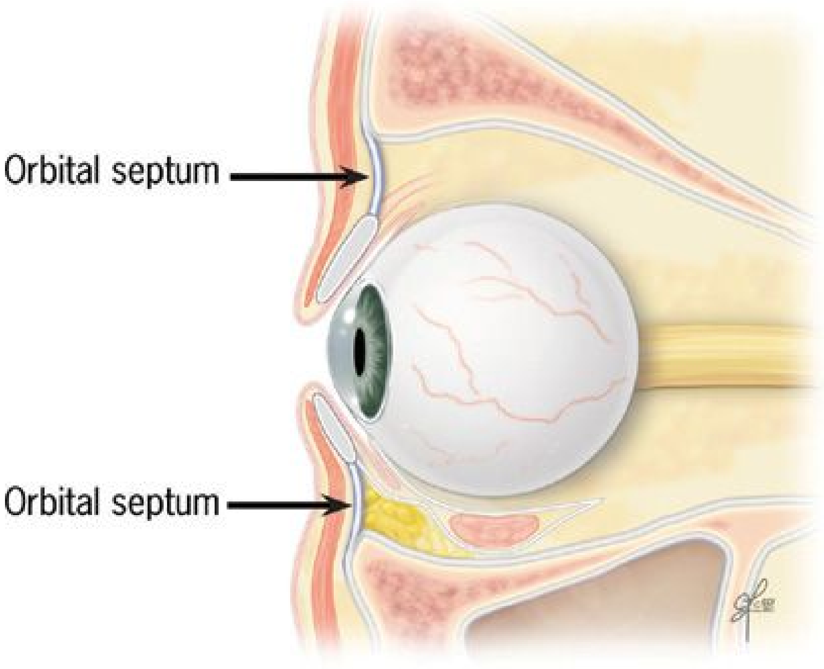

FIGURE 18-2 Illustration of a sagittal section of the orbit. The orbital septum is the anatomical landmark used to differentiate orbital (postseptal) from periorbital (preseptal) cellulitis. (*Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2013. All Rights Reserved*.)

SYNONYMS

- Post-septal cellulitis; orbital subperiosteal abscess.

EPIDEMIOLOGY

- Orbital cellulitis is mostly a disease of children, although it can be seen at any age.
- Most commonly occurs during the winter months because of the close association between upper respiratory viral infections, rhinosinusitis, and orbital cellulitis.

ETIOLOGY AND PATHOPHYSIOLOGY

- Orbital cellulitis in children is usually a complication of rhinosinusitis, especially ethmoidal sinusitis, which results in direct extension of the inflammation to the orbit.[1,3,4]
- The ethmoid sinuses are separated from the orbit by a thin and fenestrated bony structure called lamina papyracea. Loss of integrity of the lamina papyracea from inflammation results in orbital extension (**Figure 18-1**).
- Less common pathogenic causes of orbital cellulitis include penetrating trauma to the orbit, infection of the orbit following eye surgery, and bacteremic disease.
- The etiologic agent implicated depends on the mechanism of infection. *Streptococcus pneumoniae* is the most likely pathogen complicating acute sinusitis. *Staphylococcus aureus*, *Streptococcus anginosus*, and anaerobic bacteria warrant consideration when orbital cellulitis complicates chronic sinusitis. These pathogens as well as gram-negative aerobes need to be considered when the process is secondary to penetrating trauma.[1,3]
- At one time a very common pathogen, *Haemophilus influenzae* type b (Hib) has become a very rare cause of orbital cellulitis since the introduction of the Hib vaccine. However, this organism should always be considered as a potential cause of orbital cellulitis in unimmunized children.[5]

- Community-acquired methicillin-resistant *S aureus* (CA-MRSA) is an emerging pathogen causing orbital cellulitis.[6,7]
- Fungal infection (i.e., Aspergillus or mucormycosis) is a rare but life threatening cause of orbital cellulitis, occurring exclusively in immunocompromised hosts.

RISK FACTORS

- Ethmoidal sinusitis or pansinusitis.
- Upper respiratory tract infections.
- Incomplete or unimmunization.
- Eye surgery or trauma to the orbit.

DIAGNOSIS

- The diagnosis is usually made clinically and confirmed by the appropriate imaging study.

CLINICAL FEATURES

- Fever, unilateral eye pain, and eye lid swelling and erythema are the main features of orbital cellulitis (**Figures 18-1, 18-3, 18-4**).[1,4,7]

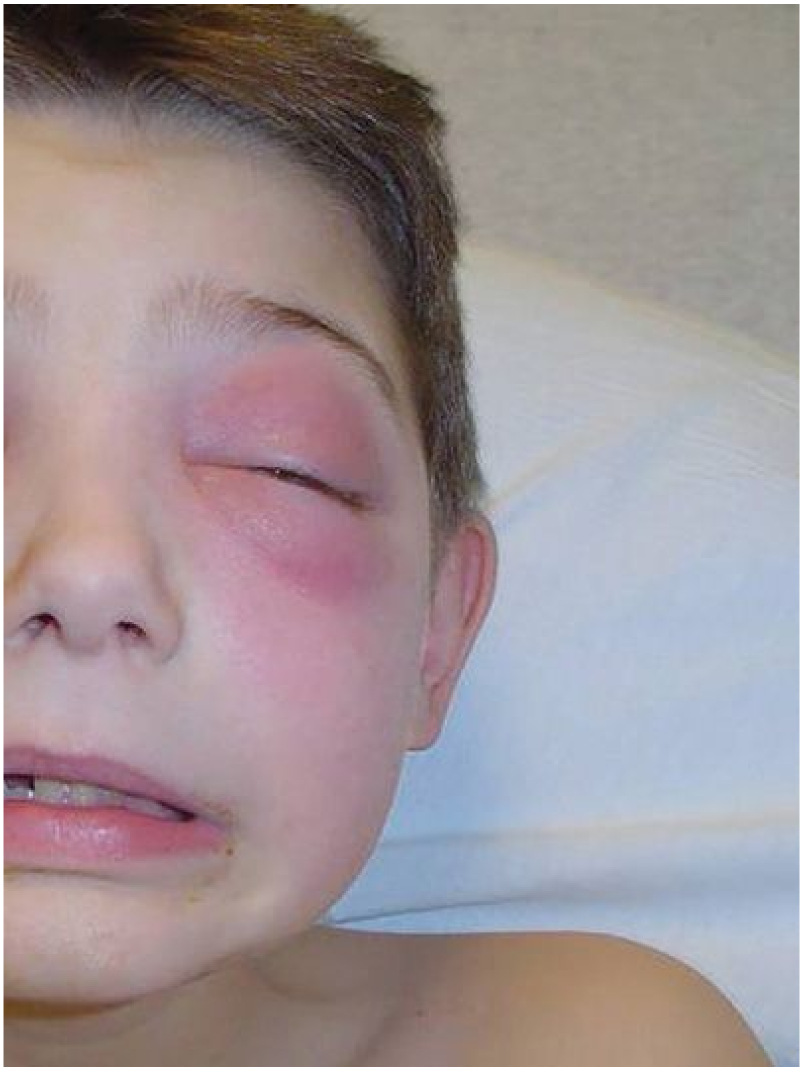

FIGURE 18-3 Orbital cellulitis in a 7-year-old boy. (*Used with permission from Camille Sabella, MD*.)

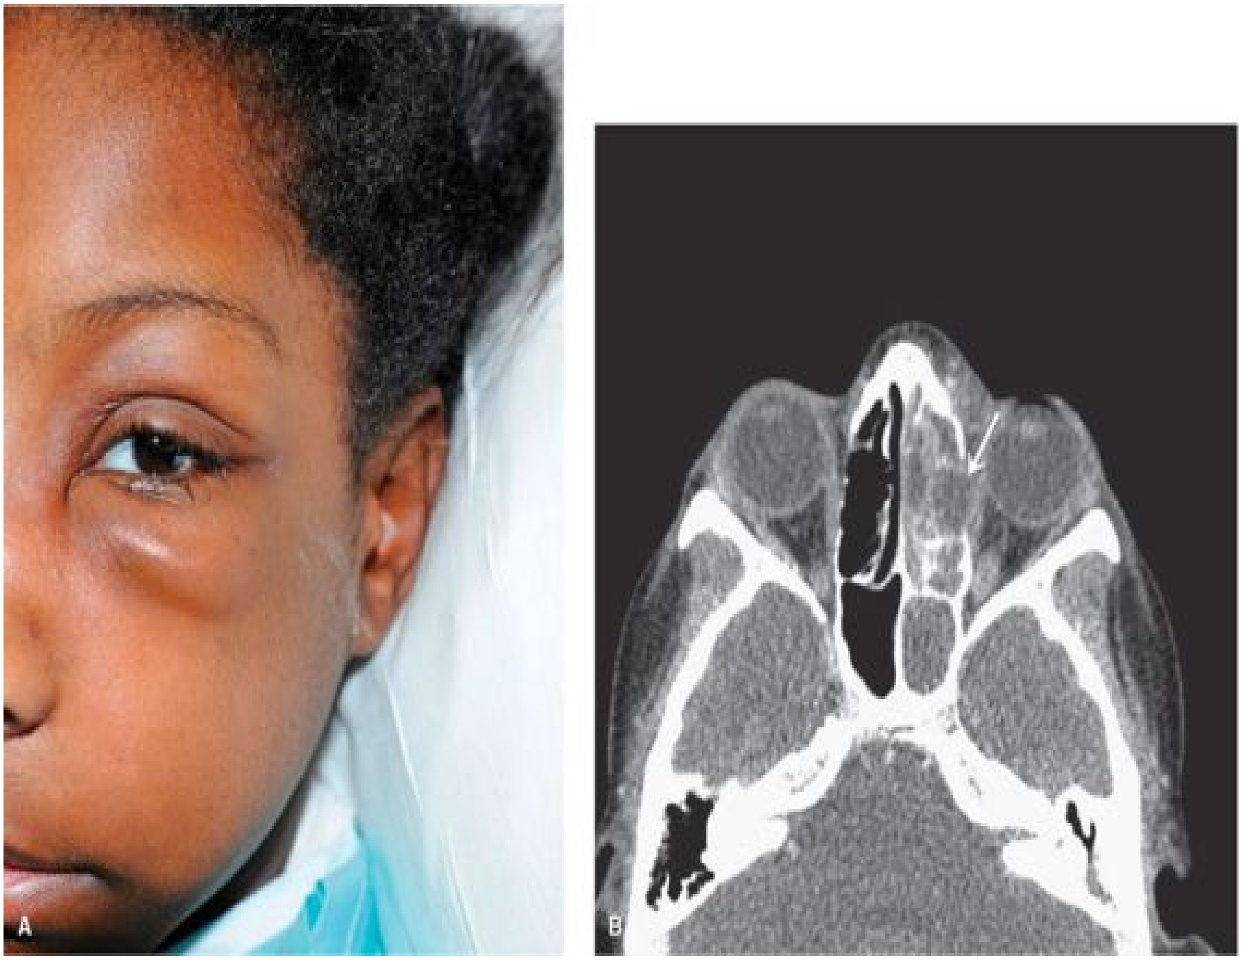

FIGURE 18-4 **A.** Left lower eyelid swelling and edema in a 9-year-old girl. **B.** CT scan revealed orbital cellulitis with a subperiosteal abscess (arrow) and extensive left-sided ethmoidal sinusitis. (*Used with permission from Camille Sabella, MD*.)

- Visual impairment, ophthalmoplegia, chemosis, and proptosis are distinctive clinical features that help distinguish orbital from preseptal cellulitis.[1,4]
- A history of sinus or upper respiratory tract infection, previous eye surgery, or trauma may help identifying the source of the infection.
- Headache, lethargy, altered mental status, or other signs of central nervous system involvement may indicate meningitis or intracranial extension.

DISTRIBUTION

- Almost always unilateral.

LABORATORY TESTING

- Peripheral leukocytosis is more common in orbital than in periorbital cellulitis.[1,2,6] However, this is neither a sensitive or specific marker for orbital cellulitis.
- Bacteremia is rare and is more common in children less than 2 years of age. These infants may have more systemic symptoms and/or peripheral leukocytosis.
- Eye drainage (clear or purulent) is not always present, and when present, culture of the material often is not predictive of the etiologic agent.
- No organism is isolated in the majority of cases, especially if surgical drainage is not performed.

IMAGING

- CT scan or magnetic resonance imaging of the orbit is used to confirm the diagnosis of orbital cellulitis.
- The presence of extensive inflammation of the retro-orbital space, especially adjacent to the ethmoid sinuses, confirms the diagnosis of orbital cellulitis (**Figures 18-1** and **18-4**).
- Orbital cellulitis may progress into a subperiosteal or an orbital abscess (**Figure 18-4**).
- Sinus involvement (sinus mucosal thickening or sinus opacification), especially of the ethmoidal sinuses, is usually present; a break in the integrity of the lamina papyracea is often appreciated (**Figures 18-1** and **18-4**).

DIFFERENTIAL DIAGNOSIS

- Preseptal cellulitis is an infection of the tissue anterior to the orbital septum, and can usually be distinguished from orbital cellulitis by the absence of proptosis and ophthalmoplegia (see Chapter 17, Preseptal (Periorbital) Cellulitis).
- Eye trauma, which may result in orbital cellulitis, is usually evident from the history.
- An allergic reaction usually results in bilateral swelling and pruritus, and the absence of fever and systemic signs of infection.
- An insect bite may result in preseptal cellulitis and can be distinguished clinically and by history.
- Eyelid edema due to hypoproteinemia or end organ failure usually is bilateral; history of chronic disease helpful in differentiating this entity.
- Hordeolum (stye)—Localized infection of the hair follicles of eye lashes or the eyelid glands, usually does not lead to significant swelling (see Chapter 10, Hordeolum and Chalazion).

MANAGEMENT

MEDICATIONS

- Children with orbital cellulitis should be hospitalized and empirically treated with broad spectrum parenteral antibiotics aimed at the most likely pathogens, based on the most likely mechanism of infection.
- A third generation cephalosporin such as ceftriaxone or cefotaxime is often combined with an antistaphylococcal agent such as clindamycin when the process is secondary to sinusitis.[1,3,7] SOR Ⓒ
- The need for empiric coverage against CA-MRSA depends on local prevalence and epidemiology.[6,8] SOR Ⓒ
- When the process is secondary to penetrating trauma or after a surgical procedure, more broad coverage may be required. In these situations,

vancomycin is often combined with an antipseudomonal agent such as ceftazidime and/or gentamicin. SOR Ⓒ

- The spectrum of antimicrobial therapy can be narrowed if culture results and susceptibilities are available.
- Intravenous therapy should be continued until the patient is nearly normal clinically. In uncomplicated orbital cellulitis, completing therapy with oral antibiotics may be appropriate. The usual duration is 2 to 3 weeks, depending on the clinical response.[1,3,6,7] SOR Ⓒ

SURGERY

- Surgical drainage may be required in cases of orbital or subperiosteal abscess, or in cases where there is a poor initial response to intravenous broad- spectrum antibiotics.[1,3,7] SOR Ⓒ
- Surgical drainage of the sinuses may also be needed in some cases.[6] SOR Ⓒ
- The drainage from purulent material obtained at the time of surgery should be sent for gram stain and culture to help guide antimicrobial therapy.

REFERRAL

- Ophthalmology, infectious diseases, and otorhinolaryngology often collaborate in cases of orbital cellulitis to determine optimal management.

PROGNOSIS

- Most patients with orbital cellulitis recover completely with antibiotic therapy and appropriate surgical intervention, when needed.
- Patients who develop severe complications, such as intracranial extension, cavernous sinus thrombosis, or vision loss, have a more guarded

prognosis.[1,7]

FOLLOW-UP

- Close monitoring of the infection for complications and to assess for the possible need for surgical intervention are important.
- Although clinical assessment is most important, repeat imaging studies may be required, especially if the response to therapy is slow.
- Long-term management of sinusitis may be required in some patients after recovery of the orbital process.

PATIENT EDUCATION

- Children who have redness or swelling around the eye, especially when associated with fever, impaired vision, or bulging of the eye, need immediate medical attention.
- Children who have signs and symptoms of sinusitis, such as severe and/or prolonged nasal congestion and cough, should be evaluated by their primary care physician.

19 EYE TRAUMA—HYPHEMA

Heidi Chumley, MD

PATIENT STORY

A 14-year-old boy was hit in the eye with a baseball and presented to the emergency department with eye pain, redness, and decreased visual acuity. There was a collection of blood in his anterior chamber (**Figure 19-1**) and he was diagnosed with a hyphema. He was given an eye shield for protection, advised to take acetaminophen for pain, and counseled not to engage in sporting activities until his hyphema resolved. He was referred urgently to ophthalmology and the eye was otherwise healthy. His hyphema resolved in 5 days.

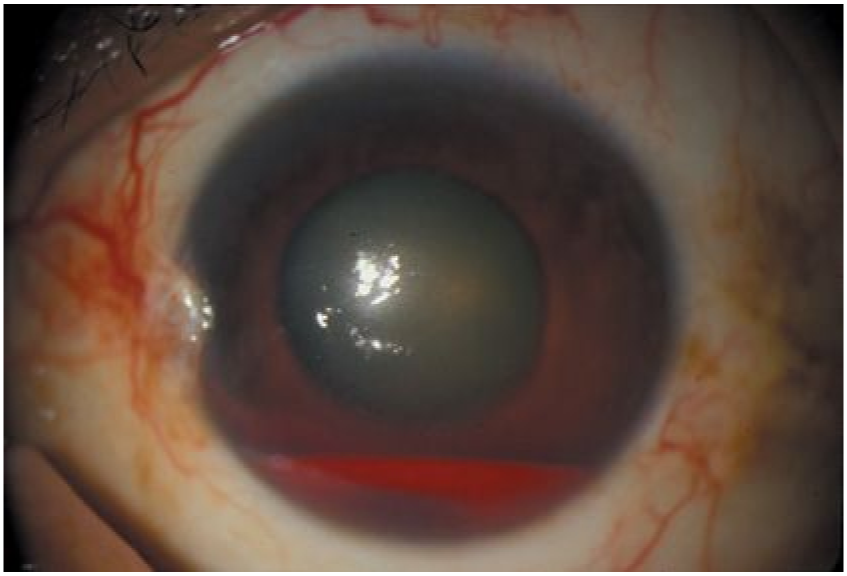

FIGURE 19-1 Layering of red blood cells in the anterior chamber following blunt trauma. This grade 1 hyphema has blood filling in less than 1/3 of the anterior chamber. (*Used with permission from Paul D. Comeau*.)

INTRODUCTION

Hyphema, blood in the anterior chamber, can be seen following eye trauma or as a result of clotting disturbances, vascular abnormalities, or mass effects from neoplasms. Traumatic hyphema occurs more often in boys and men, often related to work or sports. Hyphema typically resolves in 5 to 7 days, but some cases are complicated by rebleeding.

EPIDEMIOLOGY

- Hyphema occurs in 17 to 20 per 100,000 persons per year in the US.[1]
- Sixty percent of hyphemas result from sports injuries.[2] Sports with higher risk for eye injuries include paintball, baseball/softball, basketball, soccer, fishing, ice hockey, racquet sports, fencing, lacrosse, and boxing.

ETIOLOGY AND PATHOPHYSIOLOGY

- A hyphema is a collection of blood, mostly erythrocytes, that layer within the anterior chamber.
- Trauma is the most common cause, often resulting from a direct blow from a projectile object such as a ball, air pellet or BB, rock, or fist.
- Direct force to the eye (blunt trauma) forces the globe inward, distorting the normal architecture.
- Intraocular pressure rises instantaneously causing the lens/iris/ciliary body to move posteriorly, thus disrupting the vascularization with resultant bleeding.
- Intraocular pressure continues to rise and bleeding stops when this pressure is high enough to compress the bleeding vessels.

- A fibrin-platelet clot forms and stabilizes in 4 to 7 days; this is eventually broken down by the fibrinolytic system and cleared through the trabecular meshwork.

DIAGNOSIS

The diagnosis of hyphema is clinical, depending on the classic appearance of blood layering in the anterior chamber.

CLINICAL FEATURES

History and physical:

- Layered blood in the anterior chamber.
- History of eye trauma or risk factor for nontraumatic hyphema.
- Increased intraocular pressure (32%).
- Decreased vision.
- Hyphemas are classified according to the amount of blood in the anterior chamber:[1]
  - Grade 1: Less than 1/3 of the anterior chamber (see **Figure 19-1**); 58 percent of all hyphemas.
  - Grade 2: 1/3 to 1/2 of the anterior chamber; 20 percent of all hyphemas.
  - Grade 3: 1/2 to almost completely filled anterior chamber; 14 percent of all hyphemas.
  - Grade 4: Completely filled anterior chamber; 8 percent of all hyphemas.
- Eye trauma without hyphema (**Figures 19-2** and **19-3**) can lead to subconjunctival hemorrhage, anterior uveitis, and/or distortion of the normal architecture, including globe rupture.

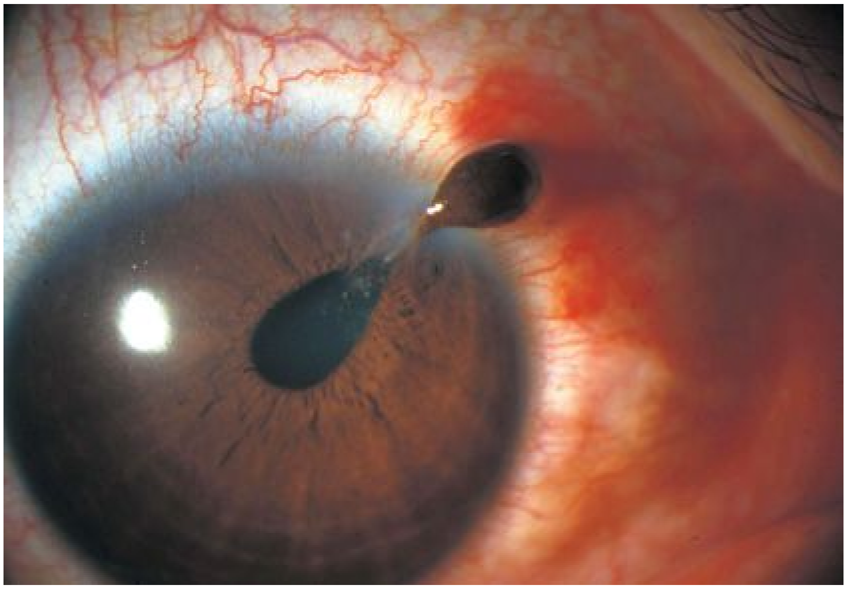

FIGURE 19-2 This young patient was hit in the eye with the corner of a laminated name card. The sharp edge perforated the cornea and pulled a portion of the iris out of the wound. Note the abnormal configuration of the pupil (dyscoria). No hyphema noted. This patient required emergent surgical repair. (*Reprinted with permission from Lo MW, Chalfin S. Retrobulbar anesthesia for repair of ruptured globes. Am J Ophthalmol. 1997;123(6):833–835. Photo by Paul D. Comeau*.)

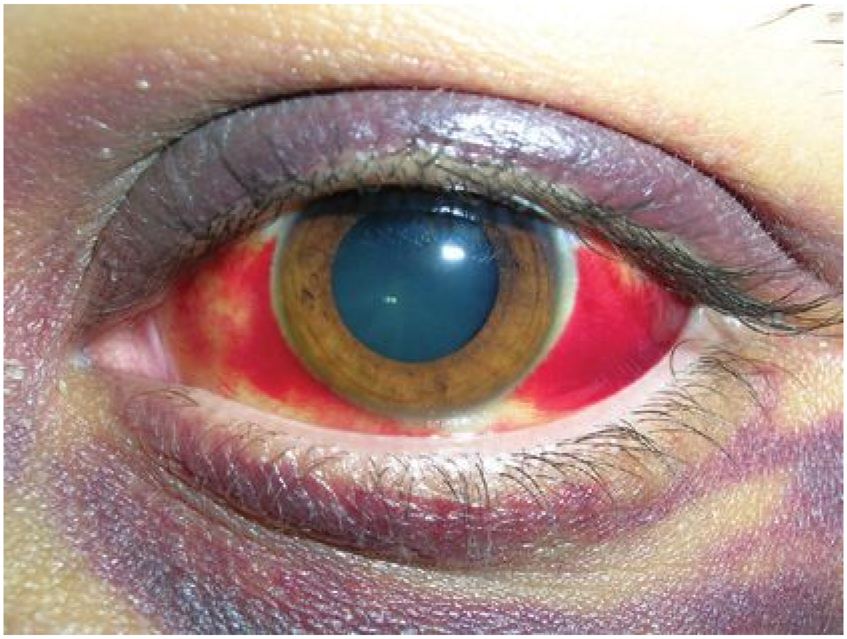

FIGURE 19-3 Subconjunctival hemorrhage and eyelid ecchymosis following accidental trauma. There was no hyphema present. (*Used with permission from Richard P. Usatine, MD*.)

LABORATORY TESTING (INCLUDE ANCILLARY TESTING, TOO)

- Consider laboratory tests to evaluate for bleeding disorders: Bleeding time, electrophoresis for sickle cell trait, platelet count, prothrombin and partial thromboplastin time, and liver tests.

IMAGING

- Consider CT imaging if a mechanism of injury suggests an associated orbital fracture or concern for orbital or intraocular foreign body.

DIFFERENTIAL DIAGNOSIS

Hyphema is an unmistakable physical examination finding that can be caused by any of the following:

- Trauma—History of trauma, including nonaccidental trauma (i.e., child abuse).
- Blood clotting disturbances—Personal or family history of bleeding disorder, little or no trauma, and black race (increased incidence of sickle trait and disease).
- Medication-induced anticoagulation—Chronic use of aspirin or warfarin and little or no trauma.
- Neovascularization—Diabetes with diabetic retinopathy, history of other ocular disease (central retinal vein occlusion), or history of prior eye surgery (cataract); without trauma, often painless, sudden, blurry vision.

- Melanoma or retinoblastoma—Variety of presentations depending on the size and location; hyphema occurs when mass effect sheers the lens/iris/ciliary body causing bleeding.
- Abnormal vasculature, that is, juvenile xanthogranuloma—Red to yellow papules and nodules in the eyes, skin, and viscera, most often present by 1 year of age.

MANAGEMENT

- Most hyphemas resolve in 5 to 7 days; management strategies protect the eye and decrease complications, including rebleeding.
- Evaluate or refer for evaluation for elevated intraocular pressure and other associated injuries. Urgent referral if concern for globe rupture.

A recent Cochrane review evaluated these interventions: antifibrinolytic agents, corticosteroids, cycloplegics, miotics, aspirin, conjugated estrogens, eye patching, head elevation, and bed rest.

- No interventions had a significant effect on visual acuity.
- Aminocaproic acid (antifibrinolytic) use resulted in a slower resolution of the primary hyphema.
- Antifibrinolytics: aminocaproic acid, tranexamic acid, and aminomethylbenzoic acid reduced the rate of secondary hemorrhage.[3]

NONPHARMACOLOGIC

- Eye patching, head elevation, and bed rest do not independently affect visual acuity. However, experts recommend to patch and shield the injured eye and allow the patient to remain ambulatory as part of a comprehensive treatment plan.[1] SOR Ⓒ

MEDICATIONS

- Although controversy remains about the best treatment, each of the following has been demonstrated to lower the risk of rebleeding in randomized-controlled trials:
    - Oral antifibrinolytic agents (aminocaproic acid 50 mg/kg every 4 hours for 5 days, not to exceed 30 g/day, or tranexamic acid 75 mg/kg per day divided into 3 doses).[4] SOR C
    - Topical aminocaproic acid (30% in a gel vehicle 4 times a day) is as effective as oral.[4] SOR C
    - Avoid aspirin and NSAIDs, which have been associated with higher rates of rebleeding.
    - Use acetaminophen, if needed, for pain.

REFERRAL OR HOSPITALIZATION

- Signs of a violated globe, such as a perforation of the cornea, conjunctiva or sclera, distorted ocular architecture, or exposed and/or distorted uveal tissue such as the iris (causing a peaked pupil), require immediate surgical evaluation and repair (see **Figure 19-2**).
- Surgical intervention has been recommended for patients with persistent total hyphema or prolonged elevated intraocular pressure.
- Outpatient management is acceptable for children if patient and parents are likely to be able to follow treatment plan.[4,5] SOR B

PREVENTION

Ninety percent of sports-related eye injuries can be prevented with appropriate eyewear.[6]

PROGNOSIS

The percentage of patients who regain 20/40 vision varies by severity of the hyphema: grade I, 80 percent; grade III, 60 percent; grade IV, 35 percent.[1]

FOLLOW-UP

Patients should be monitored daily for the first 5 or more days by a provider familiar with caring for hyphemas. Patient with a hyphema should be followed subsequently for signs of angle recession and high intraocular pressure, which predisposes the patient to traumatic glaucoma, an insidious cause of blindness in patients with a history of trauma.

PATIENT EDUCATION

- Complications include rebleeding, decreased visual acuity, posterior or peripheral anterior synechiae, corneal bloodstaining, glaucoma, and optic atrophy. Patients may need surgical or medical management for glaucoma.
- Patients who are more likely to rebleed include black patients (irrespective of sickle cell/trait status),[7,8] patients with a grade 3 or 4 hyphema, and patients with high initial intraocular pressure.
- Warn patients that they may have angle recession from traumatic causes of the hyphema. This will predispose the patient to a lifetime risk of traumatic glaucoma, which can cause blindness without any symptoms. These patients need to be monitored regularly by an ophthalmologist for increased pressure and glaucomatous nerve changes.

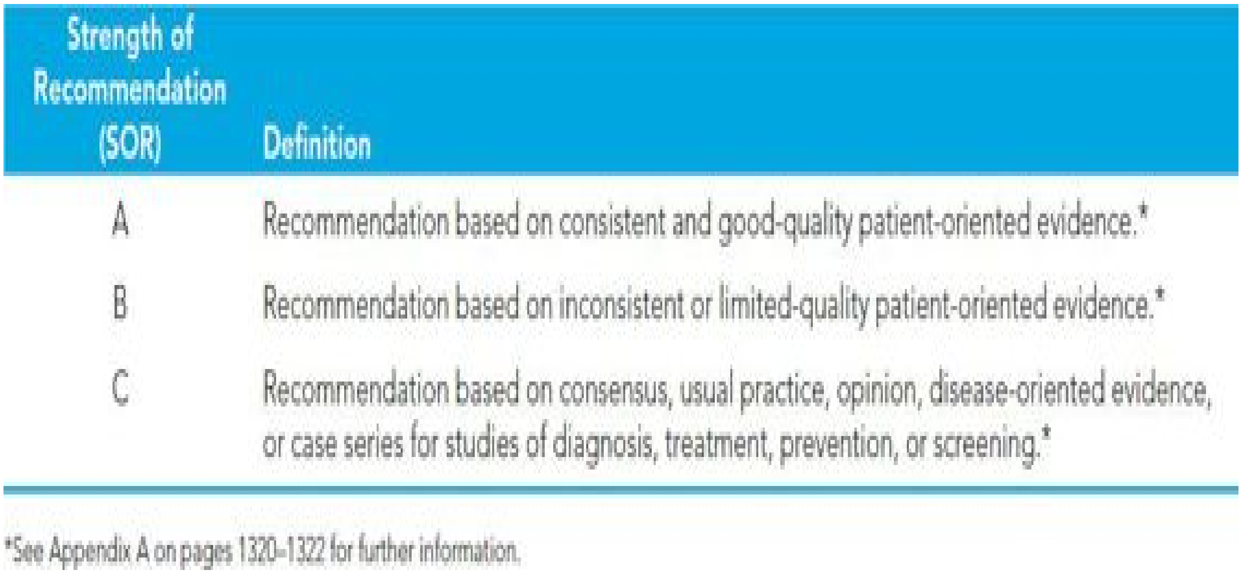
EAR, NOSE, AND THROAT



Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1320–1322 for further information.

SECTION 1 EAR

20 PREAURICULAR TAGS

Linda French, MD

PATIENT STORY

A 7-year-old boy comes into the office with his mother with complaint of a fleshy growth in front of his left ear (**Figure 20-1**). It has been present since birth. He passed his newborn hearing screen and the parents were told that it was nothing to worry about. Recently, other children have teased him about it and mom inquires about having it removed. He has no other congenital abnormalities evident to date and no chronic medical problems.

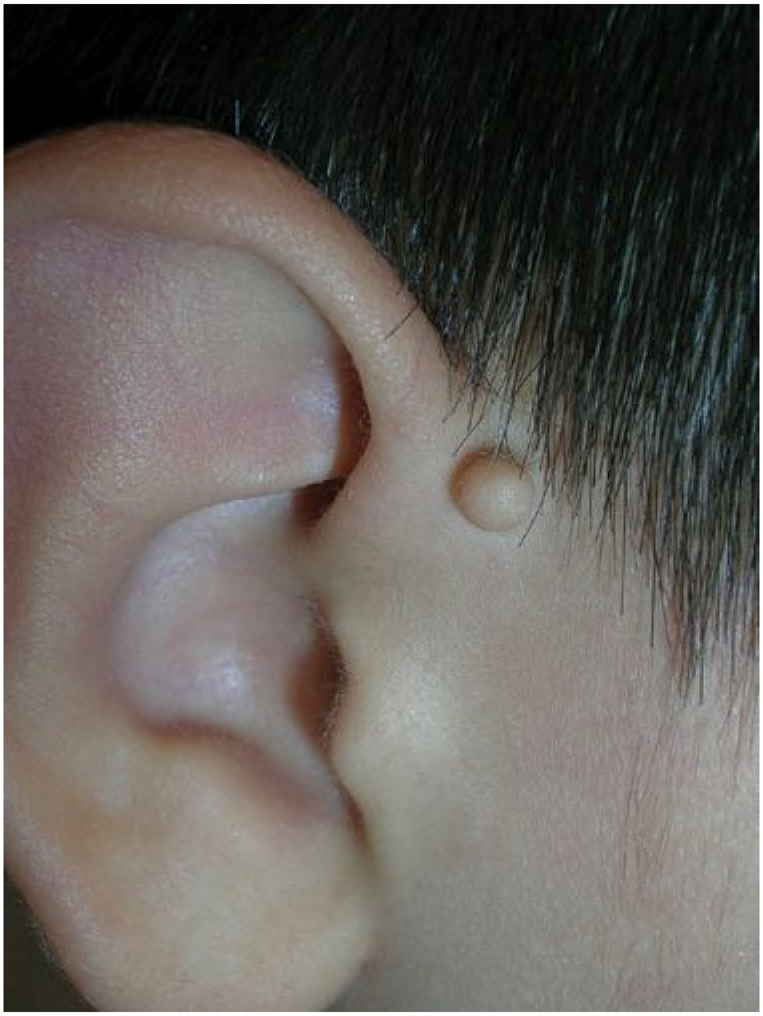


FIGURE 20-1 A preauricular skin tag in a 7-year-old boy. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Preauricular tags are benign congenital abnormalities consisting of epithelial mounds or pedunculated skin located near the front of the ear that can be associated with other conditions.

EPIDEMIOLOGY

- Occur in approximately 1 of 10,000 to 12,500 births without predilection for gender or race.
- Ear malformations may occur in isolation or as part of a constellation of abnormalities, often involving the renal system. Children have a five-fold risk of hearing impairment (8 of 10,000 vs. 1.5 of 10,000).[1]
- Postnatal hearing loss has not been associated with preauricular tags.[2]
- Several chromosomal abnormalities include preauricular tags as one of the phenotypic expressions.
- The Goldenhar syndrome includes preauricular skin tags, bilateral limbal dermoids of the eye and eyelid colobomas (see Chapter 34, Congenital Anomalies of the Head and Neck).

ETIOLOGY AND PATHOPHYSIOLOGY

- Arise from remnants of supernumerary brachial hillocks.[3]
- Early stage embryology involves the formation of several slit-like structures on the side of the head, the branchial clefts. The three hillocks between the first four clefts eventually form the structure of the outer ear. Preauricular tags are generally minor malformations arising from remnants of supernumerary branchial hillocks.[4]

DIAGNOSIS

- Based on physical examination.

CLINICAL FEATURES OF PREAURICULAR TAGS

- Fleshy knob in front of the ear (**Figures 20-1** to **20-5**).

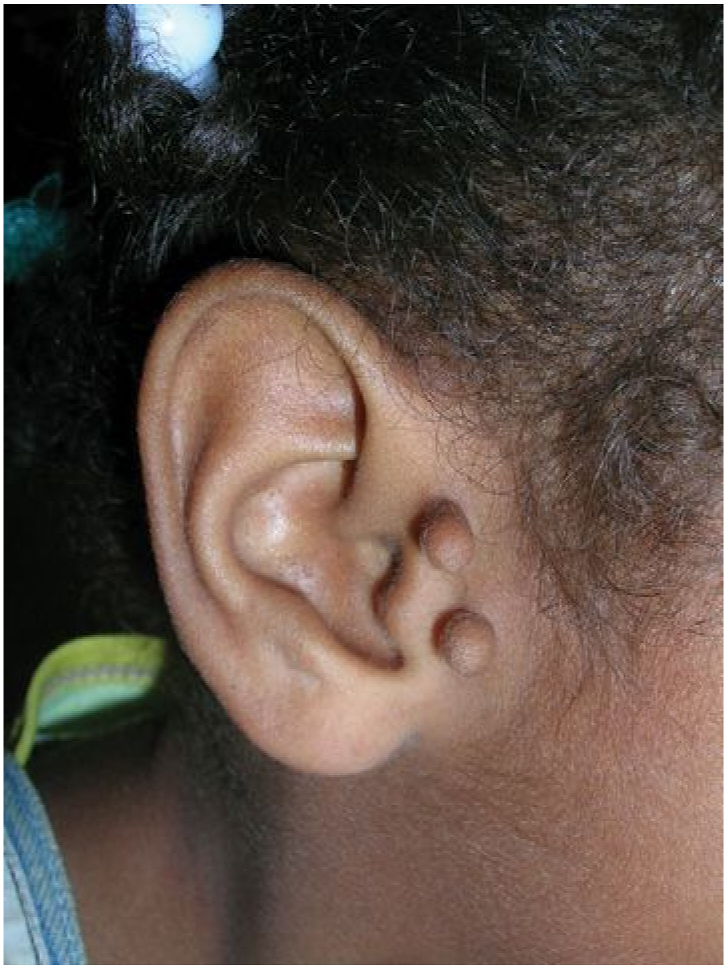

FIGURE 20-2 Two preauricular tags in a young black girl. (*Used with permission from Richard P. Usatine, MD*.)

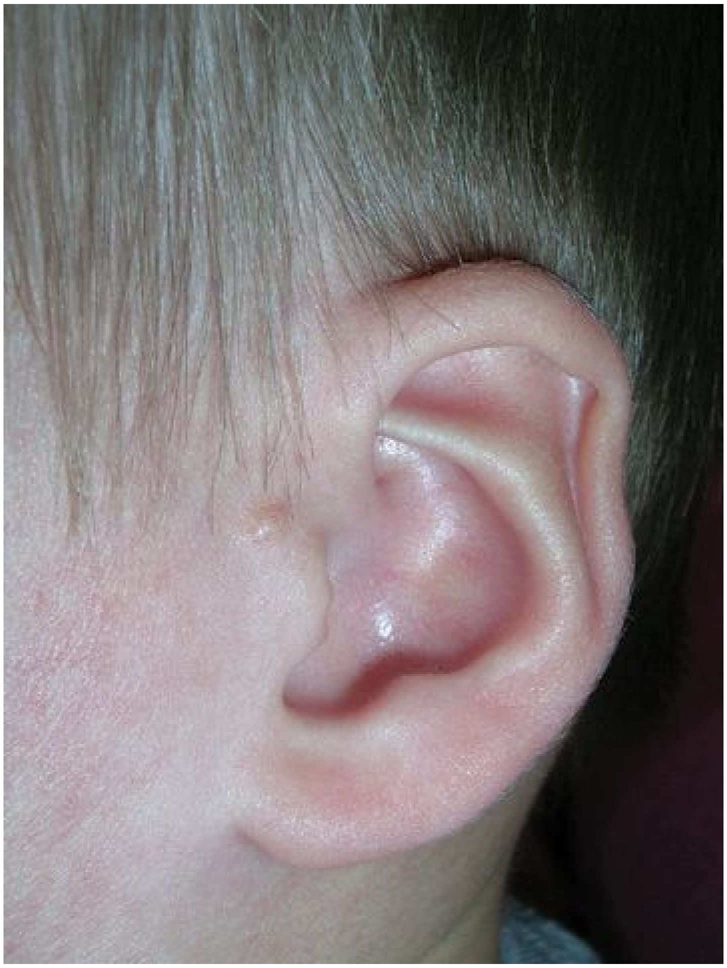

FIGURE 20-3 Preauricular tag in a 1-year-old boy. (*Used with permission from Richard P. Usatine, MD*.)

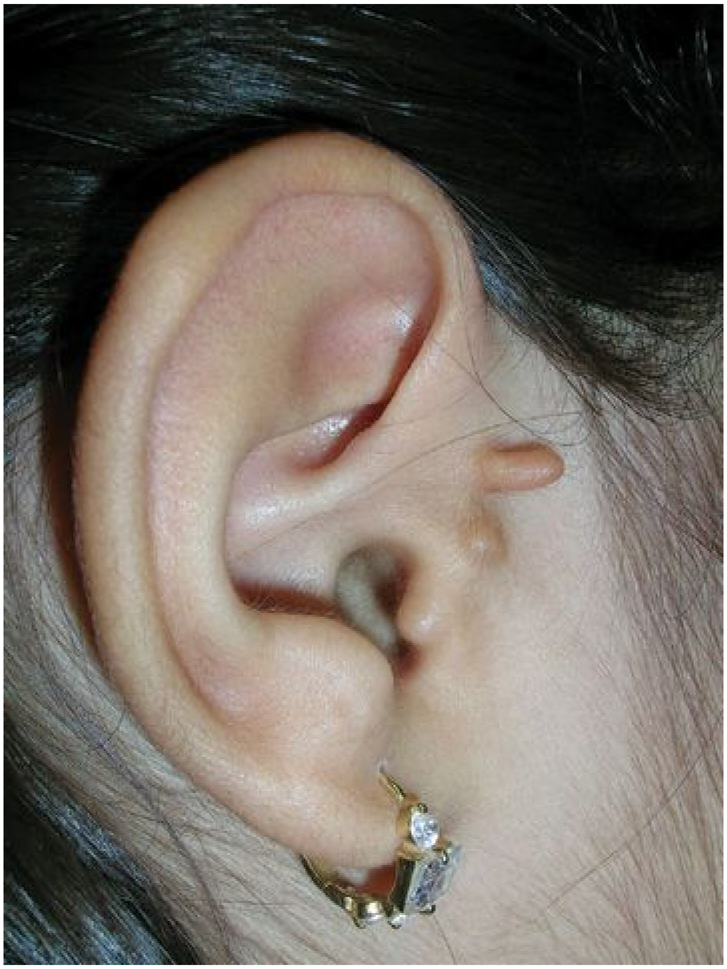

FIGURE 20-4 Two preauricular tags in a 4-year-old girl. (*Used with permission from Richard P. Usatine, MD*.)

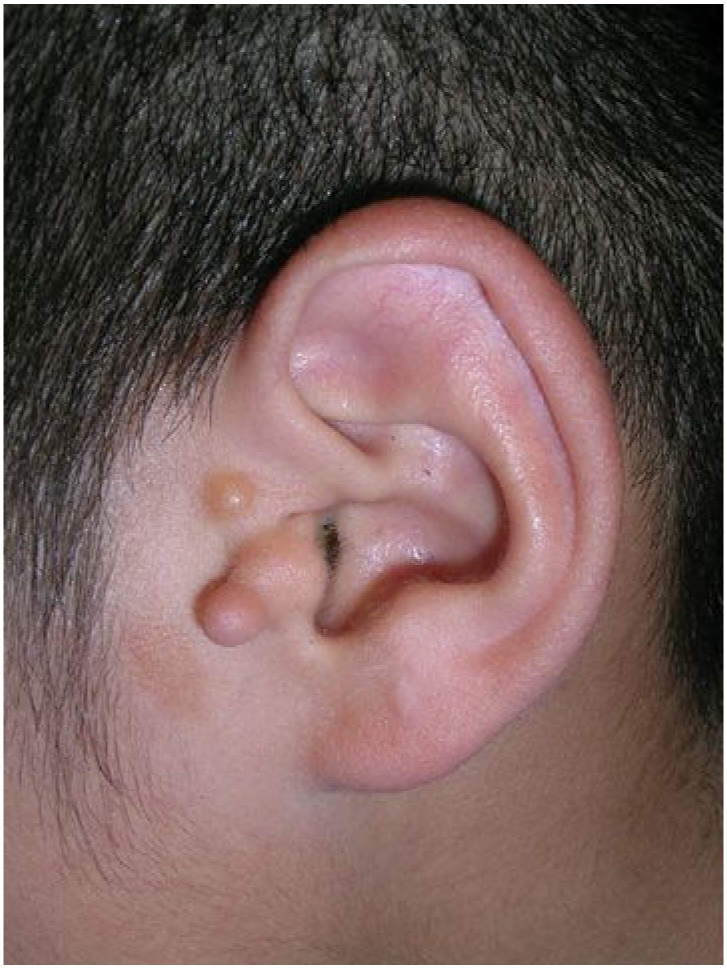

FIGURE 20-5 Two preauricular tags in a young boy. The lower preauricular tag may be considered an accessory tragus. (*Used with permission from Richard P. Usatine, MD*.)

- May be 2 tags on one side of similar or different sizes (**Figures 20-2**, **20-4**, and **20-5**).
- Present from the time of birth.
- Generally asymptomatic.

TYPICAL DISTRIBUTION

- Preauricular tags may be unilateral or bilateral, more often present on the left.

BIOPSY

- Not indicated for preauricular tag.

DIFFERENTIAL DIAGNOSIS

- The key issue in the diagnosis of preauricular tags is whether the ear tags are an isolated anomaly or part of a syndrome involving vital organs, especially the kidneys. There is no consensus about whether children with ear tags who otherwise appear to be healthy should be evaluated with renal ultrasound.[4,5]
- Accessory tragus is a preauricular tag that is adjacent to the normal tragus and may contain cartilage. The lower preauricular tag in **Figure 20-5** may be considered an accessory tragus.

MANAGEMENT

- Elective removal can be performed for cosmesis.

PATIENT RESOURCES

21 OTITIS EXTERNA

Brian Z. Rayala, MD
Camille Sabella, MD

PATIENT STORY

An 11-year-old girl with a history of psoriasis presented to her pediatrician with a 2-day history of ear pain and drainage from her right ear canal. On physical examination, she is well appearing and afebrile. She has exquisite pain on movement of her right pinna and dried drainage visible at the opening of her external auditory canal (EAC). Her EAC is erythematous and mildly edematous, but the tympanic membrane is visualized and appears normal. She also has psoriatic lesions around her ear and scalp as currently her psoriasis is not under control (**Figure 21-1**). The pediatrician makes the diagnosis of otitis externa and prescribes once daily ofloxacin drops for 7 days. The girl has a prompt response and recovers completely.

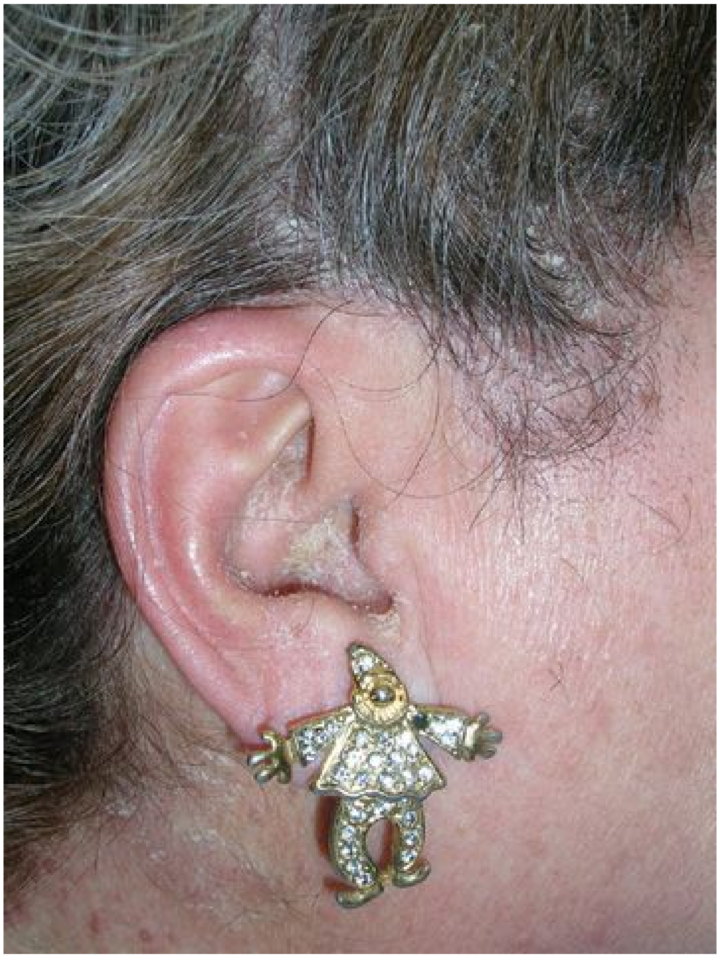

FIGURE 21-1 Dried drainage at the opening of the external ear canal in a girl with otitis externa. Note the psoriatic lesions, which predisposed this girl to otitis externa. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Otitis externa (OE) is common in all parts of the world. OE is defined as inflammation, often with infection, of the EAC.[1]

SYNONYMS

Swimmer’s ear.

EPIDEMIOLOGY

- Incidence of OE is not known precisely; its lifetime incidence was estimated at 10 percent in one study.[2]
- In temperate climates, it is more common in the summer.
- Associated with head immersion in water.

ETIOLOGY AND PATHOPHYSIOLOGY

- Common pathogens, which are part of normal EAC flora, include aerobic organisms predominantly (*P. aeruginosa and Staphylococcus aureus*) and, to a lesser extent, anaerobes (*Bacteroides* and *Peptostreptococcus*). Up to 1/3 of infections are polymicrobial. A small proportion (2% to 10%) of OE is caused by fungal overgrowth (e.g., *Aspergillus niger* usually occurs with prolonged antibiotic use).[1]
- Pathogenesis of OE includes the following:
  - Trauma, the usual inciting event, leads to breach in the integrity of EAC skin.
  - Skin inflammation and edema ensue, which, in turn, leads to pruritus and obstruction of adnexal structures (e.g., cerumen glands, sebaceous glands, and hair follicles).
  - Pruritus leads to scratching, which results in further skin injury.
  - Consequently, the milieu of the EAC is altered (i.e., change in quality and quantity of cerumen, increase in pH of EAC, and dysfunctional epithelial migration).
  - Finally, the EAC becomes a warm, alkaline, and moist environment—ideal for growth of different pathogens.

RISK FACTORS[3]

- Environmental factors:
  - Moisture—Macerates skin of EAC, increases pH, and washes away protective cerumen layer (e.g., swimming, sweating, humid environments).
  - Trauma—Leads to injury of EAC skin (e.g., cotton buds, fingernails, hearing aids, ear plugs, paper clips, match sticks, mechanical removal of cerumen).
  - Warm environments.
- Host factors:
  - Anatomical—Buildup of wax and debris that lead to retained moisture (e.g., a narrow ear canal, hairy ear canal).
  - Cerumen—Paucity of or excessive production of cerumen (results in disappearance of the protective layer and retained moisture, respectively).
  - Chronic skin disorder—for example seborrheic dermatitis, psoriasis, atopic dermatitis (**Figures 21-1** and **21-2**).

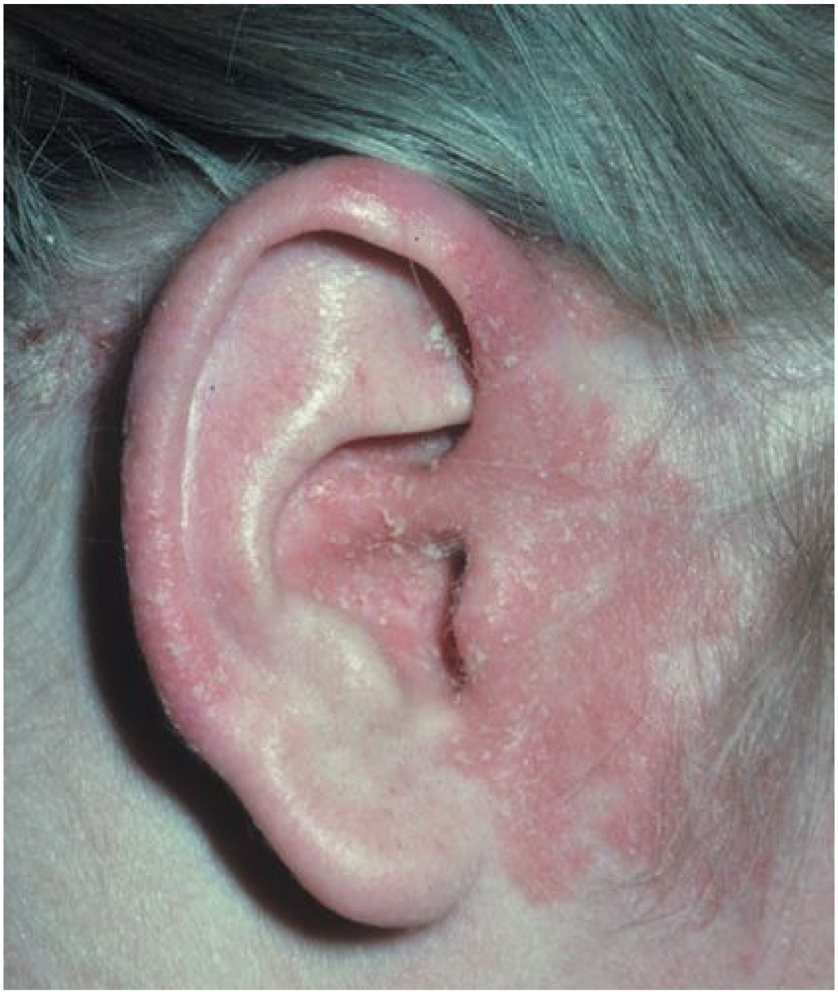

FIGURE 21-2 Seborrheic dermatitis causing erythema and greasy scale of the external ear and ear canal. The seborrheic dermatitis itself causes breaks in the skin and the coexisting pruritus may lead the patient to damage their own ear canal. All this can become secondarily infected. (*Used with permission from Eric Kraus, MD*.)

- Immunocompromise—for example HIV/AIDS, chemotherapy, diabetes, neutropenia.

DIAGNOSIS

CLINICAL FEATURES

- OE can either be localized, like a furuncle, or generalized (**Figures 21-1** to **21-3**). The latter is known as “diffuse OE,” or simply OE. Seborrheic dermatitis of the external ear and EAC can be diffuse or generalized (**Figures 21-1** and **21-2**).

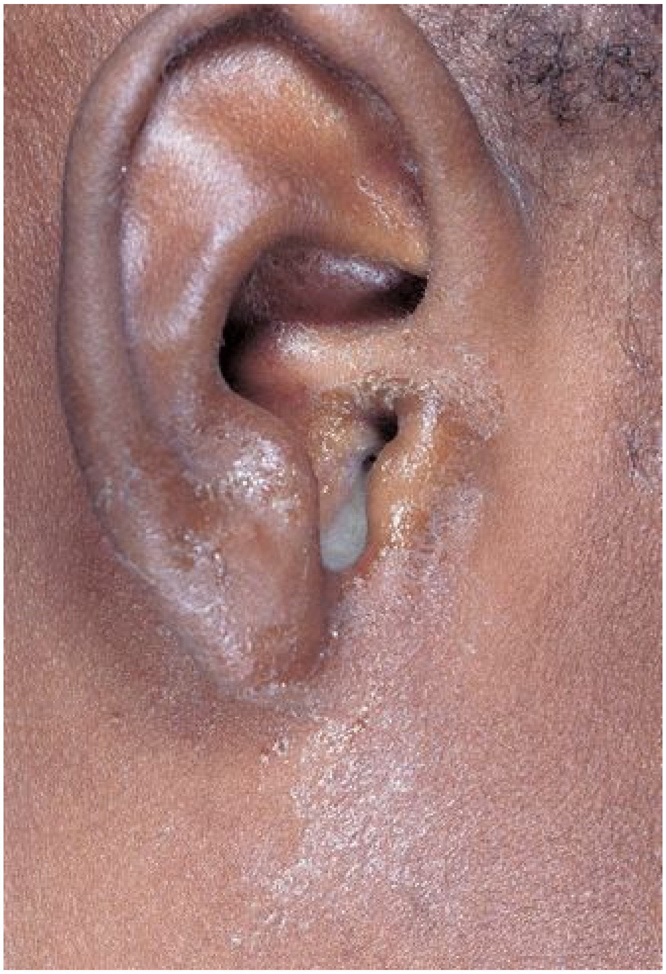

FIGURE 21-3 Purulent otorrhea in a child with otitis externa. (*Used with permission from Strange GR, Ahrens WR, Schafermeyer RW, Wiebe RA. Pediatric Emergency Medicine*, 3rd *edition: http://www.accessemergencymedicine.com*.)

- Forms of (diffuse) OE:[1]
  - Acute (<6 weeks; **Figures 21-3** and **21-4**).

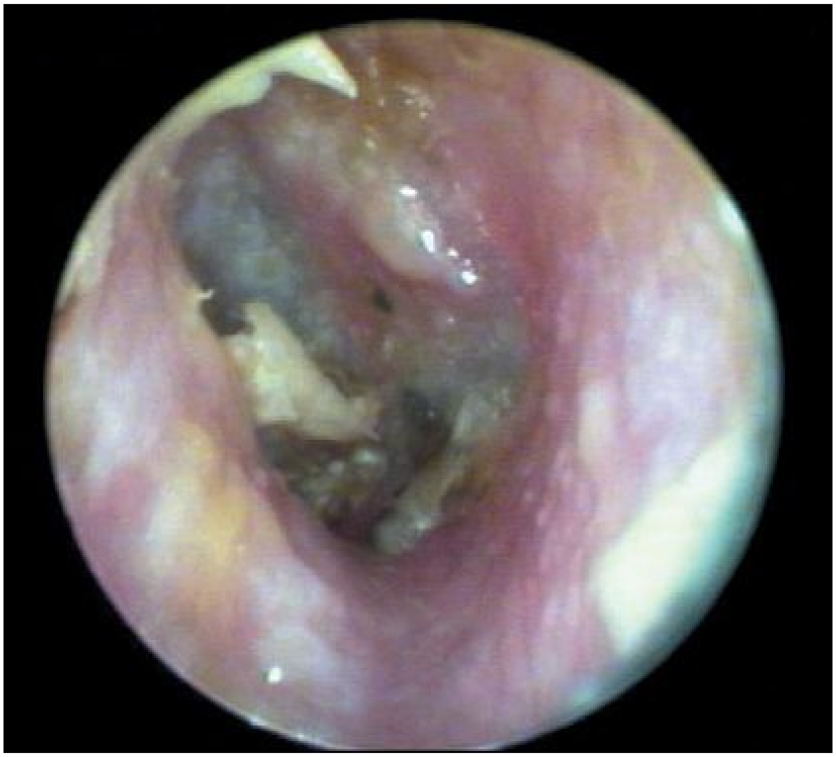

FIGURE 21-4 Acute otitis externa showing purulent discharge and narrowing of the ear canal. (*Used with permission from Roy F. Sullivan, PhD. Audiology Forum: Video Otoscopy, www.rcsullivan.com*.)

- Chronic (>3 months)—May cause hearing loss and stenosis of the EAC (**Figure 21-5**).

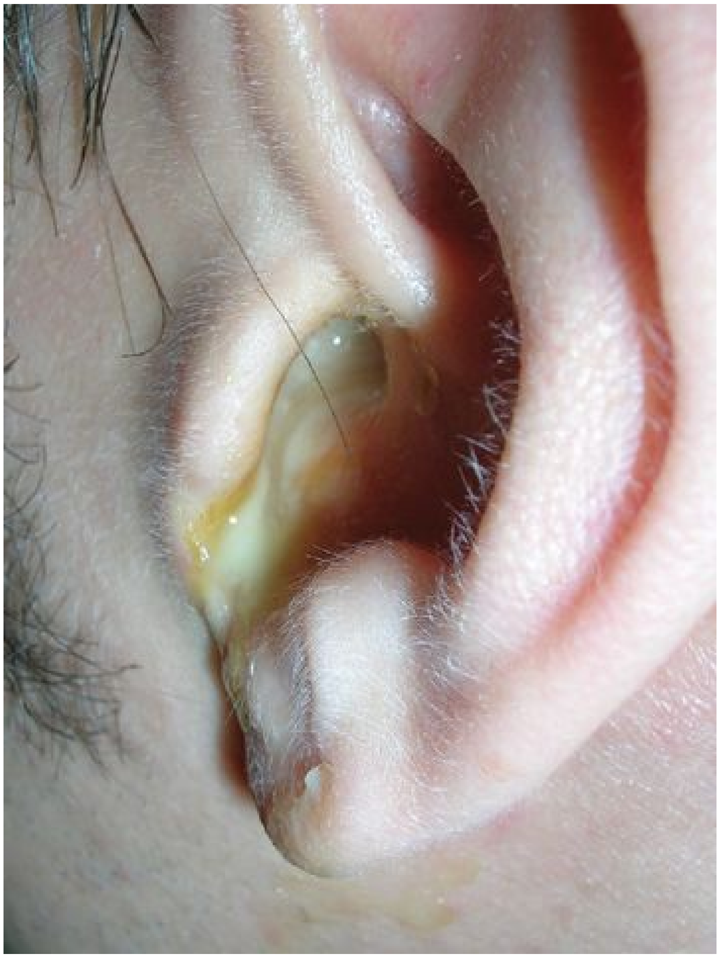

FIGURE 21-5 Chronic suppurative otitis media with purulent discharge chronically draining from the ear of this young man. This image could be seen in acute otitis media with perforation of the tympanic membrane or in a purulent otitis externa. (*Used with permission from Richard P. Usatine, MD*.)

- Necrotizing or malignant form—Defined by destruction of the temporal bone, usually in diabetics or immunocompromised people; often life-threatening (**Figure 21-6**).

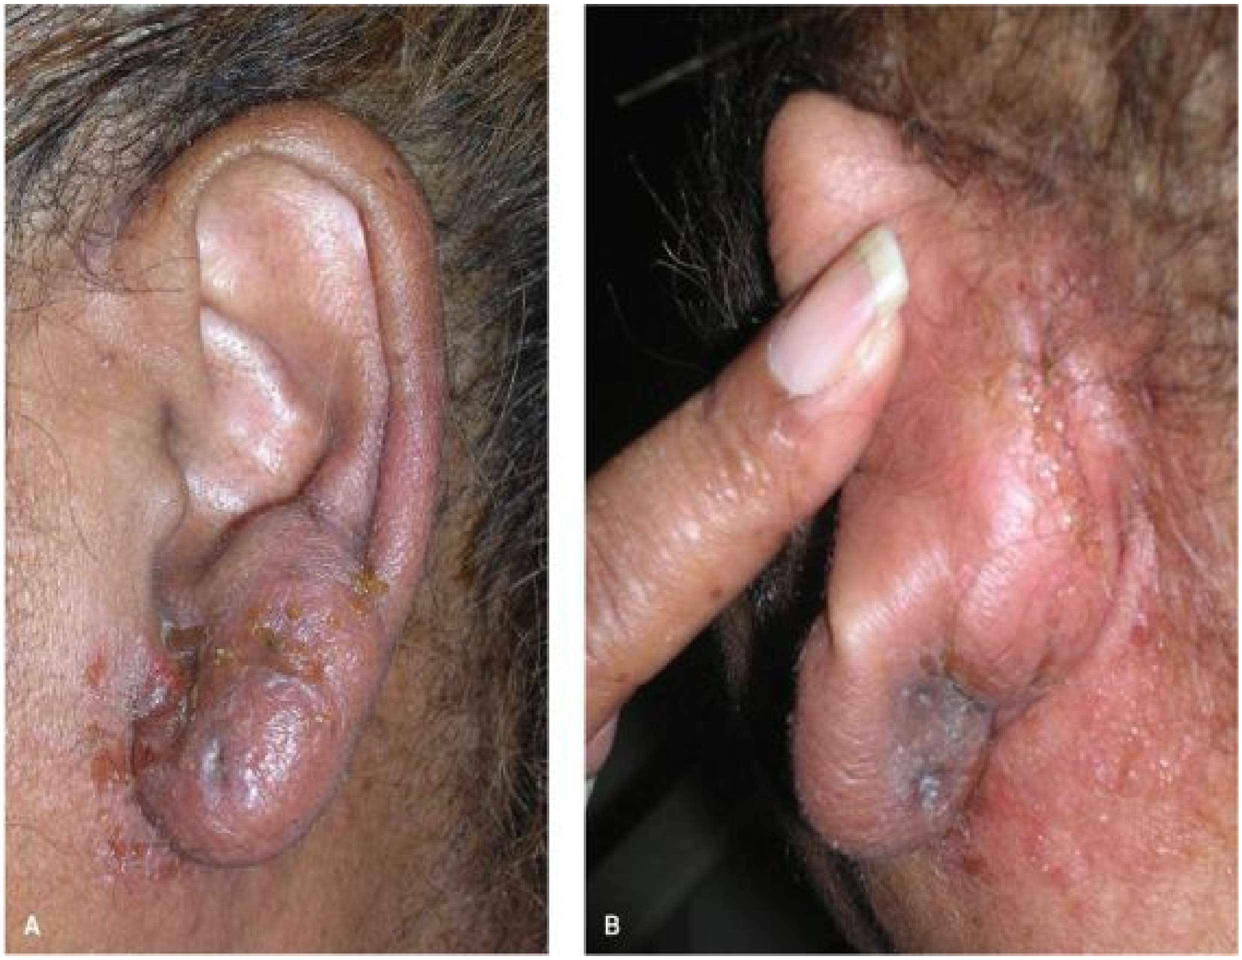

FIGURE 21-6 **A.** Malignant/necrotizing otitis externa in a young woman with diabetes. Note the swelling and honey-crusts of the pinna. The external auditory canal and temporal bone were involved. **B.** Posterior view of the swollen and infected ear. (*Used with permission from E.J. Mayeaux, MD.*)

- Key historical features include:
    - Otalgia, including pruritus.
    - Otorrhea (**Figures 21-3** to **21-5**).
    - Mild hearing loss.
- Key physical findings include:
    - Pain with tragal pressure or pain when the auricle is pulled superiorly; this may be absent in very mild cases.
    - Signs of EAC inflammation (edema, erythema, aural discharge) (**Figures 21-3** to **21-5**).

  - Fever, periauricular erythema, and lymphadenopathy point to severe disease.
  - Complete obstruction of EAC occurs in advanced OE.
- Establishing the integrity of the tympanic membrane (TM) (through direct visualization) and the absence of middle-ear effusion (through pneumatic otoscopy) is crucial in differentiating OE from other diagnoses (e.g., suppurative otitis media, cholesteatoma).

LABORATORY AND IMAGING

- Because OE is essentially a clinical diagnosis, diagnostic testing has a limited role. When a patient fails to respond to empiric treatment, obtaining a culture of aural discharge may help guide choice of treatment (antibacterial versus antifungal agents).
- If necrotizing or malignant OE is suspected, CT or MRI of the ear/skull base is warranted.

DIFFERENTIAL DIAGNOSIS

- Chronic suppurative otitis media—Otoscopy shows TM perforation; history reveals a chronically draining ear and recurrent middle-ear infections with or without hearing loss (**Figure 21-5**). At times, it is difficult to differentiate this from otitis externa because of edema and drainage in the EAC. In these cases, close follow-up in necessary in ensuring the integrity of the tympanic membrane.
- Seborrheic dermatitis involving the external ear and EAC can lead to inflammation and breaks in the skin (**Figures 21-1** and **21-2**). The coexisting pruritus can lead the patient to damage their own ear canal. This can all become secondarily infected.
- Acute otitis media with perforated TM—Presents with purulent drainage from the canal in the setting of ear pain and clinical signs or symptoms of acute illness such as fever. If the TM is visible, it will be red with a perforation.

- Foreign body in the EAC—Otoscopy, with or without aural toilet, confirms presence of foreign body (that incites an inflammatory response, leading to otalgia and otorrhea; see Chapter 24, Ear—Foreign Body).
- Otomycosis—Pruritus is generally more prominent and EAC inflammation (otalgia and otorrhea) is less pronounced; fungal organisms have a characteristic appearance in the EAC.
- Contact dermatitis—Usually caused by ototopical agents (e.g., neomycin, benzocaine, propylene glycol) or jewelry; prominent clinical features include pruritus, erythema of conchal bowl, crusting, and excoriations.

MANAGEMENT

NONPHARMACOLOGIC

- The effectiveness of ear cleaning is unknown.[3] SOR Ⓑ
- The effectiveness of specialist aural toilet (use of operating microscope to mechanically remove material from external canal) for treating OE is unknown.[1] SOR Ⓑ

MEDICATIONS

- The management of acute OE should include an assessment of pain. The clinician should recommend analgesic treatment based on the pain severity.[4] SOR Ⓑ
- Topical treatments alone are effective for uncomplicated acute OE. Additional oral antibiotics are not required.[3] SOR Ⓑ
- There is very limited evidence supporting the use of steroid-only drops for acute OE.[3] SOR Ⓑ
- Since most topical medications for OE are equally efficacious, choosing the appropriate treatment is influenced by other factors including cost,

availability, dosing frequency, risk of ototoxicity, risk of contact sensitivity, and risk of developing resistance.[3] SOR B

  - Evidence from one trial of low quality found no difference in clinical efficacy between quinolone and nonquinolone drops. Quinolones are more expensive than nonquinolones.[3] SOR B
  - Topical mixtures of antibiotics and steroids may reduce swelling, redness, drainage, and use of pain medications compared to preparations without steroids. High-potency steroids may be more effective in treating pain, inflammation and swelling than low-potency steroids.[3] SOR B
  - Acetic acid appears to be as effective as an antibiotic-steroid topical mixture after a week of therapy. In patients requiring extended therapy (>1 week). However, acetic acid was less effective and required a longer duration of treatment (i.e., 2 extra days).[3] SOR B
  - Topical aluminum acetate may be comparable to topical antibiotic-steroid medications in terms of cure rates for acute OE.[1] SOR B

- Patients can remain symptomatic for the first 6 days of therapy with topical antibiotic-steroid medications. The typical duration of therapy is 7 to 10 days. Since this standard approach may overtreat some patients and undertreat others, a good rule-of-thumb is to instruct patients to use antibiotic-steroid drops for a minimum of 1 week and to extend therapy, up to a maximum of 1 extra week, until resolution of symptoms.[3] SOR B

- The use of topical antifungal agents in OE, alone or with steroids, is not supported by evidence.[1] SOR B

- Necrotizing or malignant otitis externa: Management generally involves surgical debridement to remove necrotic tissue and intravenous antibiotics directed toward coverage of *P aeruginosa* and *S aureus* initially. An antipseudomonal agent such as pipercillin-tazobactam, ceftazidime, or cefipime, is often combined with gentamicin to treat *P aeruginosa*, and vancomcyin is used initially to cover *S aureus*. SOR C Results of cultures and histology obtained at the time of surgical debridement can guide subsequent therapy.

PREVENTION

- Prophylactic treatments to prevent OE (topical acetic acid, topical corticosteroids, or water exclusion) have not been evaluated in clinical trials.[1] SOR B

PROGNOSIS

- Acute OE often resolves within 6 weeks but can recur.

FOLLOW-UP

- If the patient fails to respond to empiric therapy within 48 to 72 hours, the clinician should reassess the patient to confirm the diagnosis of OE and to exclude other causes of illness.[4] SOR B
- Patients with symptoms that last more than 2 weeks have likely failed their initial therapy and should be considered for alternative therapy.[3] SOR B

PATIENT EDUCATION

- To avoid recurrent infections:[5]
    - Recommend that patients not use cotton swabs inserted into the ear canal.
    - Avoid frequent washing of the ears with soap as this leaves an alkali residue that neutralizes the normal acidic pH of the ear canal.
    - Avoid swimming in polluted water.
    - Ensure that the canals are emptied of water after swimming or bathing—This can be done by turning the head or holding a facial tissue on the outside of the ear to act as a wick.

- Consider ear drops for swimmers who get frequent OE. A combination of a 2:1 ratio of 70 percent isopropyl alcohol and acetic acid can be used after each episode of swimming to assist in drying and acidifying the ear canal.[5] SOR Ⓒ
- Do not use earplugs while swimming because they may cause trauma to the ear canal leading to OE.[5]

22 OTITIS MEDIA—ACUTE OTITIS AND OTITIS MEDIA WITH EFFUSION

Brian Z. Rayala, MD

PATIENT STORY

A 15-month-old boy is brought by both parents to his pediatrician with a 2-day history of fever, irritability, and frequent tugging of his left ear. This was preceded by a 1-week history of nasal congestion, cough, and rhinorrhea. On otoscopy, his left tympanic membrane (TM) appears erythematous, cloudy, bulging, and exudative (**Figure 22-1**). His left TM fails to move on pneumatic otoscopy. The physician diagnoses acute otitis media and decides with the parents to prescribe a 10-day course of amoxicillin; the child recovers uneventfully.

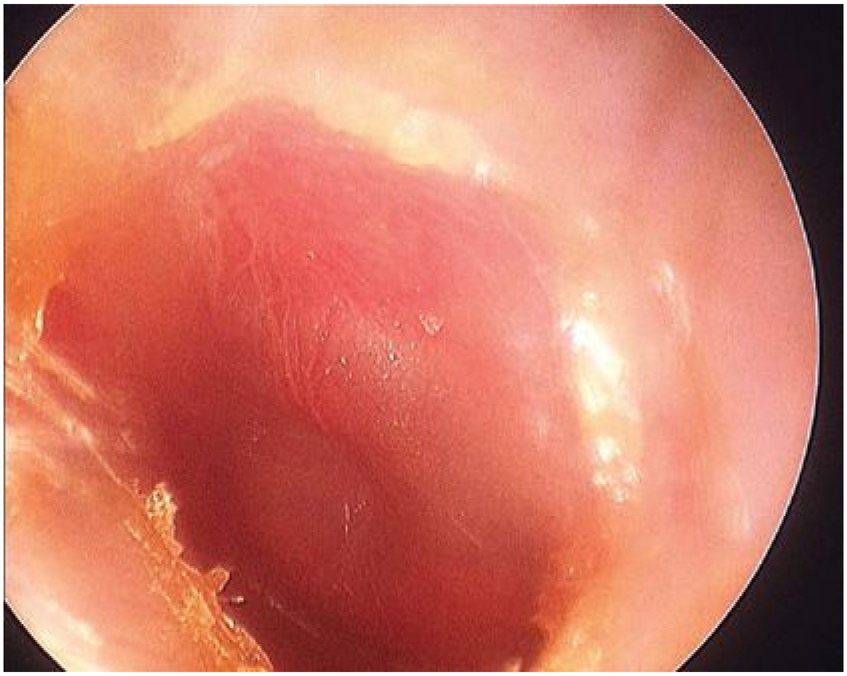

FIGURE 22-1 Acute otitis media in the left ear of a 15-month-old patient with marked erythema and bulging of the tympanic membrane. The malleus and light reflex are not visible. (*Used with permission from William Clark, MD*.)

In follow-up 2 months later, the child appears healthy and is meeting all his developmental milestones. On otoscopic examination, air–fluid levels are seen in the right ear (**Figure 22-2**). The physician explains the diagnosis of otitis media with effusion to the parents and arranges follow-up. Three months later the effusion is completely resolved.

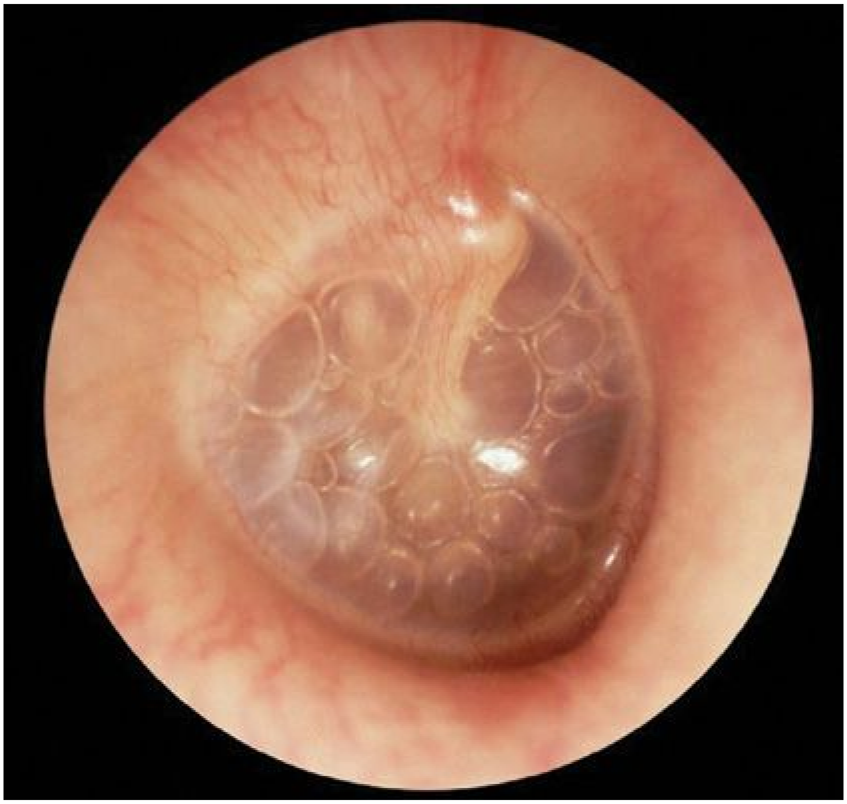

FIGURE 22-2 Otitis media with effusion (OME) in the right ear. Note multiple air–fluid levels in this slightly retracted, translucent, nonerythematous tympanic membrane. (*Used with permission from Frank Miller, MD*.)

INTRODUCTION

Acute otitis media (AOM) is the most common diagnosis for acute office visits for children.[1] AOM is characterized by middle-ear effusion in a patient with signs and symptoms of acute illness (e.g., fever, irritability, otalgia). Otitis media with effusion (OME) is a disorder characterized by fluid in the middle ear in a patient without signs and symptoms of acute ear infection; it is also very common in childhood.

EPIDEMIOLOGY

- AOM accounted for $5 billion of the total national health expenditure in 2000; more than 40 percent was incurred for children between 1 and 3 years of age.[1]
- It is estimated that 60 percent to 80 percent of children in the US develop AOM by 1 year of age and that 80 percent to 90 percent develop AOM by 2 to 3 years of age.[2,3]
- The highest incidence occurs between 6 and 24 months of age.[2,3]
- AOM is the most common reason for outpatient antibiotic treatment in the US.[4] A national survey in 1992 revealed that 30 percent of all antibiotics prescribed for children younger than age 18 years was for treatment of AOM.[5]
- OME is diagnosed in 2.2 million children yearly in the US.[6]
- Approximately 90 percent of children (80% of individual ears) have OME at some time before school age, most often between ages 6 months and 4 years.[6]
- The combined direct and indirect health care costs of OME amount to $4 billion annually.[6]

ETIOLOGY AND PATHOPHYSIOLOGY

AOM is often preceded by upper respiratory symptoms such as cough and rhinorrhea.

- Pathogenesis of AOM includes:[7]
  - Eustachian tube dysfunction (usually a result of an upper respiratory infection) and subsequent tube obstruction.
  - Increased negative pressure in the middle ear.
  - Accumulation of middle-ear fluid.
  - Microbial growth.
  - Suppuration (that leads to clinical signs of AOM).
- Most common pathogens in the US and United Kingdom are:[8,9]
  - Strains of *Streptococcus pneumoniae* not in the heptavalent pneumococcal vaccine (PCV7) (after introduction of PCV7 vaccine in 2000).
  - Nonencapsulated (nontypeable) *Haemophilus influenzae* (NTHi).
  - *Moraxella catarrhalis*.
  - *Staphylococcus aureus*.
- Viruses account for 16 percent of cases. Respiratory syncytial viruses, rhinoviruses, influenza viruses, and adenoviruses have been the most common isolated viruses.[10]

OME most commonly follows AOM; it may also occur spontaneously.

- Fluid limits sound conduction through the ossicles and results in decreased hearing.
- Reasons for the persistence of fluid in otitis media remain unclear, although potential etiologies include allergies, biofilm, and physiologic features.
- “Glue ear” refers to extremely viscous mucoid material within the middle ear and is a distinct subtype of OME.

RISK FACTORS

- The most important risk factors for AOM include young age and attendance at a child care center.
- Other risk factors include:[11]
    - White race.
    - Male gender.
    - History of enlarged adenoids, tonsillitis, or asthma.
    - Multiple previous episodes.
    - Bottle feeding.
    - History of ear infections in parents or siblings.
    - Use of a soother or pacifier.
- Second-hand smoke is a risk factor when parents smoke at home.
- Risk factors for OME include age 6 years or younger, large number of siblings, low socioeconomic group, frequent upper respiratory tract infection, tobacco exposure, daycare attendance, and bottle feeding.[12]

DIAGNOSIS

CLINICAL FEATURES OF AOM

- To diagnose AOM, the clinician should confirm a bulging TM using otoscopy, verify the acuteness of symptoms, *and* identify objective signs of middle-ear effusion (MEE) using pneumatic otoscopy and/or tympanometry.[6,13] SOR C
- Elements of the definition of AOM are:[6,13]
    - Signs or symptoms of middle-ear inflammation as indicated by:
        - Moderate to severe bulging of the TM *or* new otorrhea not attributable to acute otitis externa.
        - Mild bulging of the TM *and* recent onset (≤48 hours) of ear pain *or* intense erythema of the TM (**Figure 22-1**) in contrast to the normal TM (**Figure 22-5**).

- The presence of MEE. Although MEE is often presumed by bulging of the TM (**Figure 22-1**) or air–fluid level behind the TM (**Figure 22-2**), guidelines stress the use of objective measures of confirming MEE such as:
- Limited or absent mobility of the TM established by pneumatic otoscopy—The TM does not move during air insufflation; often initially seen as retraction of the TM (**Figures 22-3** and **22-4**).

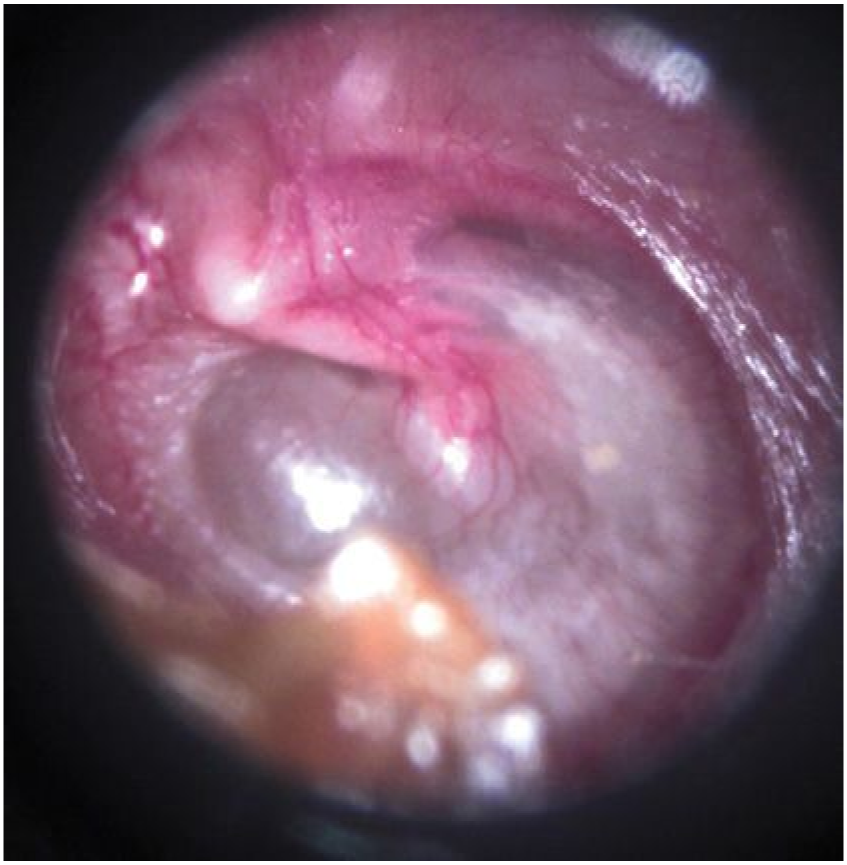

FIGURE 22-3 Otitis media with effusion in the left ear showing retraction of the tympanic membrane (TM) and straightening of the handle of the malleus as the retraction pulls the bone upward. (*Used with permission from Glen Medellin, MD*.)

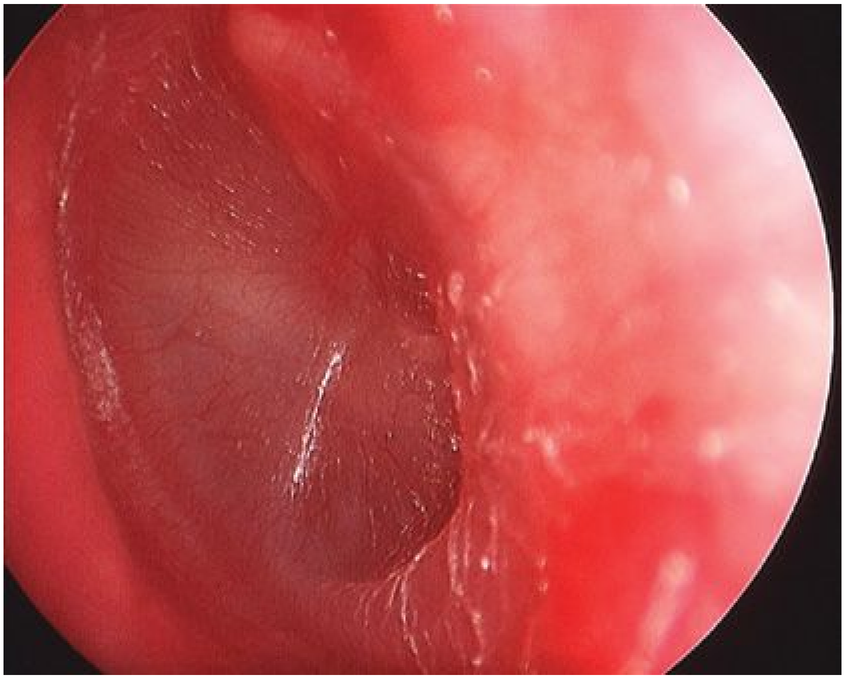

FIGURE 22-4 Early acute otitis media at the stage of eustachian tube obstruction. Note the slight retraction of the tympanic membrane (TM), the more horizontal position of the malleus, and the prominence of the lateral process. (*Used with permission from William Clark, MD.*)

  - Tympanometry demonstrating reduced or flat waveforms.

CLINICAL FEATURES OF OME

- The most common symptom, present in more than half of patients, is mild hearing loss. This is usually identified when parents express concern regarding their child's behavior, performance at school, or language development.[12]
- Absence of signs and symptoms of acute illness assists in differentiating OME from AOM.
- Common otoscopic findings include:
  - Air–fluid level or bubble (**Figure 22-2**).
  - Cloudy TM (**Figures 22-4** and **22-6**) in contrast to the normal TM (**Figure 22-5**).

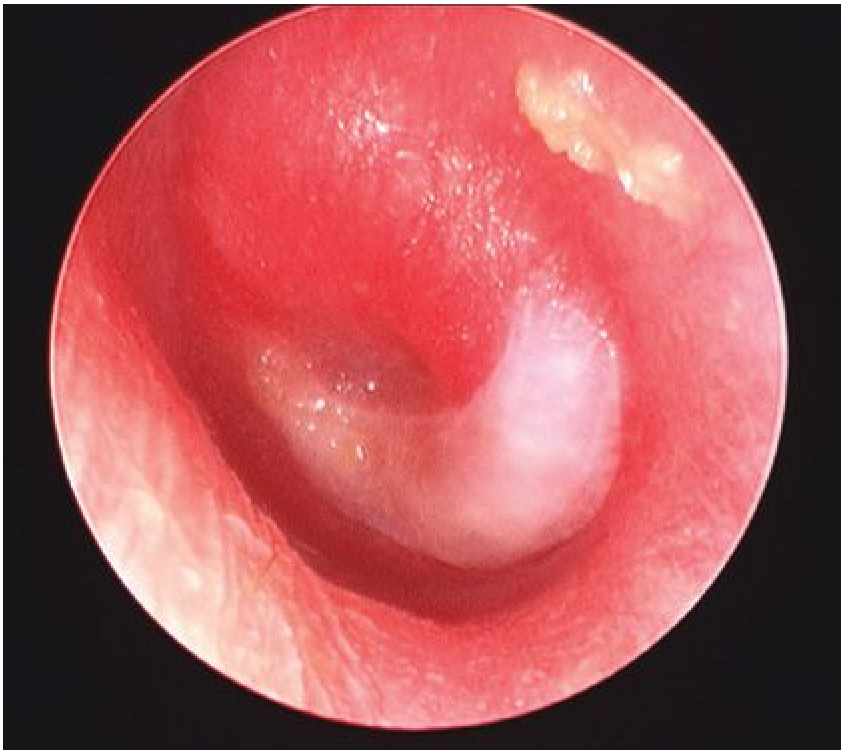

FIGURE 22-5 Acute otitis media, stage of suppuration. Note presence of purulent exudate behind the tympanic membrane (TM), the outward bulging of the TM, prominence of the posterosuperior portion of the drum, and generalized TM edema. The *white area* is tympanosclerosis from a previous infection. (*Used with permission from William Clark, MD*.)

B

FIGURE 22-6 **A.** Normal right tympanic membrane with comparison using. **B.** Normal bony landmarks of the inner ear. The ossicles were removed in this dissection. (*Used with permission from William Clark, MD*.)

- Redness of the TM is present in approximately 5 percent of ears with OME.

- Clinicians should use pneumatic otoscopy as the primary diagnostic method for OME.[14] SOR Ⓐ
  - Impaired mobility of the TM is the hallmark of MEE.
  - According to a metaanalysis, impaired mobility on pneumatic otoscopy has a pooled sensitivity of 94 percent and specificity of 80 percent, and positive likelihood ratio of 4.7 and negative likelihood ratio of 0.075.[14]

LABORATORY TESTS AND IMAGING

- Because AOM and OME are clinical diagnoses, diagnostic testing has a limited role. When clinical presentation and physical examination (including otoscopy) do not establish the diagnosis, the following can be used as adjunctive techniques:
  - Tympanometry—This procedure records compliance of the TM by measuring reflected sound. AOM and OME will plot as a reduced or flat waveform. This technique requires patient cooperation but provides more objective data.
  - Acoustic reflectometry—This procedure, very similar to tympanometry, measures sound reflectivity from the middle ear. With this test, the clinician is able to distinguish air- or fluid-filled space without requiring an airtight seal of the ear canal.
  - Middle ear aspiration—For patients with AOM, aspiration may be warranted if patient is toxic, immunocompromised, or has failed prior courses of antibiotics.

DIFFERENTIAL DIAGNOSIS

The key differentiating feature between AOM and OME is the absence of signs and symptoms of acute illness in OME (e.g., fever, irritability, otalgia). Otoscopic findings may be similar. Other clinical entities that can be confused with AOM and OME include:

- Otitis externa—Otitis externa presents with otalgia, otorrhea and mild hearing loss, all of which can be present in AOM. Tragal pain on physical exam and signs of external canal inflammation on otoscopic exam differentiate it from AOM. Careful ear irrigation if tolerated may be helpful to visualize the TM to differentiate otitis externa from AOM (see Chapter 21, Otitis Externa).
- Otitic barotrauma—This often presents with severe otalgia. Key historical features include recent air travel, scuba diving, or ear trauma, preceded by an upper respiratory infection.
- Cholesteatoma—Unlike AOM, this is a clinically silent disease in its initial stages. Presence of white keratin debris in the middle ear cavity (on otoscopy) is diagnostic (**Figures 22-7** and **22-8**).

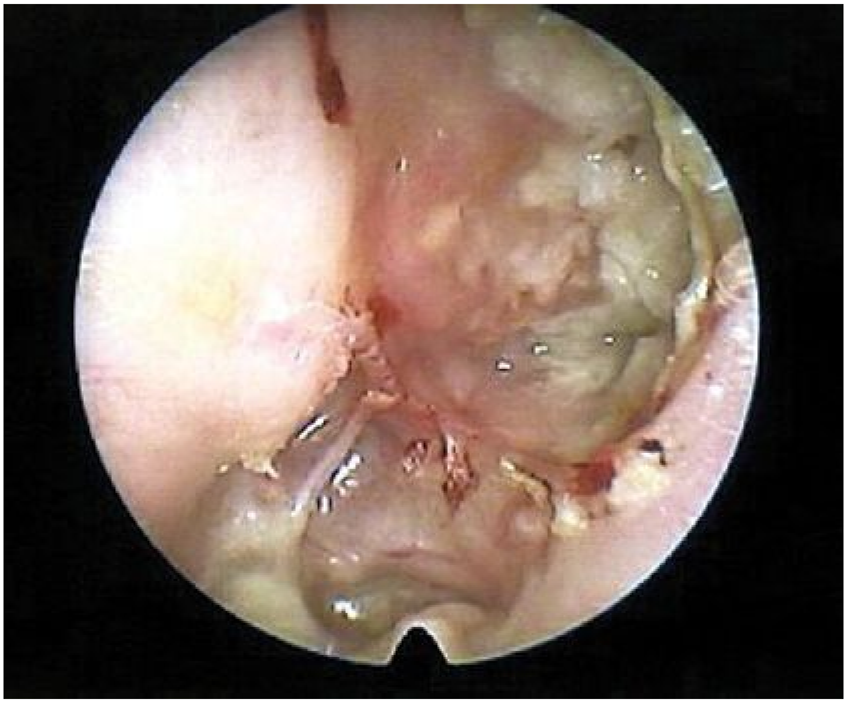

FIGURE 22-7 Cholesteatoma. (*Used with permission from Vladimir Zlinsky, MD, in Roy F. Sullivan, PhD. Audiology Forum: Video Otoscopy, www.rcsullivan.com*.)

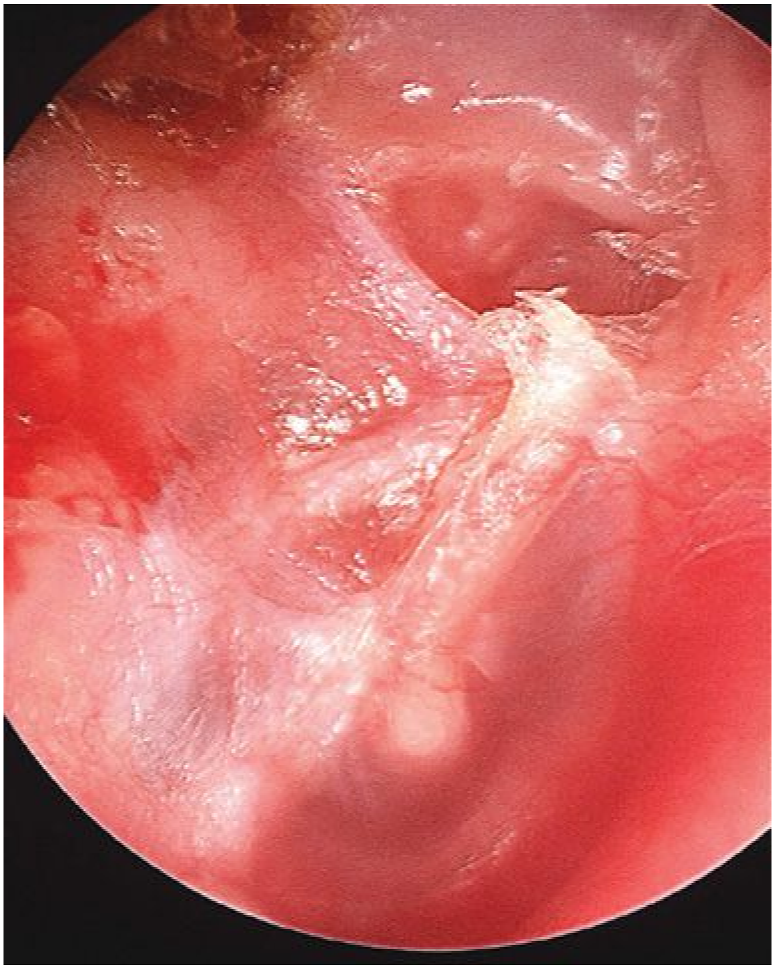

FIGURE 22-8 Primary acquired cholesteatoma with debris removed from the attic retraction pocket. (*Used with permission from William Clark, MD*.)

- Foreign body—A foreign body may present with otalgia. Otoscopy reveals presence of foreign body (see Chapter 24, Ear—Foreign Body).
- Bullous myringitis—Bullous myringitis is often associated with viral or mycoplasma infection as well as usual AOM pathogens; in approximately 1/3 of patients, there is a component of sensorineural hearing loss. Otoscopy shows serous-filled bulla on the surface of the TM (**Figure 22-9**). Patients present with severe otalgia.

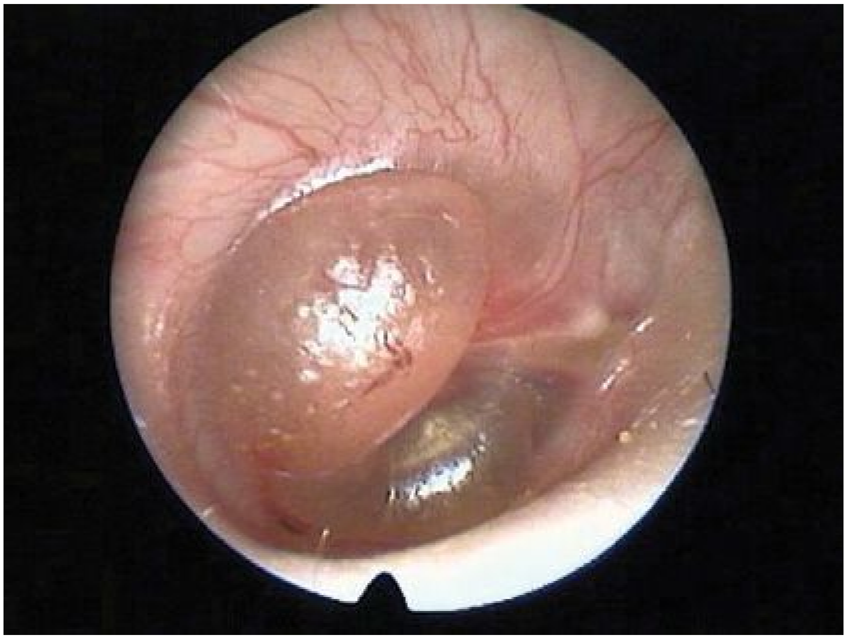

FIGURE 22-9 Bullous myringitis can be differentiated from otitis media with effusion by identifying serous-filled bulla on the surface of the tympanic membrane (TM). (*Used with permission from Vladimir Zlinsky, MD, in Roy F. Sullivan, PhD. Audiology Forum: Video Otoscopy, www.rcsullivan.com*.)

- Chronic suppurative otitis media (CSOM)—Otoscopy shows TM perforation and otorrhea; history reveals a chronically draining ear and recurrent middle-ear infections with or without hearing loss.
- Referred otalgia—This is rare in children and in cases of bilateral otalgia. Should be considered in cases of otalgia that do not fit clinical features of AOM. Referred pain is usually from other head and neck structures (e.g., teeth, jaw, cervical spine, lymph and salivary glands, nose and sinuses, tonsils, tongue, pharynx, meninges).
- Mastoiditis—Mastoiditis can be differentiated from simple AOM by the presence of increasing pain, erythema, and tenderness over mastoid bone in a patient with AOM who has not been treated with antibiotics or recurrence of mastoid pain and tenderness in patients treated with antibiotics. Recurrence or persistence of fever as well as progressive otorrhea are other historical clues. The mastoid swelling can cause the pinna to protrude further than normal (**Figure 22-10**).

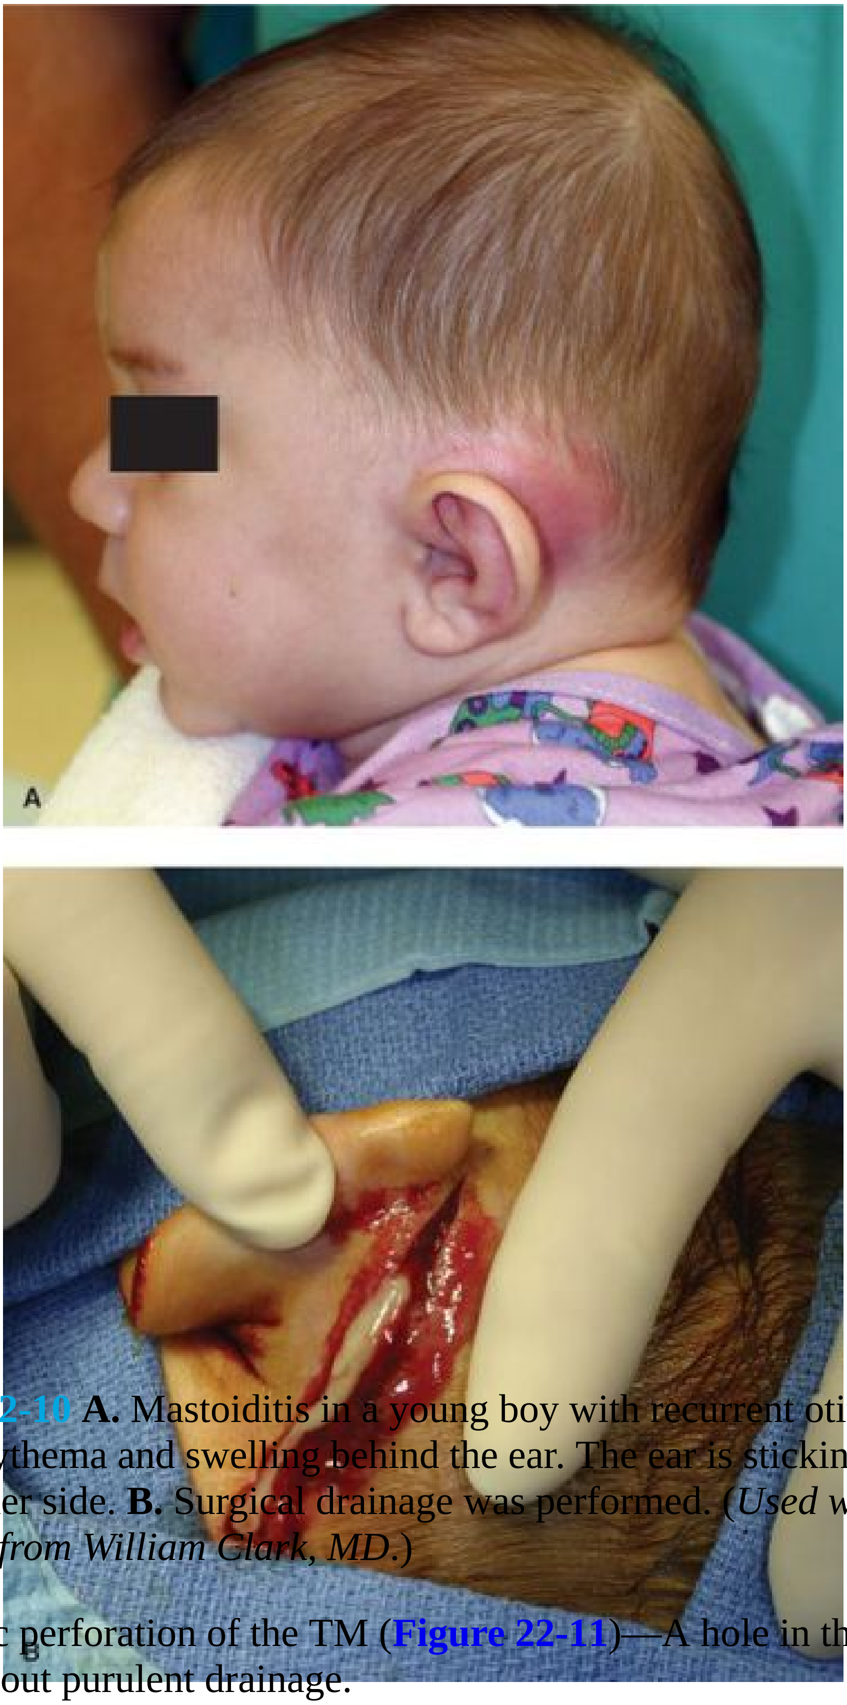

FIGURE 22-10 **A.** Mastoiditis in a young boy with recurrent otitis media. Note the erythema and swelling behind the ear. The ear is sticking out more than the other side. **B.** Surgical drainage was performed. (*Used with permission from William Clark, MD.*)

- Traumatic perforation of the TM (Figure 22-11)—A hole in the TM is seen without purulent drainage.

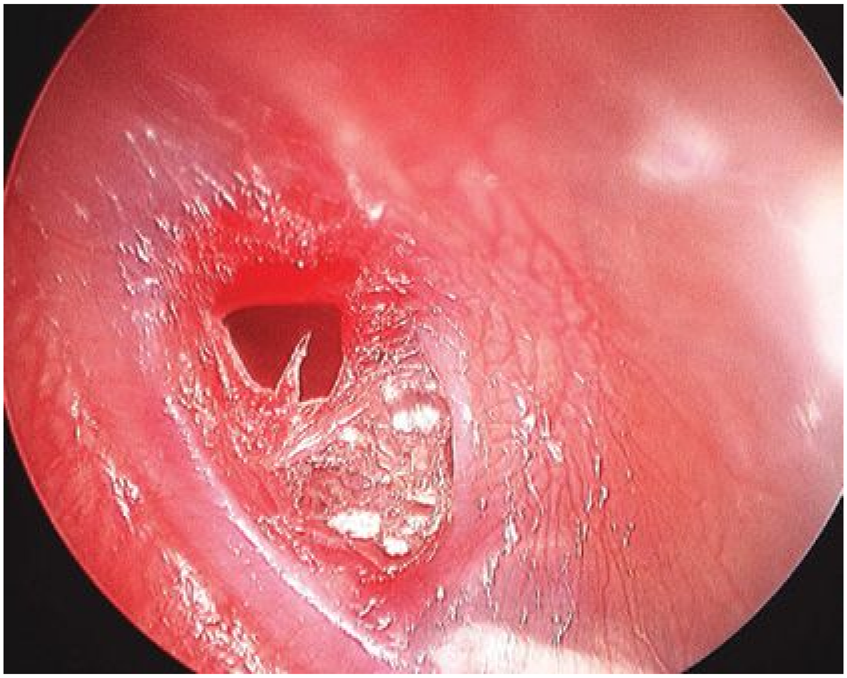

FIGURE 22-11 Traumatic perforation of the left tympanic membrane. (*Used with permission from William Clark, MD*.)

MANAGEMENT

NONPHARMACOLOGIC

Management of OME primarily consists of watchful waiting. Most cases resolve spontaneously within 3 months; only 5 percent to 10 percent last 1 year or longer. Treatment depends on duration and associated conditions. The following options should be considered:

- Document the laterality, duration of effusion, and presence and severity of associated symptoms at each assessment of the child with OME.[6] SOR Ⓒ
- Distinguish the child with OME who is at risk for speech, language, or learning problems from other children with OME and more promptly evaluate hearing, speech, language, and need for intervention in children at risk.[6] SOR Ⓒ Risk factors for developmental difficulties include:
    - Permanent hearing loss independent of OME.

  - Suspected or diagnosed speech and language delay or disorder.
  - Autism-spectrum disorder and other pervasive developmental disorders.
  - Syndromes (e.g., Down syndrome) or craniofacial disorders that include cognitive, speech, and language delays.
  - Blindness or uncorrectable visual impairment.
  - Cleft palate with or without associated syndrome.
  - Developmental delay.
- Manage the child with OME who is not at risk with watchful waiting for 3 months from the date of effusion onset (if known) or diagnosis (if onset is unknown).[6] SOR Ⓑ
- Hearing testing is recommended when OME persists for 3 months or longer or at any time if language delay, learning problems, or significant hearing loss is suspected in a child with OME.[6] SOR Ⓑ
- Autoinflation methods that attempt reopening the eustachian tube by increasing intranasal pressure may have some short-term benefits for restoring hearing in patients with OME. These methods include forced exhalation through closed nose and mouth (which may be impractical for young children), inflatable intranasal balloon, or an anesthetic mask. Acute side effects are rare and the cost is not prohibitive; however, long-term adverse effects are unknown.[12] SOR Ⓑ

MEDICATIONS

- Oral acetaminophen (paracetamol) and ibuprofen can reduce earache when given with antibiotics.[16] Anesthetic ear drops (e.g., amethocaine, benzocaine, or lidocaine) can be effective in reducing pain among children ages 3 to 18 years with AOM when used with oral analgesics.[17] SOR Ⓑ
- Antibiotics seem to be most beneficial in children ages 6 to 23 months with bilateral AOM, otorrhea, or severe signs and symptoms (e.g., moderate to severe otalgia, persistent otalgia greater than 48 hours, temperature 39 °C [102.2 °F] or higher). For most other children with

mild, unilateral disease, an observational policy based on shared decision-making seems justified.[13,15,18] SOR B

- Antibiotics can lead to more rapid reduction in symptoms of AOM, but increase the risk of adverse effects, including diarrhea, vomiting, and rash.[16] SOR B
    - Antibiotics seem to reduce pain at 2 to 7 days, and may prevent development of contralateral AOM, but increase the risks of adverse effects compared with placebo.[14]
    - There is insufficient effectiveness data regarding which antibiotic regimen is better than another.[14,16]
    - Antibiotics found to be effective in AOM include amoxicillin, amoxicillin-clavulanic acid, and cephalosporins. Amoxicillin is a good first-line treatment because it is inexpensive and children tolerate the bubblegum taste well.[13]
    - For children who have been treated with amoxicillin within the past 30 days, or with superimposed conjunctivitis suggestive of *H. influenzae*, or who previously failed amoxicillin in the setting of recurrent AOM, adding beta-lactamase coverage is recommended (e.g., amoxicillin-clavulanate). Alternative treatment for non-anaphylactic penicillin-allergic patients include 2nd-generation (e.g., cefuroxime) and 3rd generation cephalosporins (e.g., cefdinir, cefpodoxime, or ceftriaxone).[13]
    - Longer (8- to 10-day) courses of antibiotics reduce short-term treatment failure but have no long-term benefits compared with shorter regimens (5-day courses).[16,19]
    - An observational approach substantially reduces unnecessary use of antibiotics in children with AOM and may be an alternative to routine use of antimicrobials for treatment of such children.[20]
- Immediate antibiotic treatment (i.e., given at initial consultation) may reduce the duration of symptoms of AOM, but increases the risk of vomiting, diarrhea, and rash compared with delayed treatment (i.e., given after 72 hours).[16] SOR B
- Treatment of AOM with decongestants and antihistamines is not recommended.[21] SOR B

- Antihistamines and decongestants are not effective for OME.[6] Furthermore, they may cause harm in children younger than 5 years.[22] SOR A
- Antimicrobials, oral corticosteroids, and intranasal steroids are not recommended for OME.[6,23] SOR A

COMPLEMENTARY AND ALTERNATIVE THERAPY

- Current evidence is unclear on the effectiveness of zinc supplementation to prevent otitis media in young, healthy children in developing countries.[24] SOR B

REFERRAL

- Refer to a specialist (otolaryngologist, audiologist, or speech-language pathologist) if there is:[6] SOR C
    - Persistent fluid for 4 or more months with persistent hearing loss.
    - Associated speech delay.
    - Structural damage to TM or middle-ear.
- Tympanostomy tubes (or grommets) for children with recurrent AOM (3 or more episodes of AOM in 6 months, or 4 or more AOM in 1 year) diminish AOM recurrences for up to six months. Because long-term effectiveness is uncertain, clinicians should weigh this immediate benefit alongside potential adverse outcomes from the surgery.[25] SOR B
- Insertion of tympanostomy tubes in young children with persistent middle-ear infection does not improve cognitive development, language acquisition, or speech development compared with waiting 6 to 9 months for the effusion to resolve before placing the tubes.[26] Moreover, delayed insertion of tubes helps children avoid getting tubes altogether and does not result in worse developmental outcomes.[27] SOR A

- When a child becomes a surgical candidate, tympanostomy tube insertion is the preferred initial procedure; adenoidectomy should not be performed unless a distinct indication exists (e.g., nasal obstruction or chronic adenoiditis).[6] SOR Ⓑ
- Repeat surgery consists of adenoidectomy plus myringotomy, with or without tube insertion. Tonsillectomy alone or myringotomy alone should not be used to treat OME.[6] SOR Ⓑ

PREVENTION

- At best, the previously licensed PCV7 was only marginally effective in preventing AOM as an infant vaccine. However, this 6 percent to 7 percent reduction in incidence of AOM was justifiable from a public health perspective considering the significant disease burden. The PCV7 vaccine was not effective in preventing AOM in older children with prior history of AOM.[28] SOR Ⓐ
- There are insufficient data to determine the effectiveness of the currently licensed 13-valent pneumococcal vaccine (PCV13) given its recent licensure and use.
- Influenza vaccination may decrease the incidence of AOM but rigorous systematic reviews are needed to evaluate the magnitude of this effect.[13] SOR Ⓑ
- For at-risk children, long-term oral antibiotics administered for at least 6 weeks reduces the incidence of AOM while on therapy from 3 to 1.5 episodes per year. This benefit needs to be balanced against the potential side effects and the risks of antibiotic resistance.[16,29] SOR Ⓐ This practice is no longer considered routine.
- Xylitol chewing gum, lozenge or syrup prophylactically given 3 to 5 times daily among healthy children at daycare centers can prevent AOM recurrence by 25 percent. However, the safety of giving a gum or lozenge to a young child, coupled with the compliance issues raised by its

frequent administration, renders it an unrealistic preventive option.[30] SOR B

- Exclusive breastfeeding for at least 6 months appears to diminish occurrence of AOM, hence should be encouraged.[13] SOR B
- Tympanostomy tubes lead to short-term reduction in the number of episodes of AOM but increase the risk of complications (i.e., tympanosclerosis; **Figures 22-12** and **22-13**).[16] SOR B

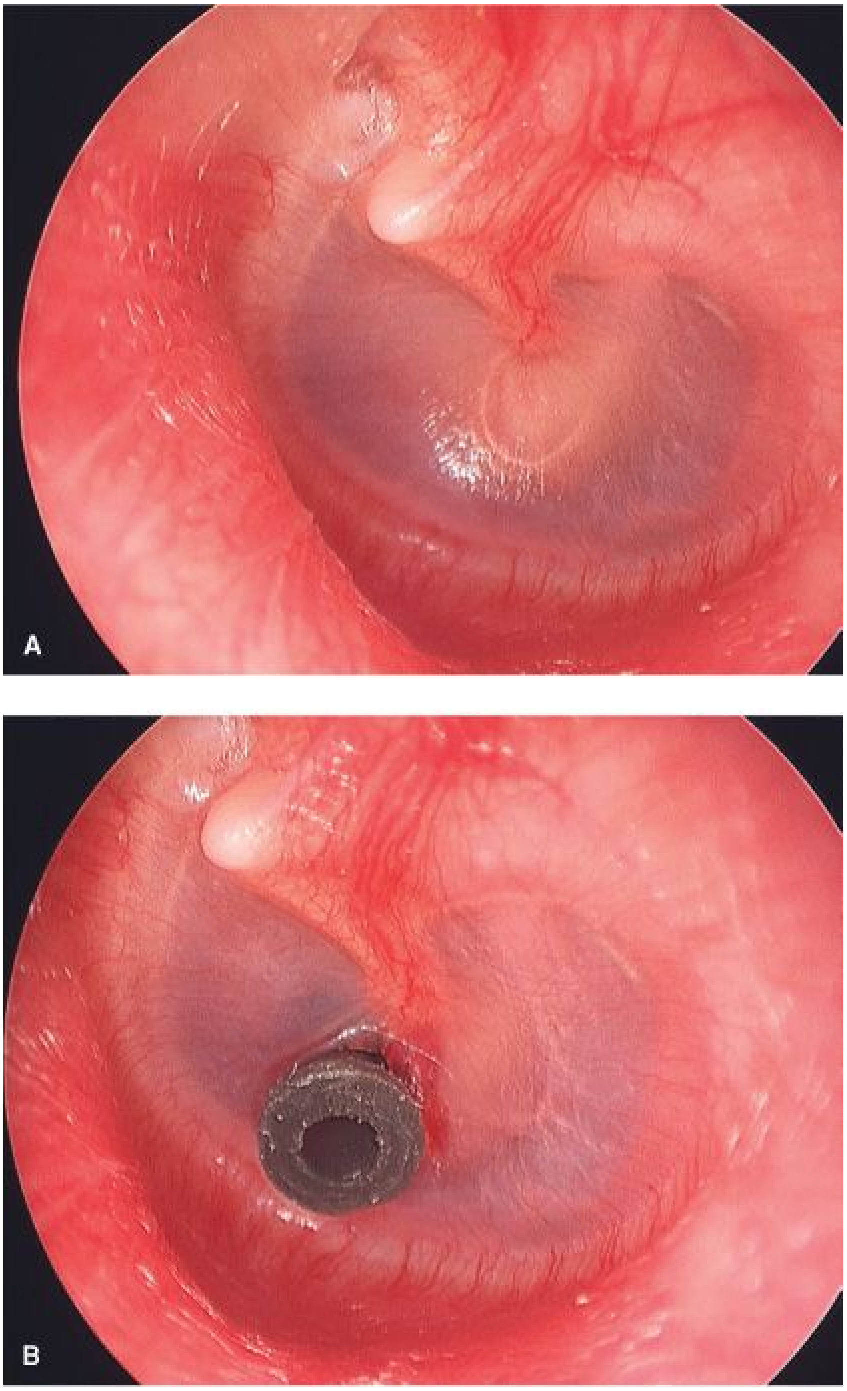

FIGURE 22-12 **A.** Left tympanic membrane (TM) of a 9-year-old girl with recurrent acute otitis media and chronic TM retractions prior to polyethylene (PE) tube placement. The circular area near the center of the TM is caused by the TM being retracted against the promontory of the medial wall of the middle ear. **B.** A fluoroplastic polyethylene (PE) tube is placed in the anterior-inferior quadrant of the TM of a 9-year-old girl with recurrent acute otitis media. It is black because it is impregnated with silver

oxide to retard the growth of bacterial microfilms. (*Used with permission from William Clark, MD*.)

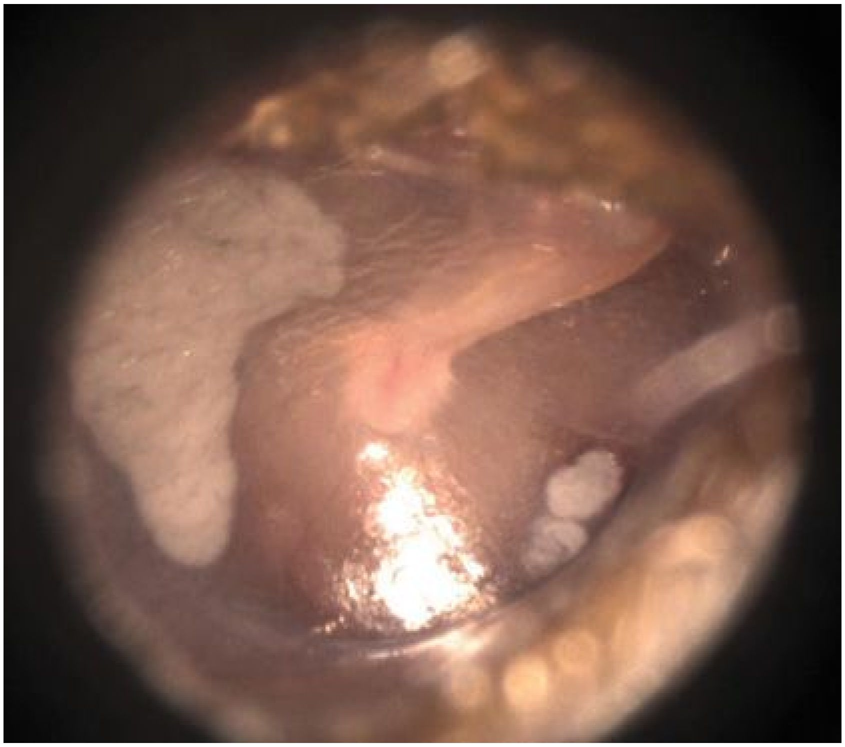

FIGURE 22-13 Tympanosclerosis as the result of previous recurrent episodes of otitis media and polyethylene (PE) tube placement. (*Used with permission from Glen Medellin, MD*.)

PROGNOSIS

- Without antibiotics, AOM resolves within 24 hours in approximately 60 percent of children and within 3 days in approximately 80 percent of children. Rate of suppurative complications if antibiotics are withheld is 0.13 percent.[31]
- Most cases of OME resolve spontaneously within 3 months; only 5 percent to 10 percent last 1 year or longer. However, effusion will recur in 30 percent to 40 percent of patients.[6]

FOLLOW-UP

- If a patient with AOM fails to respond to the initial management option within 48 to 72 hours, the clinician should reassess the patient to confirm AOM and exclude other causes of illness. If AOM is confirmed in a patient initially managed with observation, the clinician should begin antibiotics. If the patient was initially managed with antibiotics, the clinician should change antibiotics.[6] SOR Ⓑ
- Potentially serious complications of AOM, such as mastoiditis or facial nerve involvement, require urgent referral.
- There is no consensus in the medical community regarding timing of posttreatment follow-up of AOM or who should receive follow-up. There is some evidence that parents can be reliable predictors in the resolution or persistence of AOM following antibiotic treatment.[32]
- Children with persistent OME who are not thought to be at significant risk should be reexamined at 3- to 6-month intervals until the effusion is gone, significant hearing loss is identified, or structural abnormalities of the eardrum or middle ear are suspected.[6] SOR Ⓑ

PATIENT EDUCATION

- Patient education should focus on identification, prevention, and control of risk factors.
- Parents should be made aware of the high rates of spontaneous resolution of AOM and potential adverse effects of antibiotics. Providing a prescription for an antibiotic at the initial visit but advising delay of initiation of medication (i.e., observational approach for up to 48 hours) is an alternative to immediate treatment and is associated with lower antibiotic use.[20]
- Patients should be informed that the natural history of OME is spontaneous resolution.

  - Periodic follow-up to monitor resolution of MEE is extremely important.
  - If MEE is persistent and signs and symptoms of hearing loss, language difficulties, and learning problems arise, additional treatment may be considered.

23 MASTOIDITIS

Samantha Anne, MD, MS

PATIENT STORY

A 12-month-old girl presents to your office with 1-day history of fever and increasing swelling and redness behind her left ear. On examination, the left auricle is protruding and there is marked erythema, swelling, tenderness, and fluctuance overlying the left mastoid bone (**Figure 23-1**). Otoscopy reveals a purulent middle ear effusion. A computed tomography (CT) scan of the temporal bones reveals opacification of the mastoid air cells. A diagnosis of acute mastoiditis is made and the girl undergoes urgent myringotomy and tympanostomy tube placement and mastoidectomy. Postoperatively, she is treated with intravenous antibiotics and recovers completely.

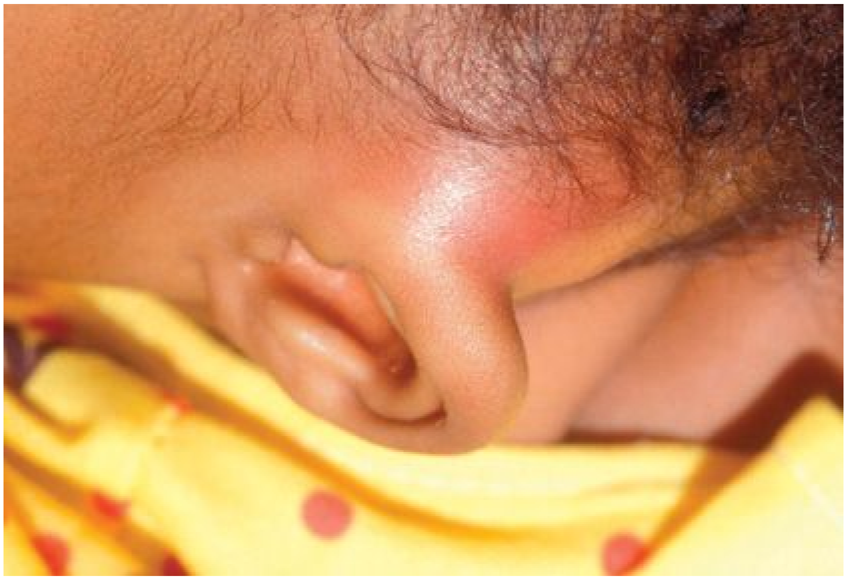

FIGURE 23-1 12-month-old girl with protrusion of the auricle and erythema and swelling in the left mastoid area. (*Used with permission from*

Johanna Goldfarb, MD.)

INTRODUCTION

Mastoiditis is a complication of otitis media, characterized by a suppurative infection of the mastoid air cells.[1] Acute mastoiditis refers to the finding of acute otitis media on otoscopy in conjunction with local inflammatory findings in the mastoid including erythema, edema, and auricular protrusion, with duration of symptoms less than one month. Coalescent mastoiditis occurs when there is an acute otitis media which progresses into an acute infection of mastoid with osteolytic changes in the bone and destruction of the mastoid air cells. Chronic mastoiditis is defined by the presence of long-standing infection in the presence of tympanic membrane perforation or tympanostomy tube or as a complication of cholesteatoma. Chronic mastoiditis follows an indolent course of infection.

SYNONYMS

Mastoid inflammation or Mastoid infection.

EPIDEMIOLOGY

- The epidemiology of acute mastoiditis is similar to that of otitis media. Thus, acute and coalescent mastoiditis occurs most frequently in children less than 4 years of age.[2]
- Although recurrent otitis media is a risk factor for mastoiditis, a significant percentage of cases of mastoiditis occur in young children who do not have a prior history of OM.[2]

- Few studies on the incidence of mastoiditis are population based; thus it is difficult to estimate the true incidence and whether the incidence is increasing.
- Chronic mastoiditis tends to occur in children with chronic otitis media, chronic otorrhea thru tympanic membrane perforation, and/or cholesteatoma.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Acute and coalescent mastoiditis may occur in children with well pneumatized mastoids with little or minimal prior history of otitis media.
- These acute infections also occur in younger children with more immature immune systems.[2]
- The infectious process usually begins with an acute otitis media that causes edema of the mucoperiosteal lining of the mastoid air cells and middle ear. This blocks the aditus of the mastoid and the Eustachian tube thereby disrupting the normal aeration.[1,3] This leads to worsening purulence and inflammation and eventually development of localized acidosis and bony septa decalcification. In addition, osteoclastic activity cases further destruction of bony septa in the mastoid causing eventual coalescence.
- Eventually as the pressure continues to increase in the mastoid, the infection progresses to either intracranial extension or thru lateral cortical bone destruction into the neck and soft tissue postauricularly.
- The microbiologic agents responsible for acute and coalescent mastoiditis include *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Staphylococcus aureus* [including methicillin-resistant strains (MRSA)] and rarely, *Pseudomonas aeruginosa*.
- S pneumoniae serotype 19A, which can be a multidrug resistant organism, has emerged as an important pathogen causing acute mastoiditis.[4]

- The microbiology of chronic mastoiditis includes *P. aeruginosa*, *S. aureus* (including MRSA), Proteus sp., and anaerobes including Peptostreptococcus, and Bacteroides.

RISK FACTORS

- Otitis media, young age, and altered immunity are risk factors for mastoiditis.
- A history of recurrent otitis media is a risk factor for acute mastoiditis.[5]
- Cholesteatoma is a risk factor for chronic mastoiditis.

DIAGNOSIS

- The diagnosis of acute mastoiditis is a clinical diagnosis based on the characteristic clinical findings.[6]
- The diagnosis of coalescent mastoiditis can be made in the appropriate clinical setting when osteolytic changes in the bone and destruction of the mastoid air cells are present.
- The diagnosis of chronic mastoiditis relies on the presence of a chronic suppurative process and evidence of inflammatory changes in the mastoid.

CLINICAL FEATURES

- Postauricular tenderness, erythema, swelling, and fluctuance are the hallmarks of acute mastoiditis.[7]
- Protrusion of the auricle is common (**Figure 23-2**); the displacement is usually downward and outward in young children and upward and outward in older children.

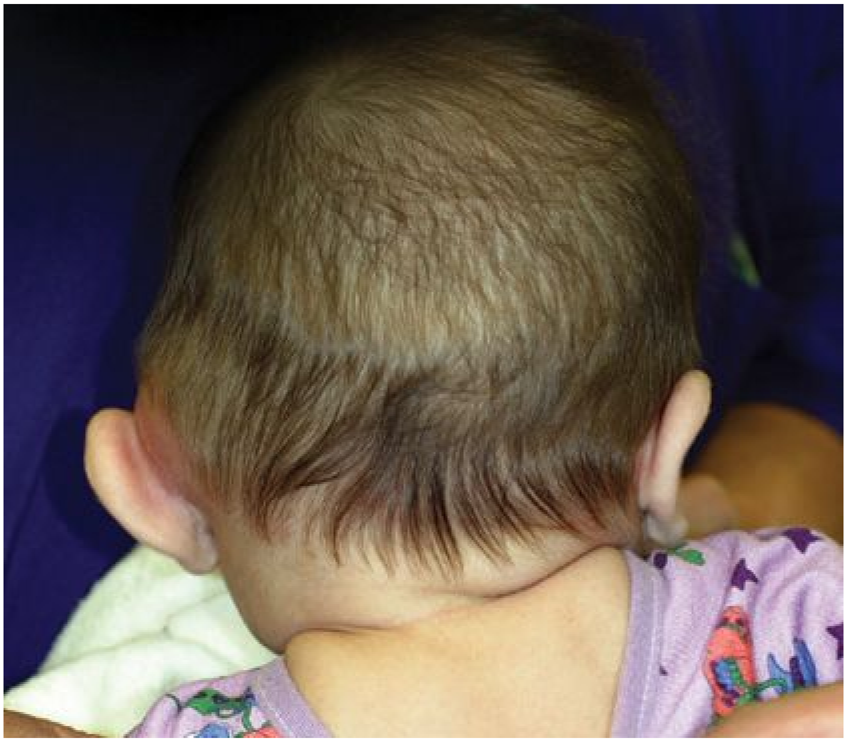

FIGURE 23-2 Mastoiditis in a young boy with recurrent otitis media. Note the erythema and protrusion of the left ear. (*Used with permission from William Clark, MD.*)

- Fever, ear pain, or irritability in younger children may be present.
- Otoscopic examination commonly reveals signs of acute otitis media (bulging or erythematous tympanic membrane; **Figure 23-3**).[6]

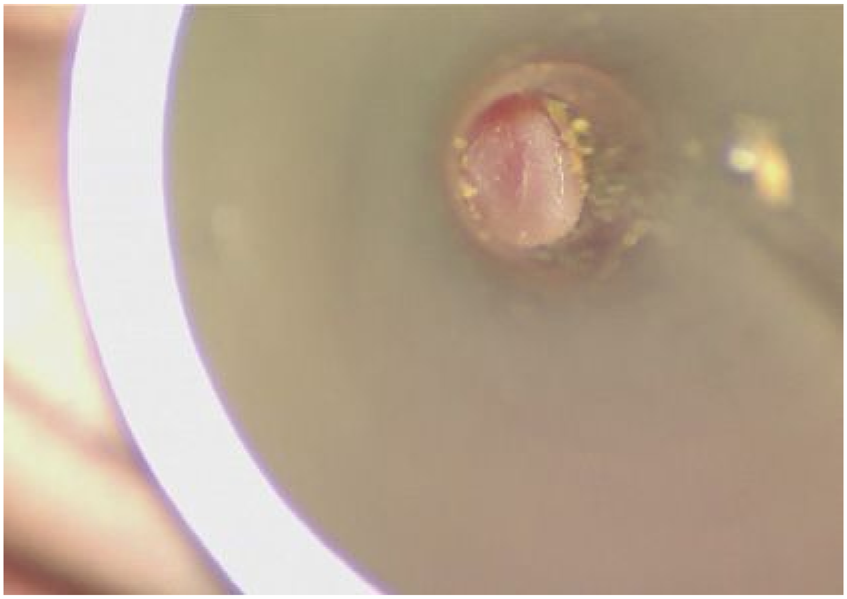

FIGURE 23-3 Picture of tympanic membrane with purulent effusion in a child about to undergo myringotomy with tube placement with coalescent mastoiditis. (*Used with permission from Prashant Malhotra, MD.*)

LABORATORY TESTING

- A complete blood count with differential may reveal a leukocytosis with a left shift.[8]
- Inflammatory markers are usually elevated with acute mastoiditis, although they may be normal early in the course and in cases of chronic mastoiditis.[9,10]
- A blood culture has low yield for ascertaining the etiologic organism, but when positive is very helpful in the specific bacteriologic diagnosis.
- Middle ear and mastoid cultures attained surgically are very helpful in directing the initial antimicrobial therapy and subsequent follow-up.

IMAGING

- Imaging is not required to make the diagnosis of acute mastoiditis in children who have classic clinical manifestations. However, imaging is helpful in cases that are not classic, and in assessing for coalescent mastoiditis and other complication of acute mastoiditis.[11]

- Imaging is also helpful in planning a management course for a patient with acute mastoiditis.
- A contrast enhanced CT of the temporal bones is the best imaging modality for acute mastoiditis. Findings include opacification of mastoid air cells, cortical bone erosion, coalescence of air cells, and post auricular fluid collections (**Figures 23-4** and **23-5**).

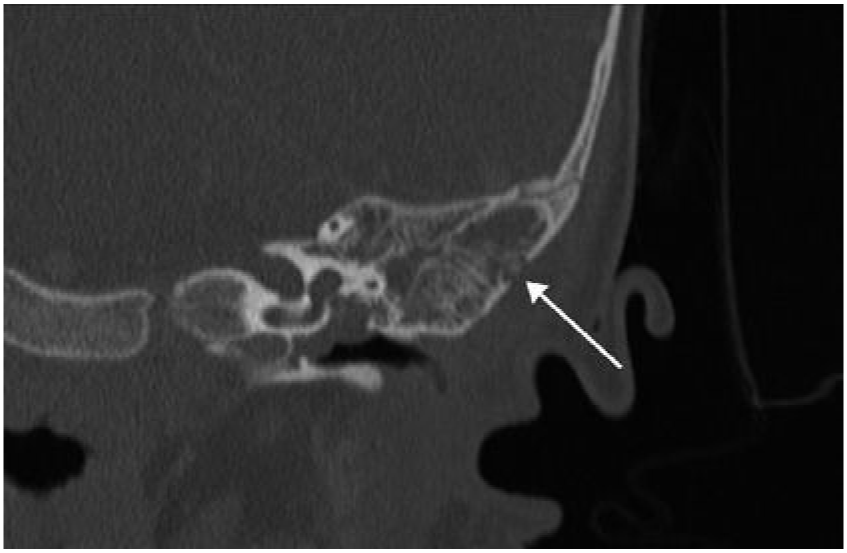

FIGURE 23-4 Computed tomography (CT) scan of the temporal bone showing localized bony destruction along the lateral margin (arrow) of the left mastoid air cells.

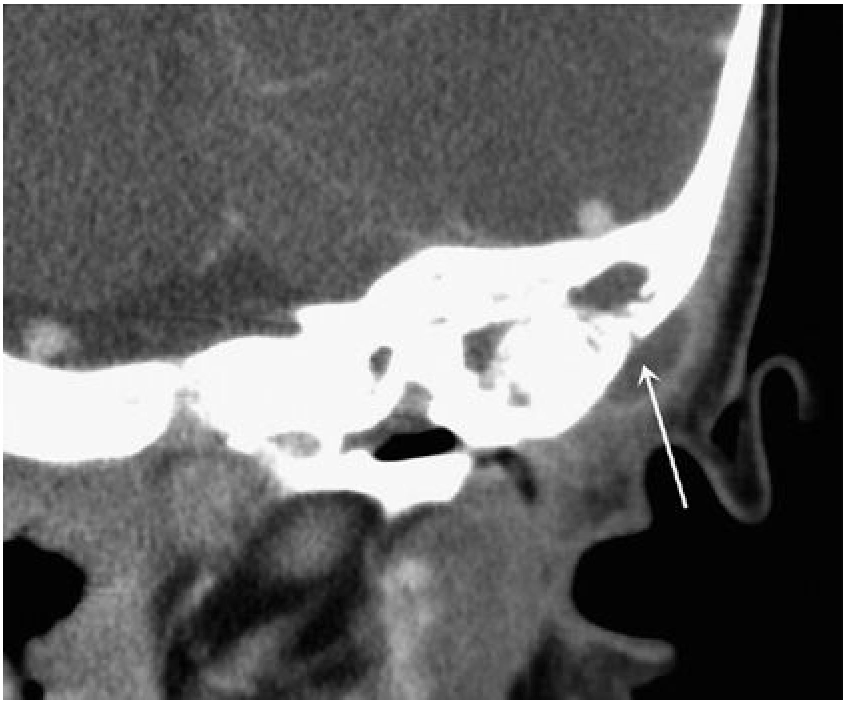

FIGURE 23-5 Computed tomography (CT) scan of the temporal bone showing prominent soft tissue thickening (arrow) overlying the posterior left temporal region with central abscess formation.

- If there is concern for intracranial complication, cranial magnetic resonance imaging with gadolinium is more sensitive than CT and recommended.[12]
- Imaging findings with chronic mastoiditis include cholesteatoma and erosion of the cortical mastoid bone (**Figure 23-6**).

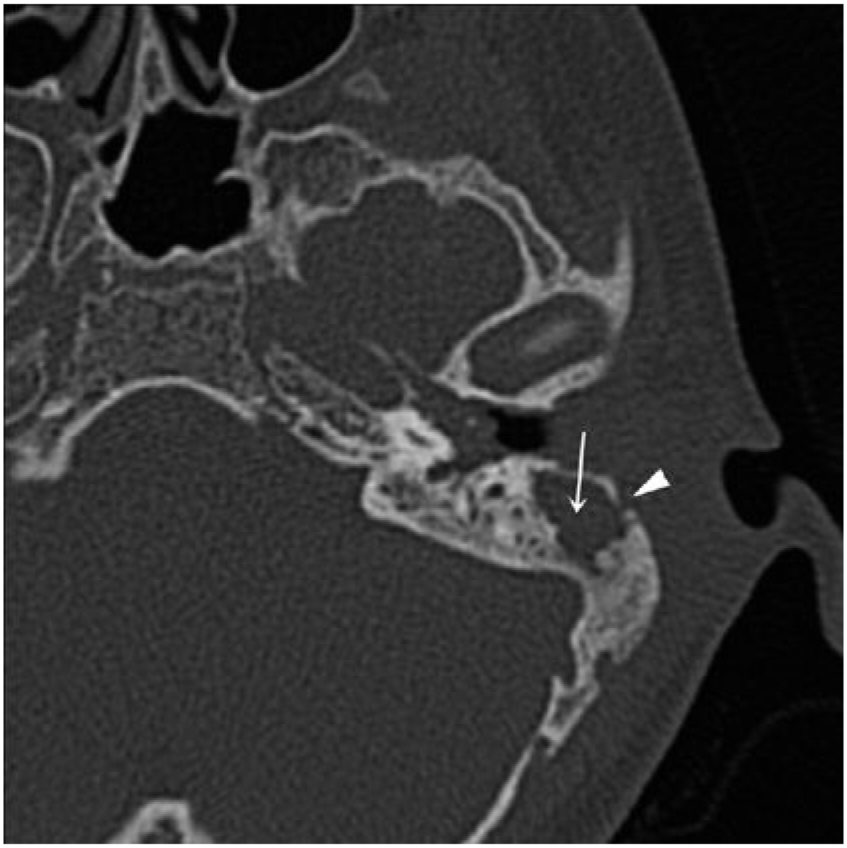

FIGURE 23-6 Chronic mastoiditis and cholesteatoma in 16 year-old. Note the soft tissue seen filling middle ear and mastoid (arrow) with erosion of lateral mastoid cortical bone (arrowhead) and posterior external auditory canal.

DIFFERENTIAL DIAGNOSIS

- Otitis externa can also cause cellulitic changes in the post auricular region which can mimic acute mastoiditis. The appearance of the external canal and the degree of tenderness of the auricle itself, rather than the postauricular area can be helpful in differentiating these entities. CT of the temporal bones also can help differentiate otitis externa from mastoiditis in that there usually will not be opacification of mastoid air cells and will reveal mostly soft tissue changes in the ear canal.

- Trauma can also cause skin discoloration, edema, and changes in postauricular area. However, the normal tympanic membrane, the lack of constitutional symptoms, lack of leukocytosis along with clinical history and imaging should easily differentiate trauma from acute mastoiditis.
- Postauricular lymphadenopathy from a viral infection or from a scalp infection may cause postauricular swelling and erythema. However, the normal auricle, tympanic membrane, and often palpable lymph node help distinguish this from mastoiditis.

MANAGEMENT

- In general, acute mastoiditis and coalescent mastoiditis can be treated with parenteral antibiotics and myringotomy with or without placement of a tympanostomy tube. SOR C
- This conservative approach is not always successful, as evidenced by one study, which showed that nearly 1/4 to 1/3 of these patients eventually required further surgical intervention.[13]
- Acute mastoiditis with intracranial complications and other suppurative complications is treated with intravenous antibiotics, myringotomy with or without placement of tympanotomy tubes, and mastoidectomy. SOR C
- Chronic mastoiditis, in general, fails to resolve with medical therapy alone and often requires mastoidectomy.

NONPHARMACOLOGIC

- If there is a tympanic membrane perforation, dry ear precautions may be necessary to prevent further infection.

MEDICATIONS

- Empiric antibiotics directed against the most likely agents must be administered. More specific therapy can be administered once the etiologic agent has been isolated.[14]
- For acute mastoiditis, a third generation cephalosporin such as Ceftriaxone is a good empiric option. Vancomycin is often added to the regimen, especially if there is high index of suspicion for a Staphylococcal infection. SOR C
- Alternative agents that have been used include penicillin with a beta-lactamase inhibitor (e.g., ampicillin-sulbactam), cefepime, and piperacillin-tazobactam.
- For chronic mastoiditis, vancomycin often is used with an anti-pseudomonal agent such as ceftazidime, cefepime or an aminoglycoside. SOR C
- Parenteral therapy should be given initially for cases of acute mastoiditis. The duration of parenteral and total antimicrobial therapy depends on clinical improvement, resolution of the findings, and the microbiology; a 3- to 4-week total course of antibiotics is commonly prescribed. SOR C
- In addition, ototopical agents such as ofloxacin or ciprofloxacin with dexamethasone can be used as an adjunct. SOR C

SURGERY

- Myringotomy with or without tympanotomy tube placement is important to perform in order to drain purulence, attain culture material, and to relieve pain.
- Mastoidectomy is important to remove diseased bone postauricularly especially in setting of acute and/or coalescent mastoiditis.
- Mastoidectomy is generally required for chronic mastoidectomy.

REFERRAL

Early consultation to otolaryngology is important to determine need for surgical intervention and to aid in attaining cultures. If intracranial involvement is present, neurosurgery consultation is important. An infectious diseases specialist is often involved in the care of these patients to direct antimicrobial therapy.

PREVENTION AND SCREENING

- Close follow-up for otitis media, surveillance for cholesteatoma, and aggressive management of worsening symptoms and signs is important in preventing progression to mastoiditis.

PROGNOSIS

- Complications of mastoiditis are related to the spread of infection to contiguous structures, and occur in approximately 10 percent to 30 percent of patients with acute mastoiditis.[6,15]
- Mastoiditis can extend posteriorly to cause sigmoid sinus thrombosis, laterally to produce subperiosteal abscess, superiorly to cause intracranial infections, or inferiorly to form a Bezold abscess, which is a neck abscess located beneath the sternocleidomastoid and digastric muscles.[16]
- Other complications of mastoiditis include facial nerve paralysis, hearing loss, labyrinthitis, and osteomyelitis of the bones of the skull.
- Intracranial complications of mastoiditis include meningitis, brain abscess, epidural or subdural abscess, and venous sinus thrombosis.
- Intracranial complications of mastoiditis, such as a brain abscess, may be the presenting complaint (**Figure 23-7**).

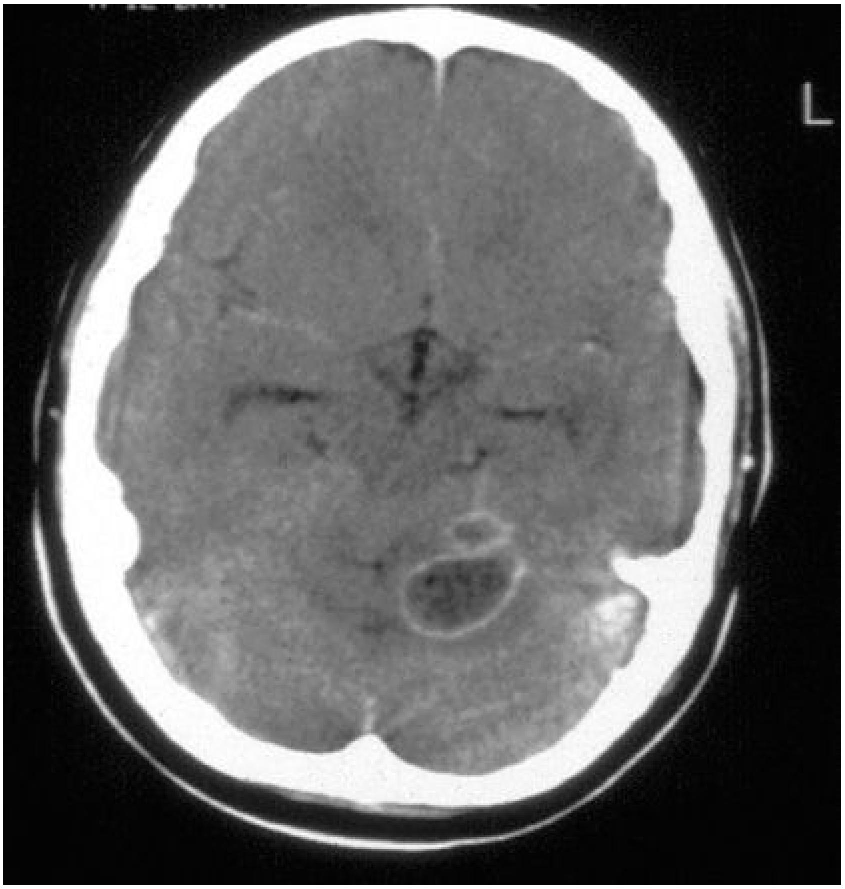

FIGURE 23-7 This adolescent presented with headache and fever and was found to have a brain abscess, which was the result of chronic otitis media and mastoiditis. (*Used with permission from Camille Sabella, MD.*)

FOLLOW-UP

- Children who are diagnosed with mastoiditis require very close follow-up to assure they respond appropriately and to limit complications.
- The timing and need for follow-up studies are determined by the type of treatment used, whether surgical and medical, and the response to treatment.

PATIENT EDUCATION

- Worsening otalgia, protrusion of the auricle, and/or erythema and tenderness behind the ear warrants immediate medical attention.

24 EAR—FOREIGN BODY

Brian Z. Rayala, MD

PATIENT STORY

A 3-year-old girl is brought by her parents to an urgent care facility after a day of crying, irritability, scant otorrhea, and frequent pulling of her right ear. Otoscopy reveals an erythematous, swollen external auditory canal (EAC) where a bead is wedged (**Figure 24-1**). The patient is referred to an otolaryngologist and the bead is removed using an operating microscope for visualization.

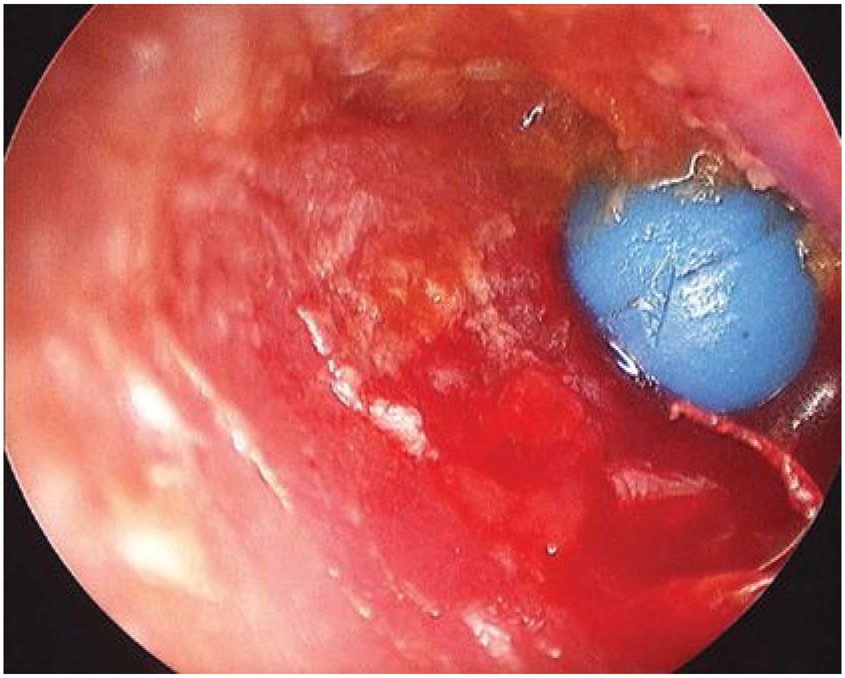

FIGURE 24-1 Foreign body (bead) in the ear canal of a 3-year-old girl with reactive tissue around it. (*Used with permission from William Clark, MD*.)

INTRODUCTION

- Children with ear foreign bodies (FBs) usually present with otalgia, otorrhea, or decreased hearing. At times, symptoms may be nonspecific, like irritability and crying. Other times, presentation may be asymptomatic.

EPIDEMIOLOGY

- Ear FBs are commonly seen in children aged 1 to 6 years.[1–3]
- Equal male-to-female ratio in the pediatric population.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- Most common FBs in children include:[5]
    - Inanimate objects such as beads (**Figure 24-1**), cotton tips, paper, toy parts, crayons (**Figure 24-2**), eraser tips, food, or organic matter, including sand (**Figure 24-3**), sticks, and stones.

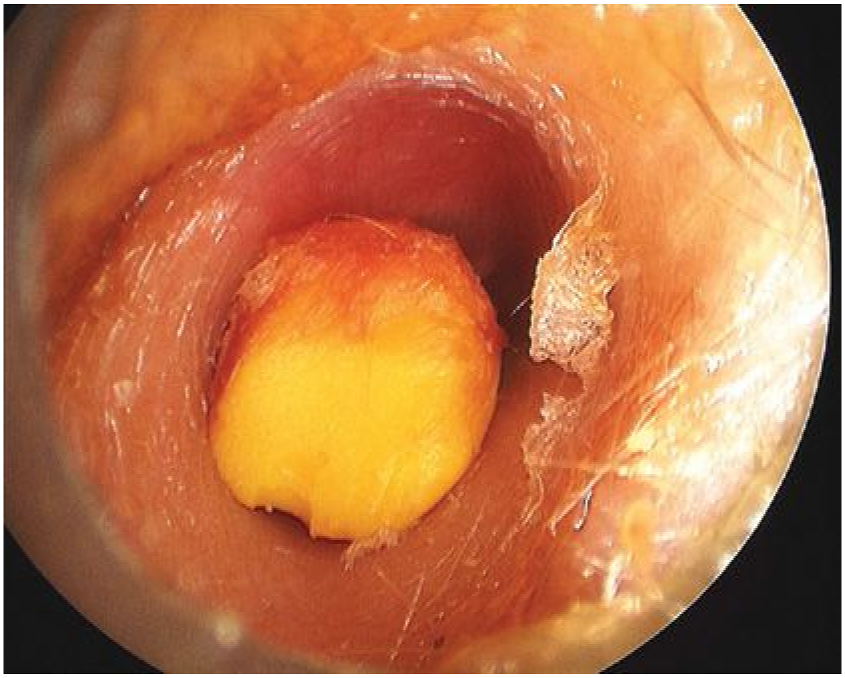

FIGURE 24-2 Piece of a crayon in the ear canal of a 4-year-old boy. (*Used with permission from William Clark, MD*.)

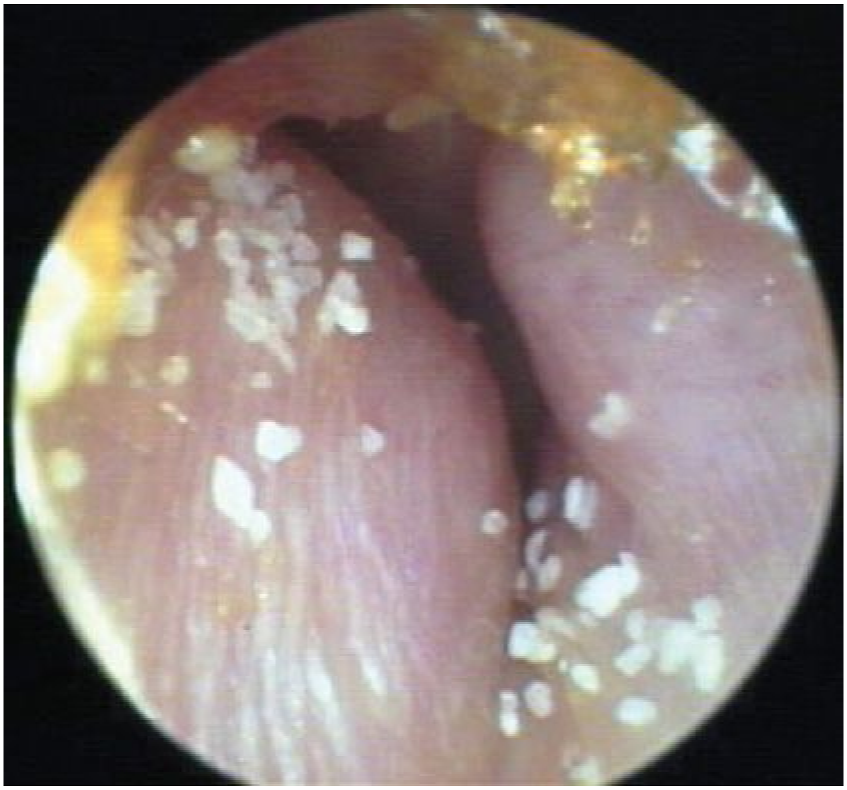

FIGURE 24-3 Beach sand granules with exostosis in the ear of a cold water surfer. The exostoses are common in cold water swimmers and surfers. (*Used with permission from Roy F. Sullivan, PhD. Audiology Forum: Video Otoscopy, www.rcsullivan.com*.)

  - Insects (**Figure 24-4**).

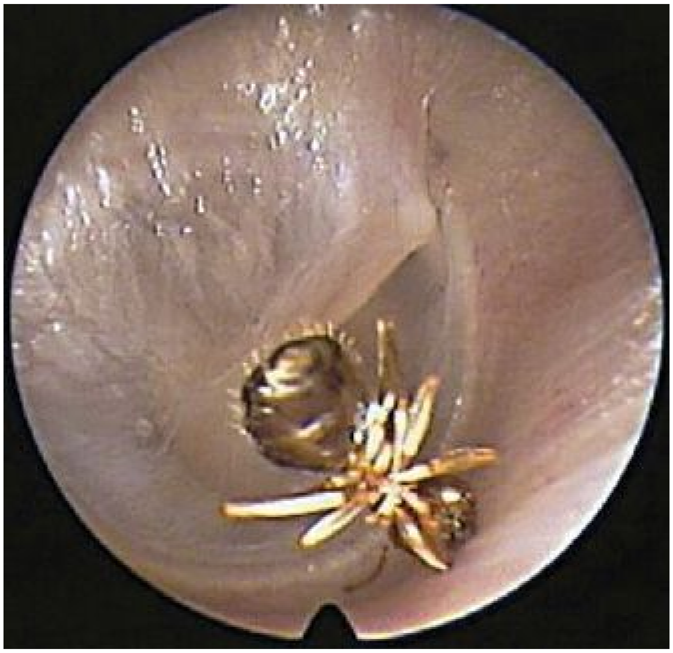

FIGURE 24-4 Ant in the ear canal. (*Used with permission from Vladimir Zlinsky, MD in Roy F. Sullivan, PhD. Audiology Forum: Video Otoscopy, www.rcsullivan.com*.)

- Pathogenesis includes some of the key elements of otitis externa (see Chapter 21, Otitis Externa):
  - Initial breakdown of the skin-cerumen barrier (caused by presence of FB).
  - Skin inflammation and edema leading to subsequent obstruction of adnexal structures (e.g., cerumen glands, sebaceous glands, and hair follicles).
  - FB reaction leading to further skin injury.
  - In the case of alkaline battery electrochemical reaction, severe alkaline burns may occur.

RISK FACTORS

- Children with attention deficit hyperactivity disorder (ADHD) may be more likely to self-insert FBs and ADHD should be considered in children with ear FBs who are older than age 5 years.[6]

DIAGNOSIS

CLINICAL FEATURES

- Key historical features include:
  - Otalgia.
  - Otorrhea or otorrhagia.
  - Mild hearing loss.
  - Irritability or crying.
  - History suspicious for FB insertion or witnessed FB insertion.
- Some children are asymptomatic.
- Hallmark of diagnosis includes visualization of FB on otoscopy (**Figures 24-1** through **24-4**).
- Otoscopy can reveal signs of EAC inflammation (e.g., edema, erythema, or aural discharge) (**Figure 24-1**).

LABORATORY AND IMAGING

- Aural FB is a clinical diagnosis. Laboratory and imaging studies have very limited use.

DIFFERENTIAL DIAGNOSIS

- Otitis externa—Presents with otalgia, otorrhea, and mild hearing loss, all of which can be present in ear FB. Absence of FB (on otoscopic exam) is the key differentiating factor (see Chapter 21, Otitis Externa).
- Acute otitis media (with or without perforated tympanic membrane [TM])—Otoscopy shows absence of FB and presence of middle-ear inflammation and effusion (i.e., bulging, erythematous, cloudy, or immobile TM). Patients present with clinical signs or symptoms of acute illness like fever (see Chapter 22, Otitis Media—Acute Otitis and Otitis Media with Effusion).
- Chronic Suppurative Otitis Media—Otoscopy shows absence of FB and presence of TM perforation; history reveals a chronically draining ear and recurrent middle-ear infections with or without hearing loss.

MANAGEMENT

PROCEDURES

- Adequate immobilization of the child (sedation if necessary) and proper instrumentation allow the uncomplicated removal of many ear FBs in the pediatric population.[7] SOR Ⓒ
    - The use of general anesthesia is preferred in very young children and in children of any age with ear FBs whose contour, composition, or location predispose to traumatic removal in the ambulatory setting.[7] SOR Ⓒ
- Ear FBs can be removed by irrigation, suction, or instrumentation. The type of procedure depends on the type of FB being removed.
    - Small inorganic objects can be removed from the EAC by irrigation. Contraindication to irrigation includes:
        - Perforated TM.
        - Vegetable matter—Irrigation causes swelling of the vegetable matter, which leads to further obstruction.
        - Alkaline (button) battery—Irrigation enhances leakage and potential for liquefaction necrosis and severe alkaline burns.

  - Objects with protruding surfaces or irregular edges can be removed with alligator forceps under direct visualization.
  - Objects that are round or breakable can be removed using a wire loop, a curette, or a right-angle hook that is slowly advanced beyond the object and carefully withdrawn.
  - Cyanoacrylate adhesive (e.g., “superglue”) has been used to remove tightly wedged, smooth, or round FBs.
  - Live insects should be killed before removing them (by irrigation or forceps). Instilling alcohol or mineral oil into the auditory canal can kill them.

REFERRAL

Referral to otolaryngology should be considered if:

- More than one attempt has been carried out without success.[8]
- More than one instrument is needed for removal.[7]
- Patients who have firm, rounded FBs (**Figure 24-1**).[9]
- Patients who have FBs with smooth, non-graspable surfaces (**Figure 24-1**).[10]

PREVENTION

- Efforts should focus on preventing small children from access to tiny objects (e.g., beads, small toys, etc.).

PROGNOSIS

- Several retrospective studies from urban emergency departments showed that emergency physicians successfully removed most FBs (53% to 80%)

with minimal complications and no need for operative removal.[7,8–10]

FOLLOW-UP

- Follow-up is very important, especially in cases where EAC inflammation or infection is likely (e.g., numerous attempts, use of numerous instruments, protracted exposure to the FB).

PATIENT EDUCATION

- Parents should be informed that successful removal depends a great deal on the length of time that the FB has remained in the EAC.

25 NASAL POLYPS

Linda French, MD

PATIENT STORY

A 14-year-old boy complains of unilateral nasal obstruction for the past several months of gradual onset. On examination of the nose, a nasal polyp is found (**Figure 25-1**).

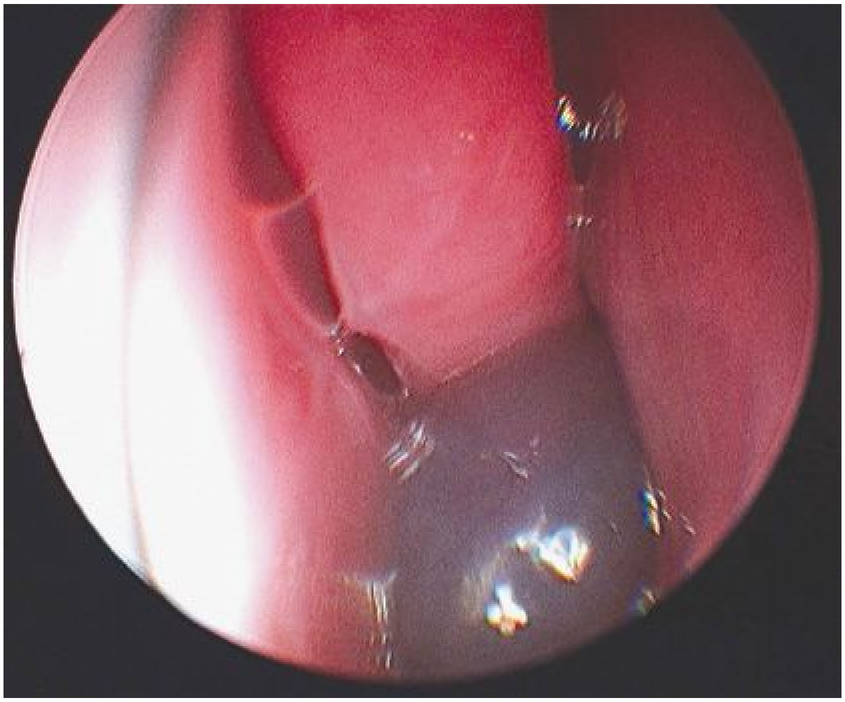

FIGURE 25-1 Nasal polyp in left middle meatus with normal surrounding mucosa. (*Used with permission from William Clark, MD.*)

INTRODUCTION

Nasal polyps are benign lesions arising from the mucosa of the nasal passages including the paranasal sinuses. They are most commonly semitransparent and pale in appearance.

EPIDEMIOLOGY[1]

- Prevalence of 0.1 percent of children of all races and classes.
- Nasal polyps are rare in children younger than 10 years old; peak age of onset is age 20 to 40 years.
- Associated with the following conditions:
  - Nonallergic and allergic rhinitis and rhinosinusitis.
  - Asthma—In 20 percent to 50 percent of patients with polyps.
  - Cystic fibrosis.
  - Aspirin intolerance—In 8 percent to 26 percent of patients with polyps.

ETIOLOGY AND PATHOPHYSIOLOGY

- Nasal polyposis is an inflammatory process. The precise cause is unknown, but genetic associations have been identified.[2]
- Infectious agents causing desquamation of the mucous membrane can play a triggering role. Presence of *Helicobacter pylori* was identified in nasal flora in all 25 patients in one case series.[3]
- Activated epithelial cells appear to be the major source of mediators that induce an influx of inflammatory cells, including eosinophils prominently; these in turn lead to proliferation and activation of fibroblasts.[4] Cytokines and growth factors play a role in maintaining the mucosal inflammation associated with polyps.
- Food allergies including milk allergy are strongly associated with nasal polyps.

DIAGNOSIS

CLINICAL FEATURES

- The appearance is usually smooth and rounded (**Figure 25-1**).
- Moist and translucent (**Figure 25-2**).

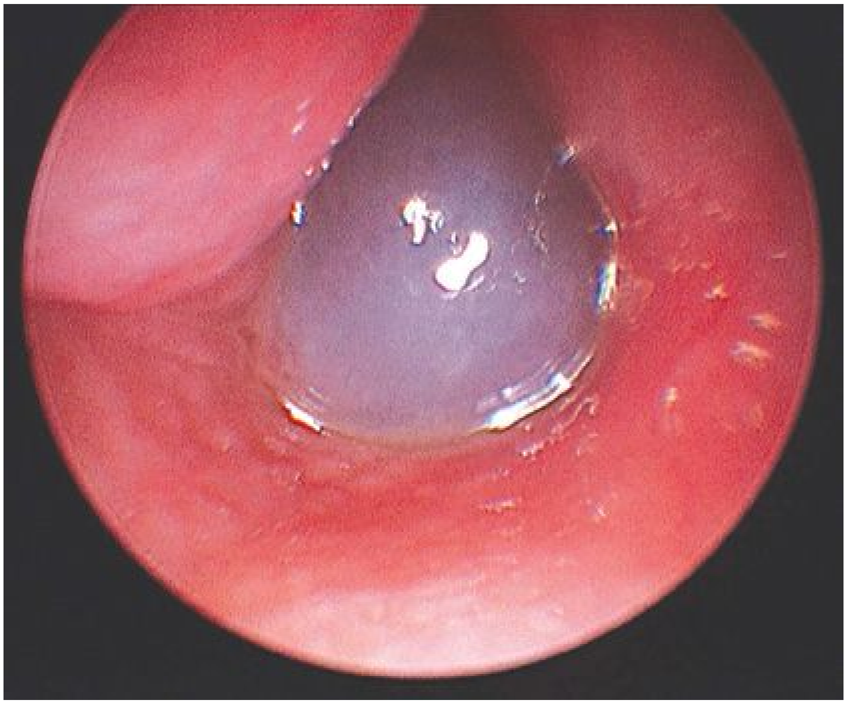

FIGURE 25-2 Nasal polyp in right nasal cavity in a patient with inflamed mucosa from allergic rhinitis. (*Used with permission from William Clark, MD*.)

- Variable size.
- Color ranging from nearly none to deep erythema.

TYPICAL DISTRIBUTION

- Nasal polyps arise most commonly from the ethmoid sinus and middle meatus.

LABORATORY AND IMAGING

- Consider allergy testing.
- In children with multiple polyps, order sweat test to rule out cystic fibrosis.
- A competed tomography (CT) of the nose and paranasal sinuses may be indicated to evaluate extent of lesion(s) (**Figure 25-3**).

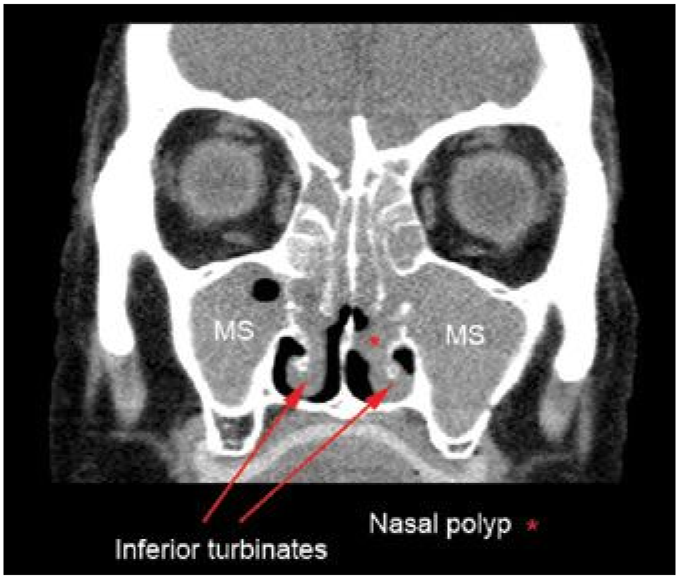

FIGURE 25-3 Computed tomography (CT) scan showing polyps (*asterisk*) and bilateral opacified maxillary sinuses (*MS*). Note the nasal polyp appears to be coming from the left maxillary sinus and is above the inferior turbinate. (*Used with permission from Richard P. Usatine, MD*.)

BIOPSY

- Not usually indicated. Histology typically shows pseudostratified ciliary epithelium, edematous stroma, epithelial basement membrane, and proinflammatory cells with eosinophils present in 80 percent to 90 percent of cases.

DIFFERENTIAL DIAGNOSIS

Many relatively rare conditions can cause an intranasal mass including:

- Rhabdomyosarcoma—Malignant tumor of childhood originating from striated muscle.
- Dermoid tumor—Inclusion cysts of ectodermal epithelial elements, usually manifest before 20 years of age; they can grow slowly.
- Hemangioma—Congenital, abnormal proliferation of blood vessels that can occur in any vascularized tissue (see Chapter 93, Childhood Hemangiomas and Vascular Malformations).
- Neuroblastoma—Unusual presentation of relatively common malignancy of childhood.
- Meningoencephalocele—Grayish gelatinous appearance.
- Angiofibroma—Locally-invasive neoplasm that appears as a firm grayish mass. Bleeds easily. Occurs in adolescent males, ages 14 to 18 years old. Undetermined etiology.[5]
- Pyogenic granuloma (see Chapter 142, Pyogenic Granuloma).[6]

MANAGEMENT

MEDICATIONS

- Medical treatment consists of intranasal corticosteroids.[7,8] SOR Ⓐ
- An initial short course (2 to 4 weeks) of oral steroids may be considered in severe cases.[9,10] SOR Ⓐ
- Steroid treatment reduces polyp size, but does not generally resolve them. Corticosteroid treatment is also useful preoperatively to reduce polyp size.
- Oral doxycycline can be considered for adolescents; 100 mg daily for 20 days was shown to decrease polyp size, providing benefit for 12 weeks in

one randomized controlled trial.[11] SOR Ⓑ

- Topical nasal decongestants can provide some symptom relief, but do not reduce polyp size.[12] SOR Ⓑ
- Montelukast reduces symptoms when used as an adjunct to oral and inhaled steroid therapy in patients with bilateral nasal polyposis.[13] SOR Ⓑ

PROCEDURES

- Surgical excision is indicated when medical treatment fails. Postoperative topical nasal steroid and/or oral montelukast treatment helps prevent recurrence.[14]
- Consider immunotherapy for patients with allergies.

PROGNOSIS

Lesions are benign but tend to recur.

FOLLOW-UP

- Periodic reevaluation is recommended because recurrence rates are high.[15]

PATIENT EDUCATION

- Patients should be informed about the benign nature of nasal polyps and their tendency to recur.

SECTION 2 NOSE AND SINUS

26 SINUSITIS

Mindy Smith, MD, MS
Camille Sabella, MD

PATIENT STORY

A 6-year-old is brought in by his mother for persistent rhinorrhea. He had what appeared to be a cold about 2 weeks prior but continues to have a stuffy nose and a constant cough, which is worse at night. He has no fever but his mother says that he appears more tired than usual and has a decreased appetite. On examination, the child has a purulent nasal discharge, nasal mucosal erythema, and allergic shiners (**Figure 26-1**); he otherwise appears healthy. You diagnose acute bacterial sinusitis (ABS) and prescribe oral amoxicillin-clavulanate. You discuss the lack of benefit of antihistamines and decongestants but offer a prescription for nasal corticosteroids, which the parent declines.

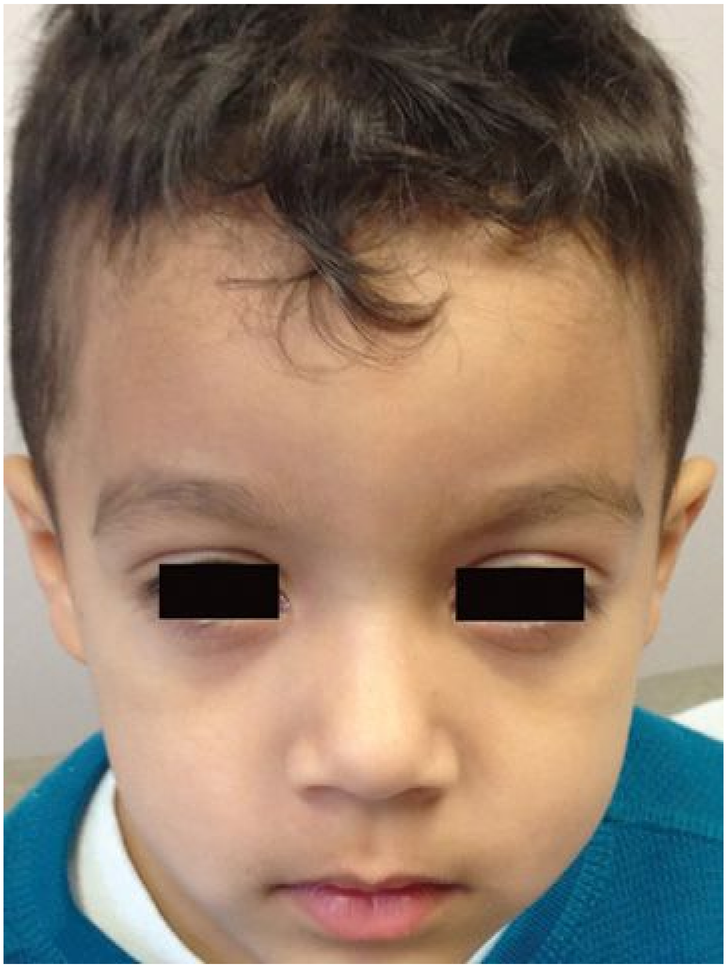

FIGURE 26-1 Allergic shiners in a child with acute bacterial sinusitis. Allergy is a risk factor for the development of acute bacterial sinusitis. (*Used with permission from Camille Sabella, MD.*)

INTRODUCTION

Sinusitis is symptomatic inflammation of the sinuses, nasal cavity, and their epithelial lining. Mucosal edema blocks mucous drainage creating a culture medium for viruses and bacteria. Sinusitis is classified by duration as acute (<4 weeks), subacute (4-12 weeks), or chronic (>12 weeks).

EPIDEMIOLOGY

- Approximately 1 percent of children per year develop sinusitis, accounting for 20 million antibiotic prescriptions; 6 percent to 7 percent of children seeking care for respiratory symptoms have acute bacterial sinusitis.[1]
- Children average six to eight colds per year. Of those, 0.5 percent to 8 percent will develop a sinus infection.[2,3]
- Risk factors include viral upper respiratory tract infection (URI) (about 80% of cases are preceded by a viral URI),[2] allergy,[4] and day care attendance.[5]
- Only 1/3 to 1/2 of primary care patients with symptoms of sinusitis actually have bacterial infection.[6]

ETIOLOGY/PATHOPHYSIOLOGY

- Sinus cavities are lined with mucus-secreting respiratory epithelium. The mucus is transported by ciliary action through the sinus ostia (openings) to the nasal cavity. Under normal conditions, the paranasal sinuses are sterile cavities and there is no mucus retention.
- The maxillary and ethmoid sinuses are present at birth and the frontal sinuses develop from the ethmoid sinuses by age 5 to 6 years.
- ABS occurs when ostia become obstructed or ciliary action is impaired, causing mucus accumulation and secondary bacterial overgrowth.
- The causes of sinusitis include:
    - Infection—Most commonly viral (e.g., rhinovirus, parainfluenza, and influenza) followed by bacteria infection (e.g., *Streptococcus (S) pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*). In the past 10 years, *S. pneumoniae* has become less common and *Haemophilus influenzae* more common as the etiologic agent of acute

    bacterial sinusitis in children.[2] In immunocompromised patients, fulminant fungal sinusitis can occur.
  - Noninfectious obstruction—Allergic, polyposis, barotrauma (e.g., airplane travel), chemical irritants, tumors, and conditions that alter mucus composition (e.g., cystic fibrosis).

DIAGNOSIS

- The diagnosis of ABS is clinical. Symptoms arising from a viral URI generally peak by day 5 or before and resolve by day 10.[1,2] ABS is diagnosed when:
  - Symptoms are present for 10 days or longer without improvement but less than 30 days.
  - Symptoms worsen after initial stability or improvement (“double worsening” or “double sickening”).
  - There are unusually severe signs and symptoms (high fever [>39°C], purulent rhinorrhea) present for at least 3 consecutive days.
- Sinusitis can be presumed when there are extra-sinus manifestations of infection (periorbital inflammation, orbital cellulitis, orbital or brain abscess), although these complications of sinusitis are infrequent (**Figures 26-2** and **26-3**).[2]

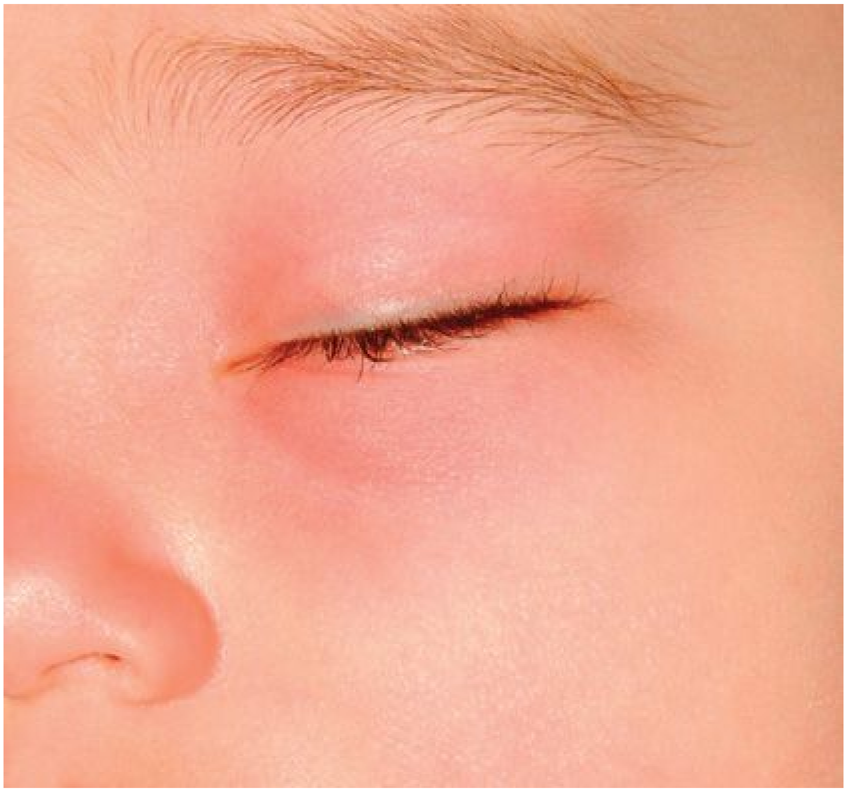

FIGURE 26-2 Periorbital erythema and swelling in a 1-year-old child with pansinusitis and left orbital abscess. (*Used with permission from Camille Sabella, MD.*)

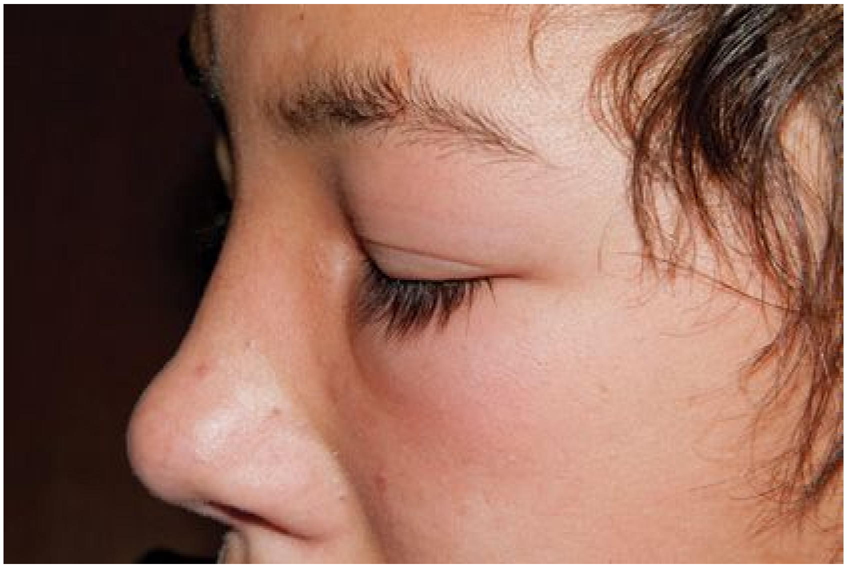

FIGURE 26-3 Periorbital swelling in a 12-year-old boy with left orbital cellulitis as a complication of acute bacterial sinusitis. (*Used with*

permission from Camille Sabella, MD.)

CLINICAL FEATURES

- Most cases occur as a complication of a viral URI or allergic inflammation.[2]
- Symptoms of URI and ABS overlap to a great extent; thus, it is the persistence of symptoms without improvement that suggests the diagnosis of ABS.
- These symptoms include nasal discharge (can be watery, mucoid, purulent or discolored) and daytime cough, which may be worse at night.
- Nonspecific symptoms include halitosis, fever, fatigue, headache, and decreased appetite.
- Physical examination findings are not particularly helpful in making the diagnosis of ABS. Erythema and swelling of the nasal mucosa are nonspecific findings.
- Complications of sinusitis are suspected in children with severe headache, seizures, focal neurologic deficits, periorbital edema, or erythema (**Figures 26-2** and **26-3**), proptosis, or abnormal intraocular muscle function.[2]

TYPICAL DISTRIBUTION

- Most sinus infections involve the maxillary sinus followed in frequency by the ethmoid (anterior), frontal, and sphenoid sinuses; however, most cases involve more than one sinus (**Figures 26-4** to **26-6**).[4]

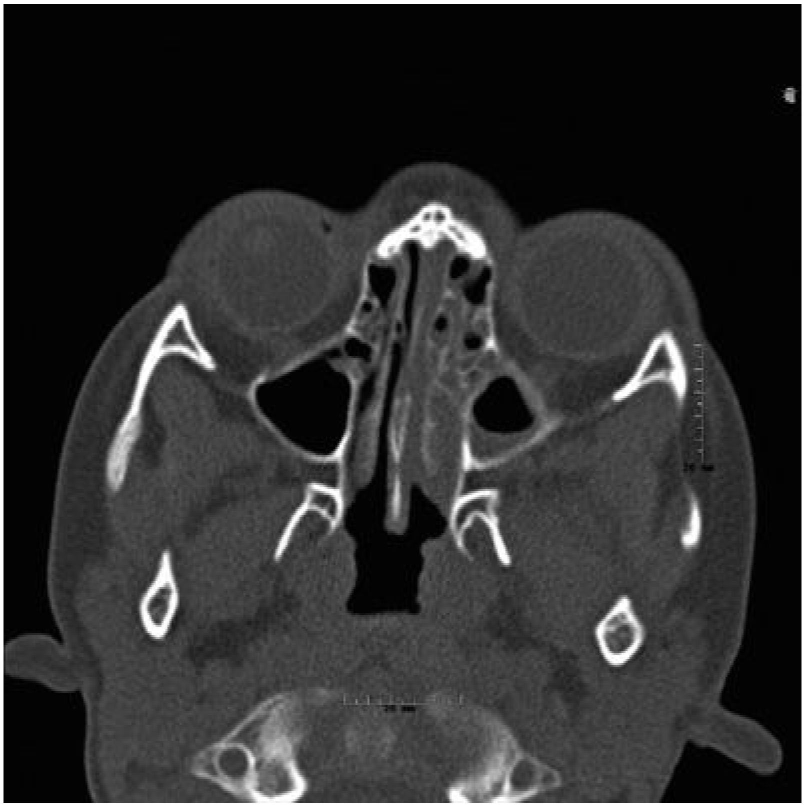

FIGURE 26-4 Opacification of the left ethmoidal and maxillary sinuses in a 5-year-old boy with acute bacterial sinusitis. Note the air-fluid level in the left maxillary sinus. (*Used with permission from Camille Sabella, MD.*)

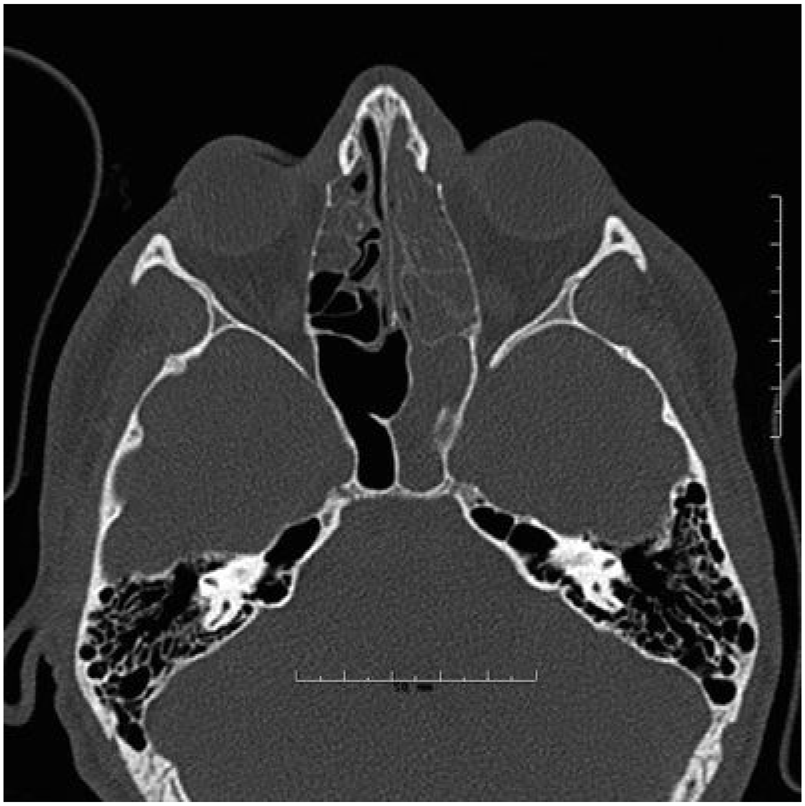

FIGURE 26-5 Opacification of the ethmoidal and sphenoid sinuses in a 16-year-old boy with acute bacterial sinusitis. (*Used with permission from Camille Sabella, MD*.)

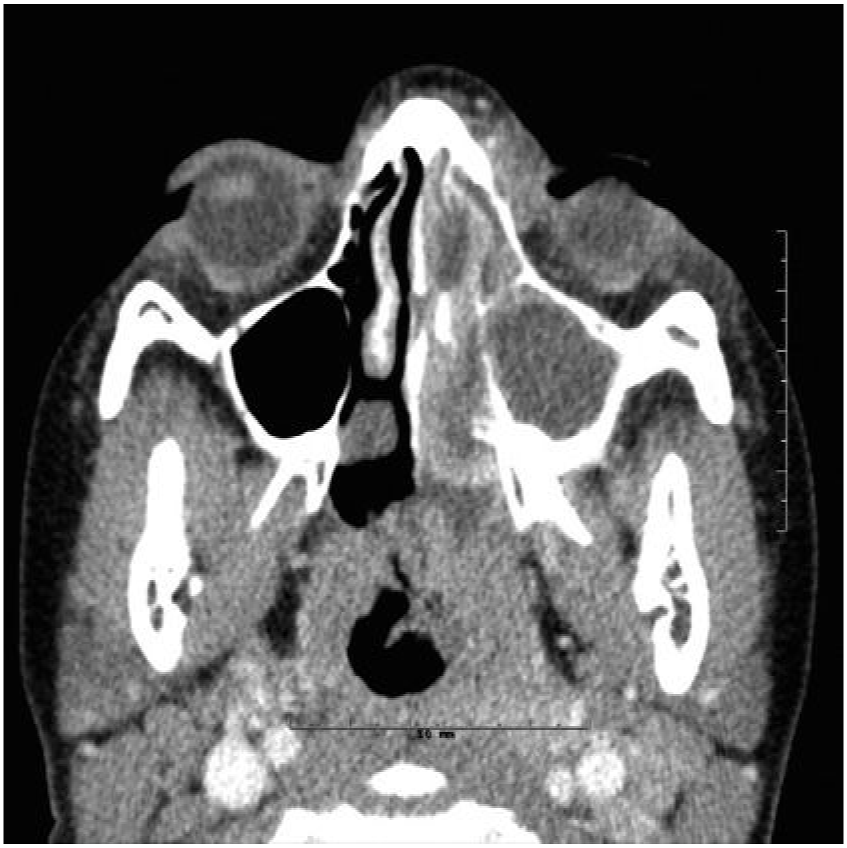

FIGURE 26-6 Opacification of the left ethmoidal and maxillary sinuses in a young girl who developed orbital cellulitis as a complication of acute bacterial sinusitis. (*Used with permission from Camille Sabella, MD.*)

- Children are more likely to have inflammation in the posterior ethmoid and sphenoid sinuses.[7]

LABORATORY AND IMAGING

- Culture of nasal or nasopharyngeal secretions is not recommended as these do not differentiate between URI and ABS.[1]
- If culture is needed due to suspected bacterial resistance or persistent infection, a meta-analysis in adult patients found endoscopically-directed middle meatal cultures to be reasonably sensitive (80.9%), specific (90.5%), and accurate (87.0%; 95% confidence interval, 81.3% to 92.8%) compared with maxillary sinus taps.[8]

- There are no trials comparing meatal cultures to maxillary sinus aspirates in children with ABS. Given that the middle meatus in children is commonly colonized with the pathogens that cause sinusitis, it is difficult to ascertain the accuracy of meatal cultures in children without comparative trials.
- The Infectious Disease Society of America (IDSA) recommends direct sinus aspiration for specimens for culture rather than nasopharyngeal swabs.[9]
- Radiography should not be obtained routinely for patients meeting diagnostic criteria for ABS, unless a complication (**Figures 26-2**, **26-3**, **26-6**, **26-7**) or alternate diagnosis is suspected. In these cases, CT or MRI is warranted.[1]

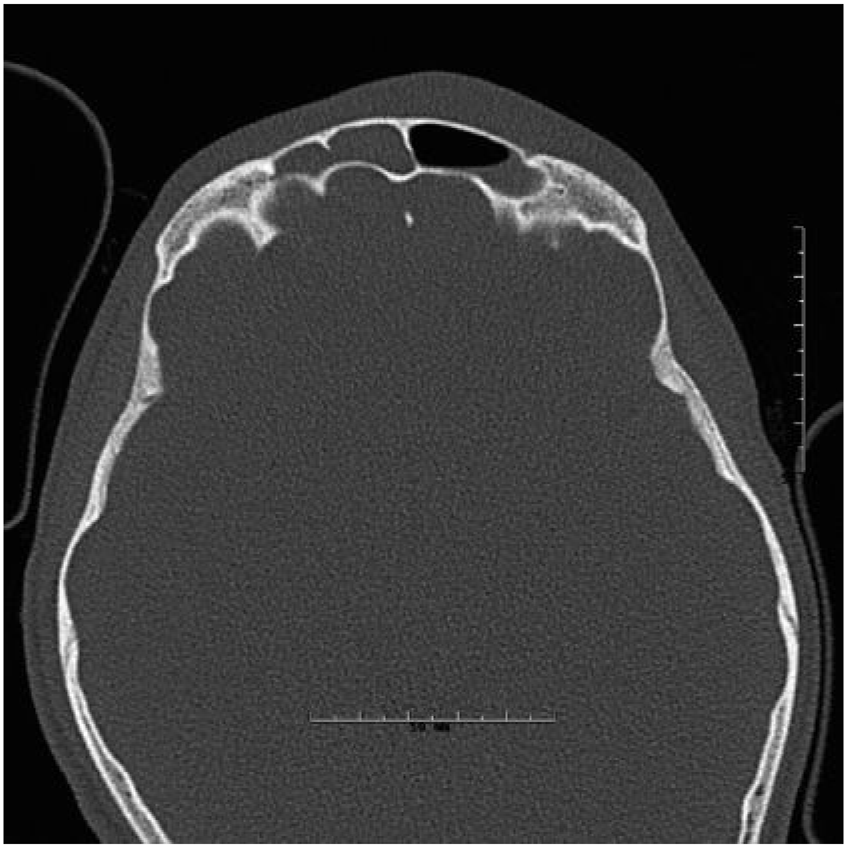

FIGURE 26-7 Air fluid level in left frontal sinus and proptosis of the frontal bone in an adolescent who developed Pott’s puffy tumor and a subdural empyema from acute bacterial sinusitis. (*Used with permission from Camille Sabella, MD.*)

  - In children with persistent ABS despite treatment, recurrent, or chronic sinusitis, the American College of Radiology recommends CT of the paranasal sinuses without contrast.[10]
  - In children with orbital or intracranial complications of ABS, the American Academy of Pediatrics recommend a contrast enhanced CT or MRI with contrast of the head and/or orbits and paranasal sinuses.

- Nasal endoscopy can be considered in patients with chronic rhinosinusitis. In one case series of adult patients with suspected chronic rhinosinusitis, the addition of endoscopy to symptom criteria had similar sensitivity (88.7% versus 84.1%) but significantly improved specificity (66% vs. 12.3%) using CT as the gold standard.[11]

REFER OR HOSPITALIZE

- Patients who are seriously ill, immunocompromised, continue to deteriorate clinically despite extended courses of antimicrobial therapy, or have recurrent bouts of ABS should be referred to a specialist.[10]

- Hospitalize patients with potentially life threatening complications including subperiosteal orbital abscess (**Figure 26-2** and **Figure 26-3**), meningitis, epidural or cerebral abscess, and cavernous sinus thrombosis. An estimated 2 percent to 30 percent of patients hospitalized with ABS have complications; most complications occur in males.[12]
  - The risks of frontal sinusitis include eroding through the frontal bone forward causing a Pott's puffy tumor (**Figure 26-7**), or inward and spreading into the brain and cavernous sinuses. In a small case series (N = 25, mostly adolescents), epidural abscess (N = 13) was the most common intracranial complication of ABS followed by subdural empyema (N = 9), meningitis (N = 6), encephalitis (N = 2), brain abscess (N = 2), and dural sinus thrombophlebitis (N = 2).[13]
  - Infection in the ethmoid sinuses is responsible for the majority of orbital complications.[13] Periorbital cellulitis is the most common complication of ABS in children, accounting for 80 percent to 90 percent of all extracranial complications.[13] Orbital complications should be suspected in children with ophthalmoplegia and/or

  proptosis.[13] Orbital abscess is highly dangerous and can also be the result of spread from the frontal sinuses.
  - In immunocompromised patients, fulminant fungal sinusitis may cause orbital swelling, cellulitis, proptosis, ptosis, impairment of extra-ocular motion, nasopharyngeal ulceration, and epistaxis. Bony erosion can occur. Nasal mucosa might appear black, blanched white, or erythematous.

DIFFERENTIAL DIAGNOSIS

- Upper respiratory tract infections—These are common infections, primarily viral (most commonly rhinovirus), that cause six to eight infections per year in children. Infections are self-limited (lasting approximately 7 to 10 days) and typical symptoms include rhinorrhea, nasal congestion, sore throat, and cough. URI often precedes acute sinusitis.
- Post-nasal drip—Lack of fever, clear discharge, cough occurring only at night.
- Reactive airway disease—History of asthma or atopy, wheezing, cough occurs at night.
- Allergic rhinitis—Sneezing, itching, watery rhinorrhea.
- Tumor—Rare; unilateral epistaxis or discharge and obstruction, recurrent sinusitis, sinus pain.

MANAGEMENT

Duration of illness assists in decision making, as most patients improve without specific treatment; a period of watchful waiting for up to 10 days is consistent with guidelines.[10] Treatment of symptoms, including pain, is important.

NON-PHARMACOLOGIC

- There is no evidence supporting the use of nasal saline irrigation for ABS in children.[14] In adults with chronic sinusitis, nasal saline irrigation provides symptom relief, both alone and as an adjunct to nasal steroids, and is well tolerated.[15] SOR Ⓑ

MEDICATIONS

- Analgesics (acetaminophen or non-steroidal anti-inflammatory drugs) should be used for pain.
- No benefit in symptom relief and significant toxicity from ABS has been demonstrated with the use of antihistamines and decongestants in children.[2,10] SOR Ⓐ
- Antihistamines should not be used for ABS, although they may be helpful in reducing allergic symptoms in children with atopy who develop ABS. SOR Ⓒ
- Intranasal corticosteroids appear to be of benefit in improvement and resolution of symptoms of ABS in adolescents and adults.[16] SOR Ⓑ The benefit of intranasal corticosteroids in young children with ABS has not been proven.[1]
- There have been no clinical trials of mucolytics reported in non-atopic children or adults with ABS. However, they may be useful in preventing crust formation and liquefying secretions. SOR Ⓒ
- Patients who fail to improve with symptomatic treatment, have severe symptoms or worsening of symptoms should be offered oral antibiotics. SOR Ⓑ Of five randomized controlled trials in children with acute sinusitis, three showed benefit; however, in the remaining two trials the antimicrobial treatment dose was suboptimal and in one, the presence of asthma and allergic conditions may have compromised accurate diagnosis or determination of treatment response.[2]
    - In the most recent trial, provision of antibiotics (90 mg of amoxicillin and 6.4 mg of clavulanate per kilogram of body weight per day,

administered in two doses) was associated with reduced treatment failure (14% versus 68% on placebo) with a number needed to treat of three.[17] The clinical success rate for the drug and clinical failure rate for placebo in this trial, however, are high. In the older Wald et al. trial, cure rate was 67 percent for amoxicillin, 64 percent for amoxicillin-clavulanate potassium, and 43 percent for placebo.[18]

- Choice of antibiotics and dosing should be made considering local resistance patterns to *S. pneumoniae* (commonly 10% to 15%) and other risk factors for bacterial resistance.
    - Amoxicillin–clavulanate (45–90 mg per kilogram per day of amoxicillin administered in two doses) rather than amoxicillin alone is recommended as empiric antimicrobial therapy for ABS in children by the IDSA.[10]
    - The American Academy of Pediatric recommends amoxicillin as the first line treatment of uncomplicated ABS when antimicrobial resistance is not suspected.[1]
    - Amoxicillin and amoxicillin-clavulanate have been best studied but there are no studies demonstrating comparative effectiveness of one antibiotic over another.[2] Macrolides and trimethoprim-sulfamethoxazole should not be used.[10]
    - High dose amoxicillin-clavulanate or amoxicillin (2 g orally twice daily or 90 mg/kg/day twice daily of amoxicillin component) is recommended as first-line therapy for children in areas where bacterial resistance rates are 10 percent or higher and for those in day care, those <2 years of age, those with comorbidities or immune compromise, and those who have been hospitalized in the past 5 days or treated with antibiotics in the past month.[10] SOR Ⓒ
    - A single-dose of intramuscular or intravenous ceftriaxone can be used for children who are unable to tolerate oral medication or unlikely to be adherent to oral therapy.[1]
    - Second-line therapy for children recommended by IDSA and AAP includes **a** third-generation oral cephalosporin (cefixime or cefpodoxime) with or without clindamycin in cases with non–type I penicillin allergy or in regions with high endemic rates of bacterial resistance.[1,10] SOR Ⓒ

  - Levofloxacin may be considered for children with a history of type I hypersensitivity to penicillin, although allergy referral for penicillin and cephalosporin skin testing is encouraged in this situation.[1,10] SOR C
  - Recommended treatment duration is 10 to 14 days or 7 days after a child is symptom-free (per AAP).[1,10] SOR C
- In a Cochrane review of fifty-nine trials evaluating antibiotic treatment for acute maxillary sinusitis, antibiotics decreased clinical failure by about 10 percent.[19] Comparisons between classes of antibiotics showed no significant differences; therefore narrow-spectrum antibiotics were recommended.[20]
- The modest benefit of antibiotics for improving rates of clinical cure or symptom improvement should be weighed against the risks of harm (primarily gastrointestinal but also skin rash, headache, dizziness, and fatigue). In the most recent Wald et al. trial, adverse effects (primarily diarrhea) occurred in 44 percent (versus 14% with placebo) and three children (11%) discontinued treatment due to medication side effects.[18]
- Intravenous antibiotics are used for complications of sinusitis with therapy dictated by culture and local resistance patterns. Combination therapy with vancomycin, ceftriaxone, and metronidazole provides coverage for most intracranial pathogens complicating ABS.[13]

PROCEDURES

- In ABS, surgery is primarily used to obtain cultures or drain fluid collections.[13]
- Immunocompromised patients with fungal sinusitis are treated with aggressive debridement and adjunctive antifungal agents.[20]
- Authors of a Cochrane review of adenoidectomy to treat chronic nasal symptoms in children found only two studies (one of recurrent otitis media); both did not show benefit.[21]
  - The presence of biofilm in adenoid samples from children with chronic rhinosinusitis compared with children who had adenoidectomy for

sleep apnea (95% versus 2%) provides some rationale for removing adenoids in children prior to proceeding to endoscopic sinus surgery.[22]

- For patients with chronic sinusitis, authors of a Cochrane review found endoscopic sinus surgery was not superior to medical treatment; in one study there was a lower relapse rate (2.4% versus 5.6% without surgery).[23] SOR B In an older meta-analysis of eight published papers (not randomized trials) and unpublished data, functional endoscopic surgery in children was highly successful (88.7% positive outcomes) with a 0.6 percent complication rate.[24] SOR C
- Smoking and exposure to smoke increase the risk of sinusitis. Thus, avoidance will help to lower the risk of sinusitis, especially in children with a history of allergies, who are already at higher risk for developing ABS.

PROGNOSIS

- Based on a Cochrane review, cure or improvement rate for acute sinusitis within two weeks was high in both the placebo group (80%) and the antibiotic group (90%).[19] In the trials conducted with children, cure rates were 64 percent to 86 percent on antibiotics and cure rates on placebo were an absolute rate of 20 percent lower.[2]
- An unknown number of children develop chronic rhinosinusitis.[25]

FOLLOW-UP

- For children who fail first-line antibiotic treatment after 3 to 5 days, a nonbacterial cause or resistant organism should be considered and antibiotic coverage should be broadened or a different antibiotic class should be chosen (e.g., amoxicillin-clavulanate, respiratory fluoroquinolone).[1,10] SOR C

- If the child still fails to improve, refer to a specialist and consider imaging (CT or MRI to investigate non-infectious causes or complications) and direct sinus aspirate or meatal cultures.[10]
- The role of bacteria and inflammatory mediators in chronic rhinosinusitis is unclear; none-the-less, antibiotics (e.g., amoxicillin-clavulanate) for 3 to 4 weeks and intranasal steroids are often used.[26] Assessing children for allergy and systemic predisposing factors (e.g., cystic fibrosis, primary ciliary dyskinesia) can help direct treatment.

PATIENT EDUCATION

- Persistent nasal congestion and rhinitis (more than 10 days after a cold) or worsening or severe symptoms (fever, facial pain) following a cold may indicate a sinus infection and patients should see their primary provider. Symptoms due to a cold usually abate within one week.
- Methods to improve sinus drainage (oral and nasal decongestants and nasal saline irrigation) have not been shown to work in children but intranasal steroids may prove useful.

27 COMPLICATIONS OF SINUSITIS

Janalee Holmes, MD
Prashant Malhotra, MD, FAAP

PATIENT STORY

A 10-year-old girl has a 2-week history of daily headaches and rhinorrhea. She is admitted from the emergency department to the pediatric intensive care unit for a 2-day history of worsening left frontal headache, mental status changes including lethargy and slurred speech, nausea, and mild periorbital edema. Computed tomography (CT) demonstrates opacification of bilateral frontal, maxillary, and anterior ethmoid sinuses as well as pneumocephalus (**Figure 27-1A**). Magnetic resonance imaging demonstrated extensive left sided subdural empyema (worse frontal and temporal) and diffuse bilateral dural enhancement (**Figure 27-1B**). She is urgently treated via a combined surgical approach with pediatric otolaryngology for bilateral endoscopic sinus surgery and pediatric neurosurgery for left craniotomy. She subsequently had 10 weeks of intravenous antimicrobial therapy. Her immediate postoperative course was complicated by seizures; she has now made a full recovery and is doing well.

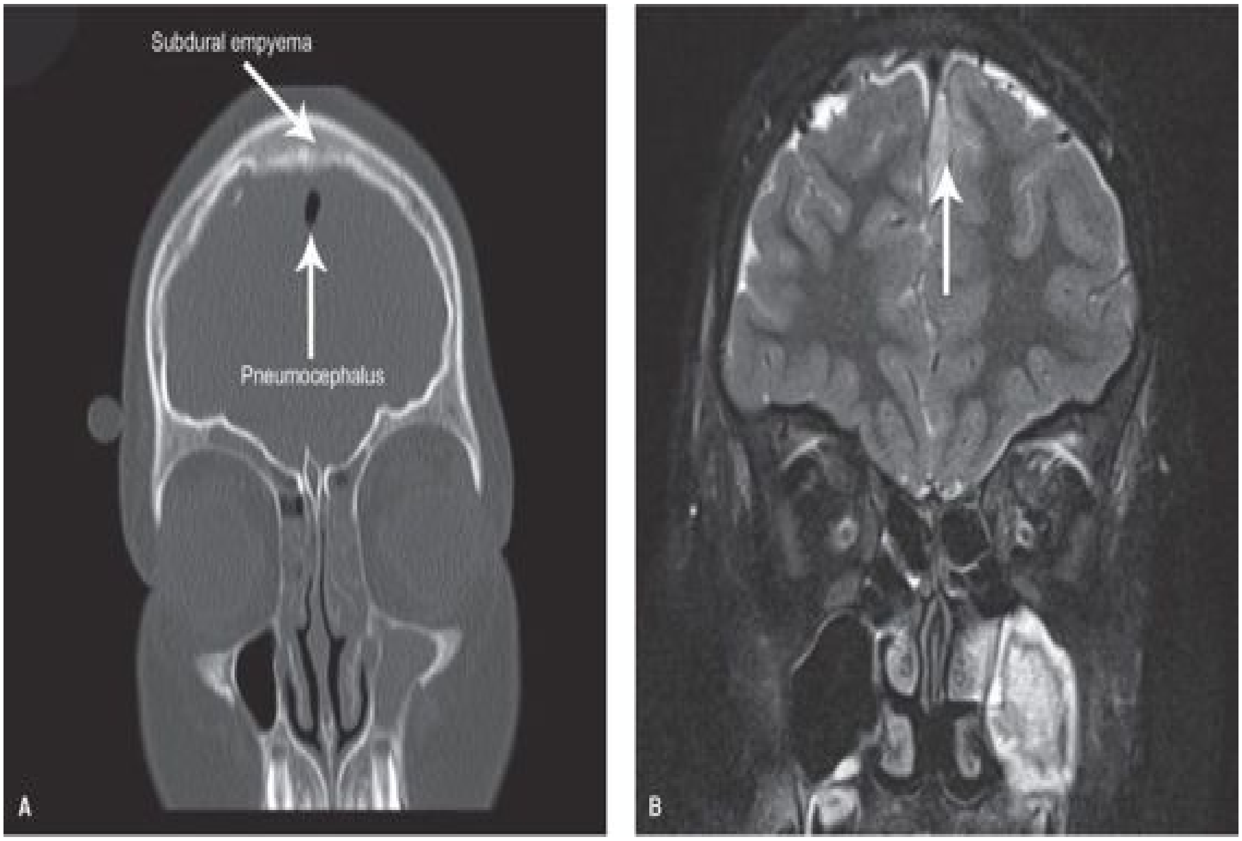

FIGURE 27-1 **A.** Coronal CT scan demonstrating bilateral ethmoid and left maxillary sinus opacification along pneumocephalus, in a 10-year-old with intracranial extension from frontal sinusitis leading to subdural empyema. **B.** Same patient, coronal T2 MRI demonstrating a hyperintense extra-axial collection (arrow) along the falx to the left of midline and uniform dural enhancement overlying both cerebral hemispheres. (*Used with permission from Prashant Malhotra, MD*.)

INTRODUCTION

Complications of acute sinusitis are typically extensions of infection beyond the paranasal sinuses into adjacent structures and can have devastating consequences, including blindness, neurologic morbidity, and even death.

SYNONYMS

Periorbital cellulitis, subperiosteal abscess, orbital cellulitis, orbital abscess, cavernous sinus thrombosis, meningitis, subdural abscess, subdural empyema, pyocele, mucopyocele, intracranial abscess, or invasive fungal sinusitis.

EPIDEMIOLOGY

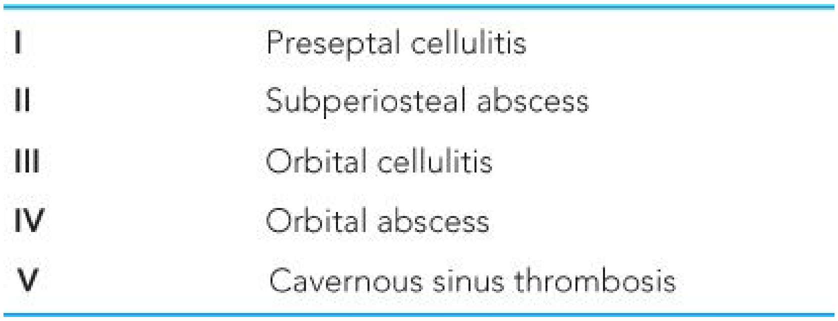
- Orbital complications account for 90 percent of acute complications from sinusitis and approximately 3 percent of all acute rhinosinusitis.[1]
- Children younger than age 7 years of age develop isolated orbital complications associated with acute ethmoiditis.[2]
- Children older than 7 years, mostly teenage males, are more likely to develop intracranial complications.[2,3] This is likely related to the age related development of the frontal and sphenoid sinuses.

ETIOLOGY AND PATHOPHYSIOLOGY

- Children have a high rate of upper respiratory infections (URI) and viral rhinosinusitis.
- Congenital or traumatic dehiscences in the lamina papyracea and skull base provide potential routes for direct spread.
- The diploic veins of the skull and ethmoid bone as well as the ophthalmic veins are valveless and allow for communication between the nose, sinuses, face, orbit, cavernous sinus, and intracranial system.
- The combination of phlebitis and direct entry of bacteria into perivascular structures results in a continuum of inflammatory and infectious changes.

- The valveless intracranial venous system allows for further spread of thrombophlebitis and septic emboli.
- Complications can be orbital (**Table 27-1**),[4] intracranial, or involving adjacent bone.

TABLE 27-1 Chandler Classification of Orbital Complications[4]



I	Preseptal cellulitis
II	Subperiosteal abscess
III	Orbital cellulitis
IV	Orbital abscess
V	Cavernous sinus thrombosis

- Intracranial complications can include meningitis, epidural or subdural abscess or empyema, and intracerebral abscess or venous sinus thrombophlebitis.
- Culprit bacteria in children include the usual acute rhinosinusitis bacteria (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*); however, suppurative complications are also associated with other Streptococcus species, *Staphylococcus aureus*, anaerobes (such as *Bacteroides* and *Fusobacterium* species), and polymicrobial infections.[9]
- Local bony complications include mucocele, pyocele, or mucopyocele, as well as osteomyelitis.

RISK FACTORS

- Children with immune deficiencies, cystic fibrosis, and ciliary dyskinesias are more likely to develop acute bacterial rhinosinusitis.[5,6]
- Orbital complications are associated with ethmoiditis in 86 percent of cases.[1]

- Intracranial complications are more likely in children with frontal sinusitis, adolescent age, and male gender.[3,7]

DIAGNOSIS

CLINICAL FEATURES

- Every patient with a possible complication of sinusitis should have an examination with anterior rhinoscopy or nasal endoscopy to evaluate for polyps or purulent drainage in the middle meatus.
- Endoscopy can also assist in identifying local complications and anatomic abnormalities such as mucopyocele.
- The eye must be assessed for visual acuity, extraocular movements, and proptosis. Upper and lower lid edema and erythema are common, and conjunctiva should be assessed for chemosis. Fluctuance of lids consistent with abscess is rare (**Figure 27-2A**,**B**).

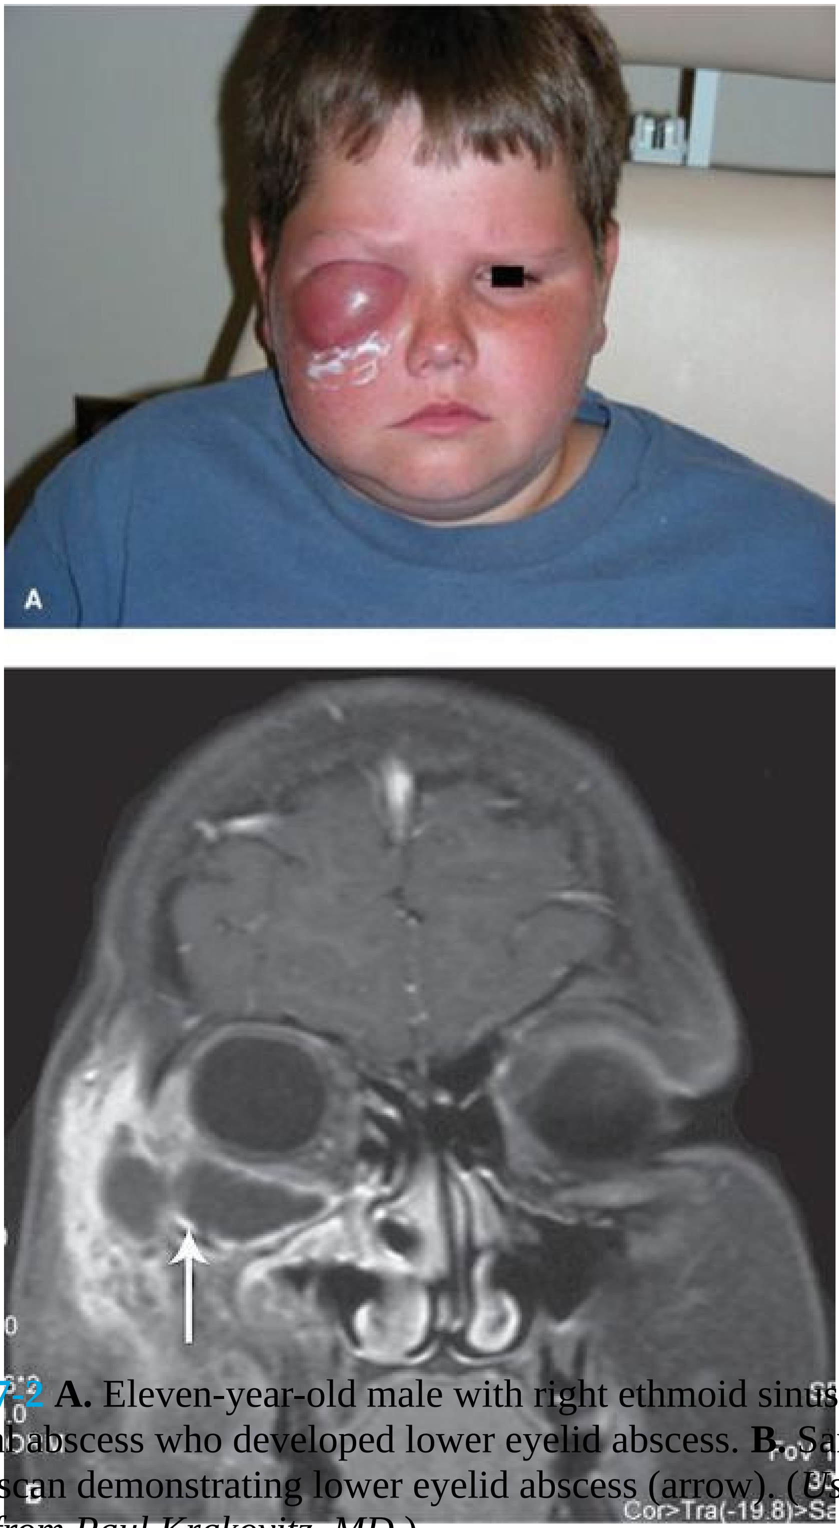


FIGURE 27-2 **A.** Eleven-year-old male with right ethmoid sinusitis, subperiosteal abscess who developed lower eyelid abscess. **B.** Same patient, coronal CT scan demonstrating lower eyelid abscess (arrow). (*Used with permission from Paul Krakovitz, MD.*)

- The orbital septum is a fascial continuation of the periosteum extending into the upper and lower eyelids, and is a physiologic barrier to the orbit. When post-septal involvement is suspected an ophthalmologic consultation should be obtained immediately to help with surgical planning.

- Generalized symptoms indicative of increased intracranial pressure include frontal or retro-orbital headache, nausea and vomiting, altered mental status, nuchal rigidity, abducent nerve palsy, and papilledema.
- Late intracranial findings include seizures, hemiparesis, and focal neurologic findings.[8]
- Specific complications of sinusitis and their common clinical findings are summarized in (**Table 27-2**).

TABLE 27-2 Complications of Sinusitis and Their Corresponding Clinical Findings

Complication	Clinical Findings
Preseptal cellulitis	Eyelid edema, erythema, and tenderness (**Figure 27-3**). No deficits in extraocular movement or visual acuity.
Subperiosteal abscess	Eyelid edema, erythema, and tenderness, and possibly proptosis and impaired extraocular muscle movement. Can have downward and laterally displaced globe (**Figures 27-4** and **Figure 27-5**).
Orbital cellulitis	Eyelid edema and erythema, proptosis, chemosis, limited or no impairment of extraocular movements or vision. Normal visual acuity.
Orbital abscess	Significant exophthalmos, chemosis, ophthalmoplegia, and visual impairment (**Figures 27-6**).
Cavernous sinus thrombosis	Bilateral orbital pain, chemosis, proptosis, ophthalmoplegia, cranial neuropathies (IV, V1, V2, and VI), picket-fence fevers, meningismus, lethargy.
Meningitis	Headache, neck stiffness, and high fever, vomiting.
Epidural abscess	Headache, fever, and local pain and tenderness. Unenhanced CT reveals a hypodense or isodense crescent-shaped area adjacent to the inner table of the skull.
Subdural abscess	Headache, fever, meningismus, focal neurologic deficits, and lethargy with rapid deterioration. MRI demonstrates a low signal on T1 images and high signal on T2 images with peripheral contrast enhancement (**Figures 27-1**).
Intracerebral abscess	Fever, headache, vomiting, lethargy, seizures and focal neurologic deficits. Frontal deficits can include changes in mood and behavior. Lumbar puncture can be life threatening. MRI demonstrates a cystic lesion with a distinct hypointense strongly enhancing capsule on T2 images.
Venous sinus thrombosis	Extremely ill with meningeal signs or other serious neurologic symptoms. Picket fence fevers. MRI may reveal focal defects of enhancement. MR angiogram and venogram can further delineate.
Pott's puffy tumor or frontal bone osteomyelitis	"Puffy" fluctuant forehead swelling, frontal pain, fever (**Figures 27-7**).
Mucocele, pyocele, mucopyocele	Proptosis and impaired extraocular muscle movement (**Figure 27-8**).

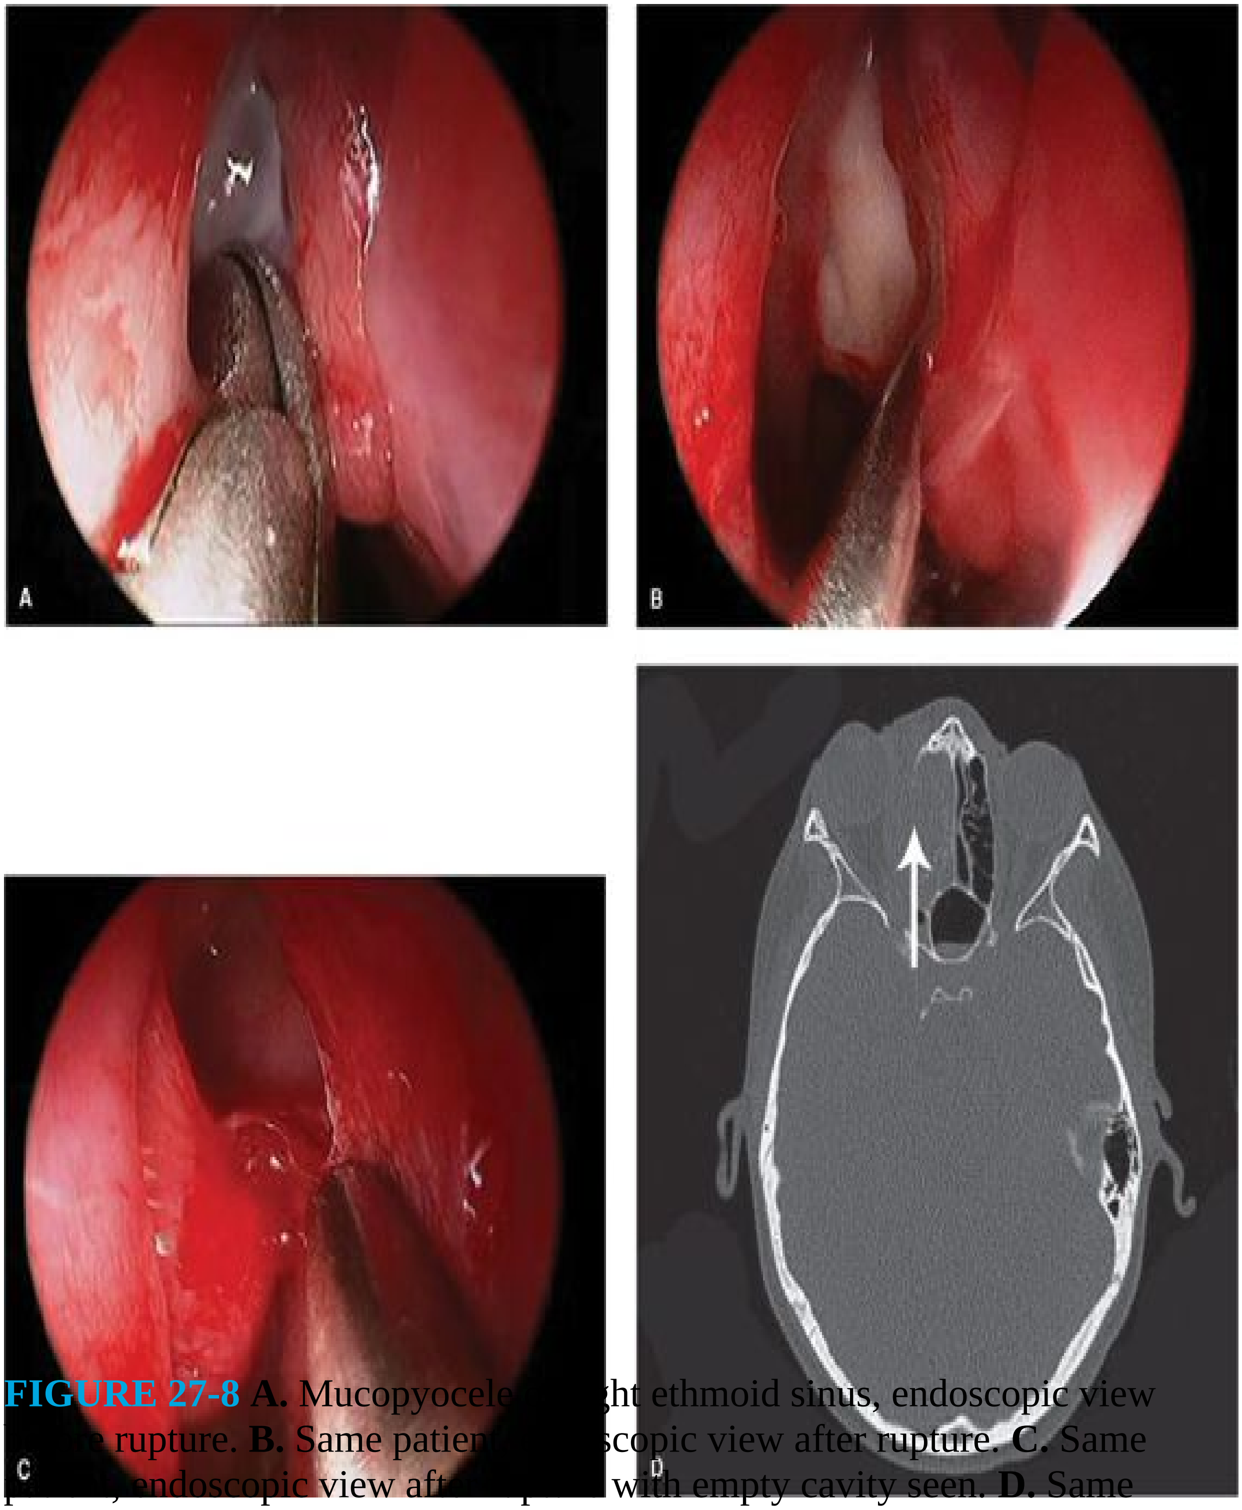

FIGURE 27-8 **A.** Mucopyocele of right ethmoid sinus, endoscopic view before rupture. **B.** Same patient, endoscopic view after rupture. **C.** Same patient, endoscopic view after rupture with empty cavity seen. **D.** Same patient, CT scan. Note expansion and erosion of right ethmoid cells as well as dehiscence of lamina papyreacea (medial orbital wall) (arrow). (*Used with permission from Prashant Malhotra, MD*.)

LABORATORY TESTING

- A white blood cell count is helpful in evaluating for leukocytosis.
- Lumbar puncture should be considered when there is concern for intracranial infection.

IMAGING

- Contrast-enhanced CT is indicated whenever there is suspicion of post-septal involvement or an intracranial complication.
- CT should also be considered when preseptal inflammation progresses in 24 to 48 hours despite treatment, symptoms are severe (ill appearing, high fevers), or in patients who are immunocompromised.
- Contrast-enhanced magnetic resonance imaging (MRI) is performed when intracranial complications is suspected and should include axial and coronal T1 and T2 images.

DIFFERENTIAL DIAGNOSIS

- Trauma—History and lack of sinusitis on examination and imaging will help to differentiate from sinusitis complication.
- Foreign body—Same as for trauma.
- Eyelid infection—Physical examination findings and lack of sinusitis on examination and imaging will help to differentiate.
- Invasive fungal sinusitis—see the following.
- Orbital hematoma—Diagnosis based on characteristic appearance on examination and imaging.
- Otitis media—Often present concurrently with sinusitis (see Chapter 22, Otitis Media—Acute and OME).
- Nasal polyposis—Usually evident on examination and nasal endoscopy.

- Sinonasal mass—Usually evident on examination, imaging, and nasal endoscopy.
- Orbital mass—Imaging and intraoperative findings will help to differentiate.

MANAGEMENT

MEDICATIONS

- Prompt identification and initiation of treatment is critical.
- Preseptal cellulitis often can be treated with oral antibiotics as an outpatient and with close follow-up (see Chapter 17, Preseptal (Periorbital) Cellulitis).
- The other complications require initial medical treatment with broad-spectrum intravenous antibiotics (often followed by oral therapy). SOR Ⓒ
- Topical nasal decongestant and saline irrigations are frequently used, but utility is debated. SOR Ⓒ
- Antibiotics that cross the blood–brain barrier should be used when there is intracranial involvement.
- Corticosteroids and anticonvulsants can be administered to treat any secondary cerebral edema. SOR Ⓒ
- The use of anticoagulants in venous thrombosis is controversial.

SURGERY

- Surgical intervention is recommended in cases where there is loss in visual acuity on initial evaluation, severe orbital complications, intracranial abscess, progression of orbital signs, symptoms despite medical treatment, or lack of improvement within 48 hours despite aggressive medical treatment. SOR Ⓒ

- Functional endoscopic sinus surgery or conventional open sinus surgery to drain the involved sinuses is performed on a case-by-case basis. SOR Ⓒ
- Drainage of subperiosteal abscesses should be done in the same setting either by endoscopic techniques, medial canthal, or via a transconjunctival incision depending on the location of the abscess.[10] SOR Ⓒ
- The CT dimensions of a subperiosteal abscess that can be treated medically have been debated; when the abscess is wider than 10 mm, decision to proceed immediately for drainage can be considered.[11]
- Treatment of Pott’s puffy tumor includes drainage of the abscess with removal of infected bone followed by at least 6 weeks of antibiotics. SOR Ⓒ
- Neurosurgical management of intracranial infection can be done concurrently with sinus surgery.

REFERRAL

- Ophthalmologic evaluation should be performed if orbital cellulitis, orbital abscess, or subperiosteal abscess is present, or if there is any change in vision or ocular mobility. Visual acuity, intraocular pressures, and complete ophthalmologic exam should be documented prior to surgical intervention.
- Neurosurgical evaluation should be performed if there are any concerns for intracranial extension.
- Pediatric otolaryngology evaluation should be considered if any complications of sinusitis are encountered, for medical and possible surgical intervention of source infection, as well as possibility of endoscopic transnasal approaches to abscesses.
- Infectious disease consultation, to guide antimicrobial choice and length of therapy, is suggested if suppurative complications are present.

PREVENTION AND SCREENING

- Appropriate management of acute bacterial rhinosinusitis is the most effective means of prevention.
- This can be made according to guidelines such as those from the 2012 Infectious Diseases Society of America.[12]

PROGNOSIS

- Children with intracranial extension are typically hospitalized and treated for longer durations than those with intraorbital extension; however, the risk of persistent sequelae is not higher.[13]
- Persistent sequelae include diplopia, vision loss, hemi-paresis, aphasia, and other neurologic deficits; this is reported to occur in about 3 to 23 percent of cases.[11–14]

FOLLOW-UP

- The timing of follow-up is determined by the severity of the disease process.
- Patients with complications other than preseptal cellulitis will be managed in the inpatient setting.
- Close follow-up is required in all patients to prevent progression and visual impairment.
- Patients are typically seen at 1 week following endoscopic sinus surgery for debridement.

INVASIVE FUNGAL SINUSITIS

- Invasive fungal sinusitis is a unique and important complication where prompt recognition can be lifesaving and deserves special mention. This devastating infection can occur in children in immunocompromised states such as hematologic or lymphoid malignancies, post-transplant, immunodeficiency disorders, or poorly controlled type 1 diabetes mellitus.
- Invasive fungal sinusitis may be heralded by fever, facial pain, numbness in trigeminal distribution, sinus symptoms (congestion, rhinorrhea), palatal fistula, overlying skin changes, or signs of orbital or intracranial extension.[15,16]
- Nasal endoscopy and biopsy should be promptly performed as soon as there is concern for invasive fungal sinusitis. Fungal hyphal elements with submucosal infiltration, angio-invasion, and necrosis are diagnostic.[15–17]
- Contrast enhanced CT scan and MRI is performed when invasive fungal sinusitis are suspected and includes axial and coronal T1 and T2 images (**Figures 27-9A,B**).

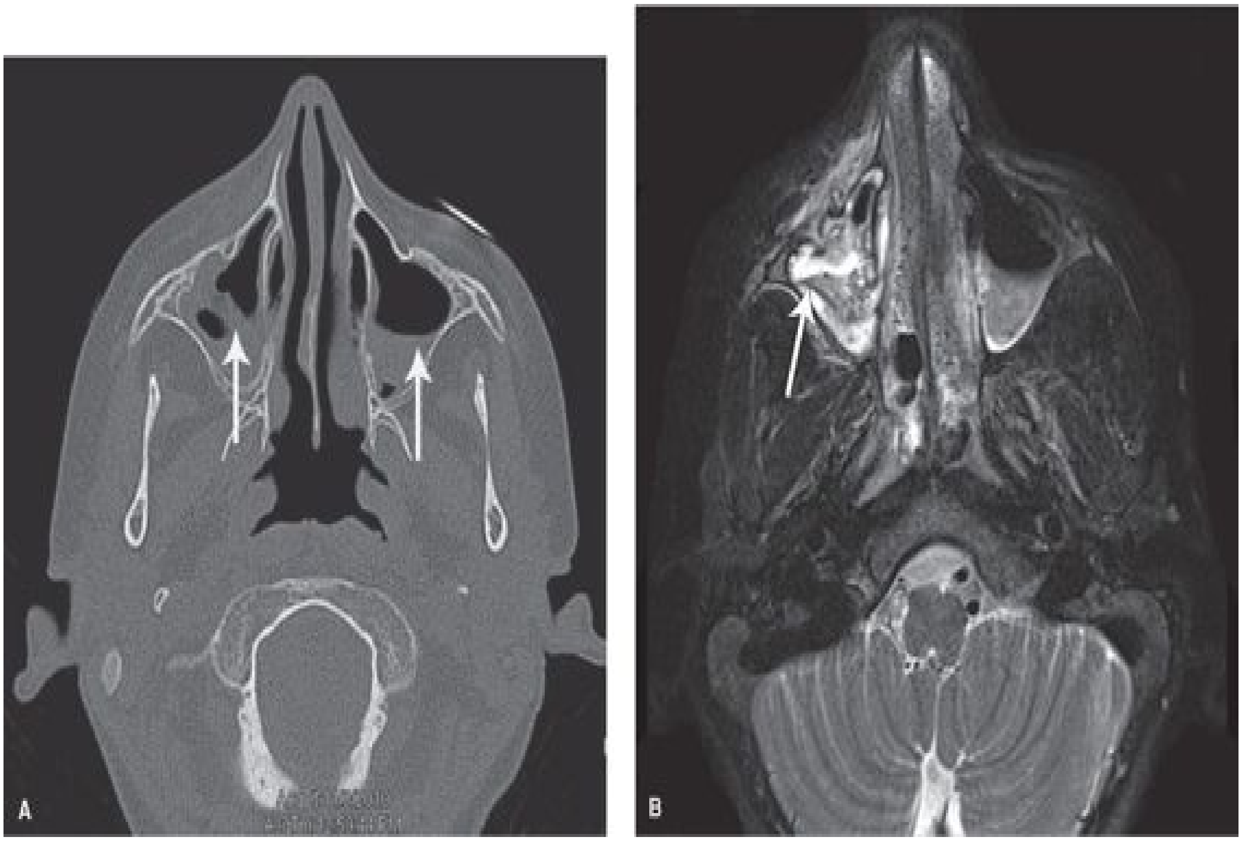

FIGURE 27-9 **A.** Mild maxillary air-fluid levels bilaterally (arrows) on axial CT scan in a 9-year-old boy with combined variable immunodeficiency, and aplastic anemia, who presented with nasal congestion and malar pain and numbness on the right. Nasal endoscopy and biopsy demonstrated invasive *Aspergillus* infection. **B.** Same patient, T2-weighted MRI scan demonstrating extension of invasive fungal sinusitis along infraorbital nerve into soft tissues of cheek (arrow). This patient and his family elected medical and palliative therapy instead of radical, disfiguring surgery and died 3 months later. (*Used with permission from Prashant Malhotra, MD*.)

- Treatment usually requires multi-agent parenteral antifungal therapy along with radical surgical debridement.[15,17] Surgical treatment is aggressive, often disfiguring.
- Mortality rates are high and range from 50 to 90 percent.[17–19]

PATIENT EDUCATION

- Severe or prolonged congestion, nasal drainage, facial pain, and/or fever requires medical attention.
- Blurry or double vision, eye pain, neck stiffness, severe headaches, or changes in mental status should be evaluated urgently.
- Nonresponse to therapy for sinus infections also warrants medical attention.

28 SCARLET FEVER AND STRAWBERRY TONGUE

M. Jason Sanders, MD
Linda French, MD

PATIENT STORY

A 7-year-old boy is brought to the pediatrician’s office with a rough red rash on his trunk (**Figures 28-1** and **28-2**) along with fever and a sore throat. The sandpaper rash and signs that are consistent with strep pharyngitis lead the physician to diagnose scarlet fever. The physician explains the diagnosis to the mother and oral penicillin V is prescribed. The boy feels markedly better by the next day and the mother continues to give the penicillin for the full 10 days, as directed, to prevent rheumatic fever.

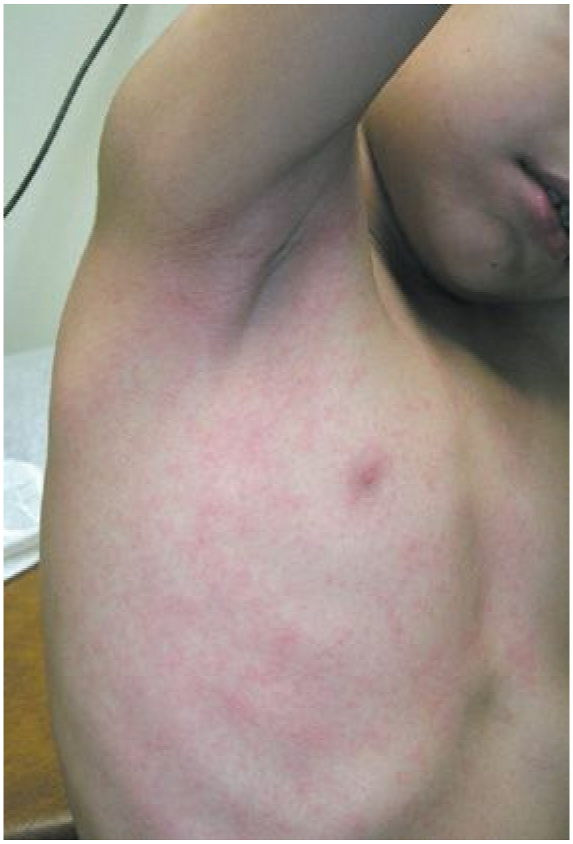

FIGURE 28-1 Sandpaper rash on the trunk and in the axilla of a 7-year-old boy with scarlet fever. (*Used with permission from of Richard P. Usatine, MD*.)

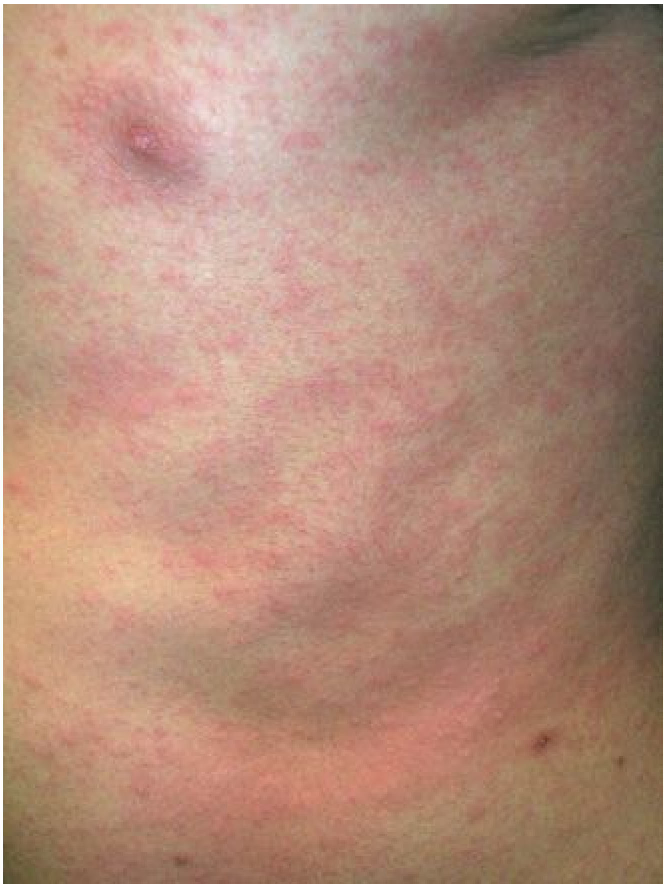

FIGURE 28-2 Scarlatiniform rash comprising small papules and erythema on the trunk of a febrile child with strep pharyngitis. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Scarlet fever is an illness caused by toxin-producing group A β-hemolytic *streptococcus* (strep) infection. Most commonly, scarlet fever evolves from an exudative pharyngitis.

Strawberry tongue may be observed in patients with scarlet fever and usually develops within the first 2 to 3 days of illness. A white or yellowish coating usually precedes the classic red tongue with white papillae (**Figure 28-3**).

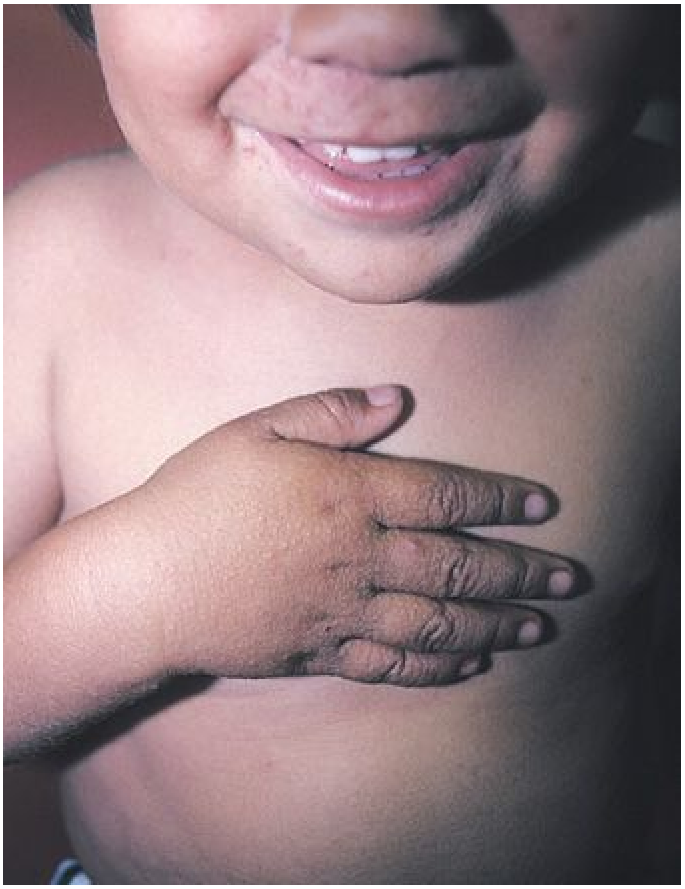

FIGURE 28-3 Sandpaper rash (scarlatiniform) seen prominently on the hand of a child recovering from strep pharyngitis. (*Used with permission from Richard P. Usatine, MD*.)

EPIDEMIOLOGY

- Scarlet fever is predominately seen in school-age children with no gender predilection.
- Majority related to strep pharyngitis, with 1 in 10 developing scarlet fever (**Figures 28-1**, **28-2**, and **28-4**).

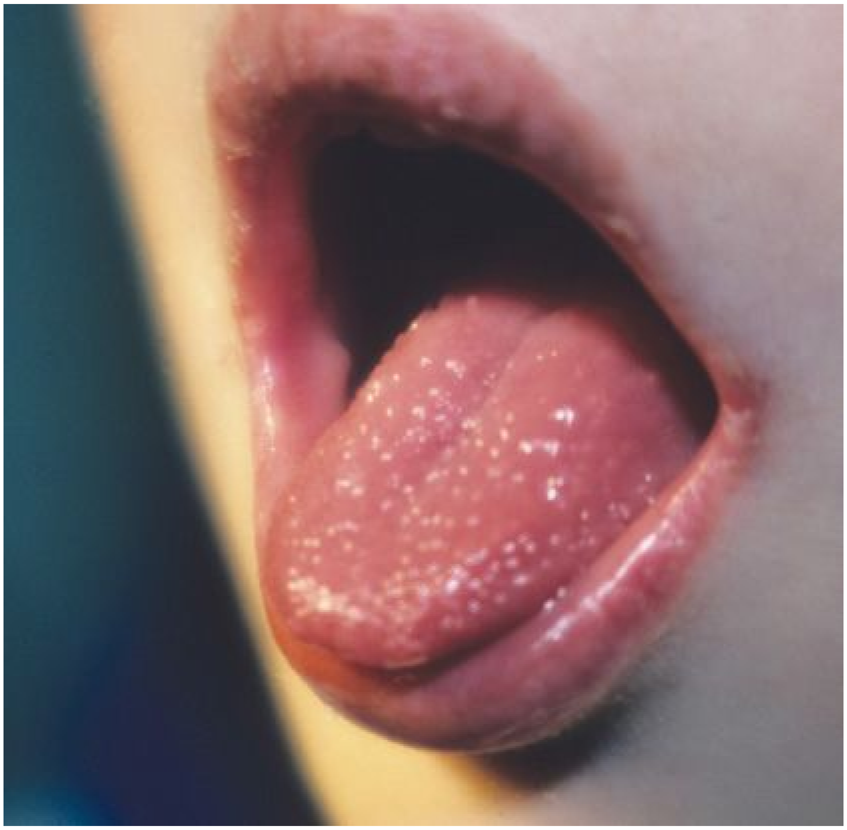

FIGURE 28-4 Strawberry tongue in a child with scarlet fever caused by strep pharyngitis; note marked erythema and prominent papillae. (*Used with permission from of Richard P. Usatine, MD.*)

- Prevalent in late fall to early spring.
- Strawberry tongue (**Figure 28-4**) is most commonly seen in children in association with scarlet fever or Kawasaki disease.
- Can be present with other group A strep infection.
- In cases of strep, a white membrane through which the papillae are seen can initially cover the tongue followed by desquamation of the membrane (with the appearance as in **Figure 28-4**).

ETIOLOGY AND PATHOPHYSIOLOGY

- Transmission of *Streptococcus pyogenes* (Group A) (GAS) occurs via respiratory secretions.
- Virulent GAS incubates over 2 to 7 days. M protein serotypes of GAS are typically more invasive, with greater potential for progression to rheumatic fever or acute glomerulonephritis if untreated.[1]
- Fever and rash are related to pyrogenic A–C and erythrogenic exotoxins produced by GAS.[2]
- Infection can originate from other sites like skin (e.g., cellulitis) and seed blood (bacteremia) or organ systems (e.g., pneumonia).
- Strawberry tongue results from a general inflammatory response during the early course of the disease.

DIAGNOSIS

CLINICAL FEATURES

- Headache, sore throat, cervical lymphadenopathy, abdominal pain, nausea and vomiting, decreased oral intake, malaise, and fever can precede rash. Cough and rhinorrhea are usually not present.
- Oropharyngeal findings include:
    - Strawberry tongue—Erythematous and sometimes edematous tongue with prominent papillae (**Figure 28-4**).
- Tongue is sometimes covered by a white membrane/coating through which the papillae can be seen.
- Not typically painful.
- Forchheimer spots—Palatal and uvular petechiae and erythematous macules.
- Initial sandpaper rash, associated with blanching erythema and occasional pruritus, erupts in 1 to 2 days (**Figures 28-1** to **28-3**).[2]

- Pastia's lines are pink or red lines seen in the body folds (especially elbows and axilla) during scarlet fever. Linear hyperpigmentation can persist after the rash fades (**Figure 28-1**).
- Desquamation of the skin (especially of the hands and feet) ensues in 3 to 4 days as rash fades and can persist for 2 to 4 weeks.[1]

TYPICAL DISTRIBUTION

- Progresses centrally (torso) to peripherally (extremities) and can be prominent on the face, chest, palms, fingers, and toes.[1]

LABORATORY TESTS AND IMAGING

- Throat swab for rapid strep testing (screening) and/or culture (confirmation) is usually performed.
- Complete blood count (CBC), if indicated, to look for:
  - Elevation of white blood cell count with left shift.
  - Elevated platelet count—Seen with Kawasaki disease (after 1 week).
- Antistreptolysin-*O* titer is obtained to confirm prior infection or support suspected poststreptococcal complication, such as rheumatic fever.[3]
- Acute phase reactants (C-reactive protein [CRP] and erythrocyte sedimentation rate [ESR]) can be elevated, and is useful in monitoring nonsuppurative complications such as rheumatic fever.[4]
- If Kawasaki disease is suspected, two-dimensional echocardiography or angiography is obtained to detect coronary artery abnormalities. The initial echocardiogram should be performed as soon as the diagnosis is suspected to establish a baseline for longitudinal follow-up of coronary artery morphology, left ventricular and left valvular function, and the evolution and resolution of pericardial effusion when present.[4] SOR C

DIFFERENTIAL DIAGNOSIS

The rash of scarlet fever can be confused with the following:

- Allergic/contact dermatitis—Often localized to areas of contact; prominent pruritus and skin vesicles often in linear streaks (see Chapter 130, Atopic Dermatitis and Chapter 131, Contact Dermatitis).
- Viral exanthem—Many viral exanthems have prodromal phases with fever followed by skin rashes that can be macular or maculopapular including measles (see Chapter 111, Measles), rubella (tender retroauricular, cervical, and occipital lymphadenopathy; rash starts on face and spreads and fades quickly), and roseola (rash occurs at the end of a period of 3 to 5 days of high fever). Lack of sandpaper feel and oral findings help distinguish.
- Staphylococcal scalded skin syndrome (see Chapter 105, Staphylococcal Scalded Skin Syndrome)—Rash can also follow a prodrome of malaise and fever but is macular, brightly erythematous, and initially involves the face, neck axilla, and groin. Skin is markedly tender and large areas of the epidermis peel away.
- Erythema toxicum—Rash of newborns; often blotchy, evanescent, macular erythema that can include pale yellow or white wheals or papules on an erythematous base (see Chapter 92, Normal Skin Changes).

The differential diagnosis for strawberry tongue includes:

- Kawasaki disease (**Figure 28-5**)—Fever persists at least 5 days and there must be the presence of at least four principal features including the following (see Chapter 177, Kawasaki Disease):[4]

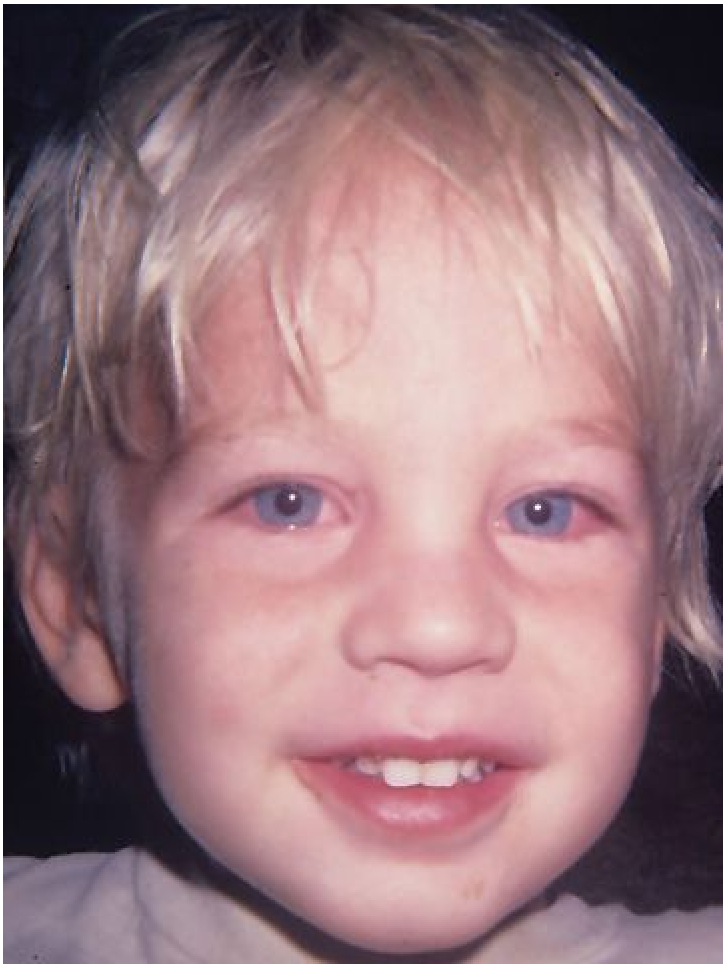

FIGURE 28-5 Child recovering from Kawasaki disease. Note the conjunctival injection that still remains. (*Used with permission from Greg Thompson, MD.*)

  - Changes in extremities—Acute: Erythema of palms and soles; edema of hands and feet. Subacute: Periungual peeling of fingers and toes in weeks 2 and 3.
  - Polymorphous exanthem.
  - Bilateral bulbar conjunctival injection without exudate.
  - Changes in lips and oral cavity—Erythema, lips cracking, strawberry tongue, diffuse injection of oral, and pharyngeal mucosae.
  - Cervical lymphadenopathy (>1.5 cm diameter), usually unilateral.
- Viral stomatitis with eruptive lingual papillitis—Lack of other features for scarlet fever or Kawasaki's will assist in differentiating.

- Red-colored food dyes—History is helpful; edema and prominent papillae will be absent.

MANAGEMENT

NONPHARMACOLOGICAL

- Supportive care with oral fluids and age-appropriate symptomatic measures, such as salt-water gargles, and an antipyretic as needed are recommended.

MEDICATIONS

- For scarlet fever and strawberry tongue caused by group A *Streptococcus*:
    - Oral penicillin (penicillin V 25 to 50 mg/kg per day for 10 days [maximum 1500 mg per day] or amoxicillin 50 mg/kg per day [maximum 1200mg per day]).
    - Macrolide (azithromycin 12 mg/kg per day once daily on day 1 [maximum 500 mg per day], followed by 6 mg/kg per day once daily on days 2 to 5 [maximum 250 mg per day]) or clindamycin 20 mg/kg per day for 10 days (maximum 1800 mg per day) in penicillin-allergic patients.[5] SOR Ⓐ
    - Cephalosporins are an efficacious alternative if no history of immediate penicillin hypersensitivity (cefuroxime axetil 20 mg/kg per day for 10 days [maximum 500mg per day]); cephalosporins were more effective than penicillin in a metaanalysis.[6] SOR Ⓐ
    - Symptoms typically resolve in 4 to 7 days.
- For strawberry tongue caused by Kawasaki disease (also see Chapter 177, Kawasaki Disease):
    - Intravenous gammaglobulin (IVIG), 2 g/kg in a single infusion, within 7 to 10 days of onset for Kawasaki disease to reduce subsequent coronary artery abnormalities.[4] Additional IVIG infusion may be

  considered if defervescence is not achieved in the first 1 to 2 days.[7] SOR A

  - In the acute phase, aspirin is also administered at 80 to 100 mg/kg per day in 4 doses with IVIG followed by low-dose aspirin (3 to 5 mg/kg per day) until the patient shows no evidence of coronary changes by 6 to 8 weeks after the onset of illness.[4] SOR C

REFERRAL OR HOSPITALIZE

- Hospitalization should be considered if a patient is dehydrated or exhibits cardiorespiratory instability. It should also be considered for cases of complicated scarlet fever, streptococcal toxic shock, staphylococcal scalded skin syndrome, rheumatic fever, acute glomerulonephritis, or Kawasaki disease (when suspected).
- Cardiology, infectious disease, or nephrology consultation should be considered in severe cases.

PROGNOSIS

Scarlet fever usually follows a benign course. Rarely, it is complicated by septic shock and multi-organ failure, suppurative complications such as peritonsillar abscess, or nonsuppurative complications such as rheumatic fever or poststreptococcal glomerulonephritis.

FOLLOW-UP

- Routine follow-up is not required unless the illness is protracted or a complication is suspected.
- For patients with uncomplicated Kawasaki disease, echocardiographic evaluation should be performed at the time of diagnosis, at 2 weeks, and

at 6 to 8 weeks after onset of the disease.[4] Recent studies show that repeat echocardiography performed 1 year after the onset of the illness is unlikely to reveal coronary artery enlargement in patients whose echocardiographic findings were normal at 4 to 8 weeks.[4] SOR Ⓒ

PATIENT EDUCATION

- Contact your physician for fever recurrence, atypical or persistent rash, and new symptoms or potential complications (meningitis, sinusitis, otitis media, oropharyngeal abscess, pneumonia, acute glomerulonephritis, or rheumatic fever).
- Completion of a prescribed antibiotic course is encouraged to decrease the incidence of recurrence and potential complications.[3]

SECTION 3 MOUTH AND THROAT

29 UPPER RESPIRATORY INFECTIONS INCLUDING PHARYNGITIS

Brian Williams, MD
Melissa A. Scholes, MD
Richard P. Usatine, MD
Mindy A. Smith, MD
Camille Sabella, MD

PATIENT STORY

A mother brings her nine year-old daughter to the pediatrician’s office with complaints of sore throat, fever, and malaise for 2 days. The girl has not had cough or runny nose. The mother is concerned about strep throat because a classmate of the daughter’s was just diagnosed with this. On exam, the girl has erythematous tonsillar pillars, palatal petechiae, and impressive cervical lymphadenopathy (**Figure 29-1**). A throat swab for rapid streptococcal antigen is positive and the girl is treated with penicillin VK for 10 days and recovers completely.

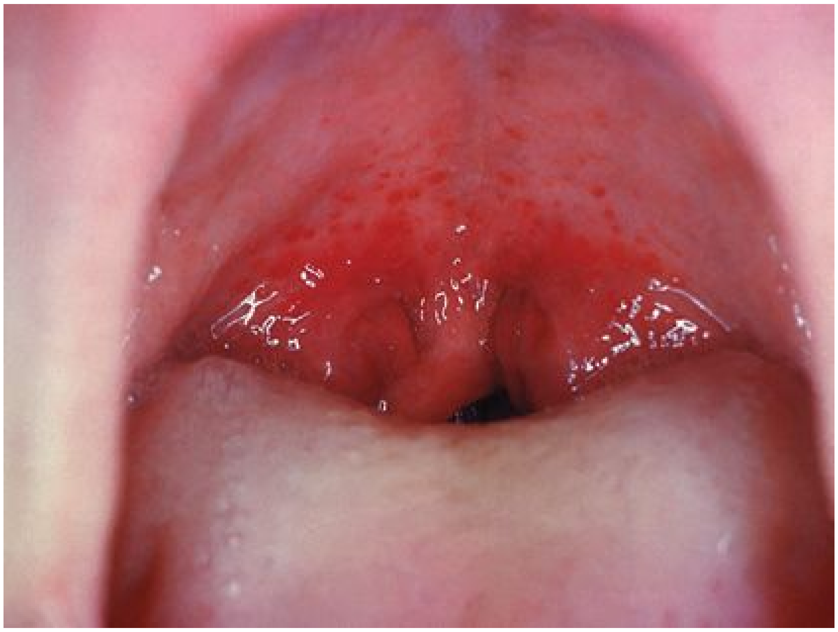

FIGURE 29-1 Erythema and edema of the pharynx, and palatal petechiae in a child with Group A Streptococcal pharyngitis. (*Used with permission from CDC/Public Health Image Library/Heinz F. Eichenwald, MD*.)

INTRODUCTION

Upper respiratory tract infection (URI), also known as the common cold, and pharyngitis, inflammation and pain of the pharyngeal tissues, including the pharynx, tonsils and adenoids are among the most common illnesses of childhood. URIs are characterized by rhinorrhea, nasal congestion, and sore or scratchy throat. They are caused by viruses. Symptoms and signs of pharyngitis include throat soreness or scratchiness, fever, headache, malaise, rash, joint and muscle pains, and cervical lymphadenopathy. Viruses are responsible for the majority of cases of pharyngitis in infants and children, although Group A β-hemolytic streptococci (GABHS) are important causes of pharyngitis because of their ability to cause suppurative (peritonsillar and parapharyngeal abscesses) and nonsuppurative (acute rheumatic fever and glomerulonephritis) complications.

EPIDEMIOLOGY

- Acute URI and pharyngitis account for 3.4 percent and 1 percent of primary care visits, respectively.[1]
- Viral infections account for the vast majority of cases of URI and 60 to 90 percent of cases of pharyngitis in children. GABHS is responsible for the majority of bacterial pharyngitis.
- In temperate climates, the highest prevalence of URI and pharyngitis occurs from autumn until spring. This corresponds directly with circulating viruses over this period of time.
- Frequency of URIs varies with age: highest frequency is in children 1 to 5 years of age, who experience 7 to 8 colds per year; infants less than one year of age average 6.5 colds a year; adolescents average 4.5 colds per year.[2]
- Highest incidence of GABHS pharyngitis is in school-aged children and adolescents.
- Acute rheumatic fever is rare in the US (see Chapter 45, Acute Rheumatic Fever).
- Viruses causing URIs and pharyngitis can be spread via small particle aerosol (Influenza and Coronaviruses), large particle droplet (Rhinoviruses), or direct hand-to-hand transmission (Rhinoviruses and RSV).
- Up to 14 percent of deep neck infections result from pharyngitis.[3]

ANATOMY

- The lingual tonsils on the base of tongue, the lateral palatine tonsils (“tonsils”) and the superior pharyngeal tonsils (“adenoids”) together make up Waldeyer’s ring. This ring of lymphoid tissue is favorably located for airborne and food-related antigen exposure.

- Adenoids and tonsils are predominantly B-cell organs and immunologically most active between the ages of 4 and 10 years.[4,5] Overall, data show that adenotonsillectomy does not significantly affect the immune system adversely.

ETIOLOGY AND PATHOPHYSIOLOGY

- Rhinoviruses are the most common cause of URIs and pharyngitis in children; other viruses implicated include coronaviruses, respiratory syncytial virus (RSV), human metapneumovirus, influenza virus, parainfluenza viruses, adenovirus, enteroviruses (i.e., herpangina), and human bocavirus.[6]
- Herpes simplex virus, human immunodeficiency virus, syphilis, and *Neisseria gonorrhoeae* are causes of pharyngitis in sexually active adolescents.
- Viruses that infect nasal epithelial cells release cytokines and other inflammatory mediators, producing an inflammatory response of polymorphonuclear cells such as albumin and bradykinins that are responsible for the clinical symptoms of URI.
- The paranasal sinuses and middle ear are commonly involved during uncomplicated URIs. Thus, it is common to have abnormal CT and MRI scans of the sinuses and middle ear fluid during URIs.[7,8]
- Some viruses, such as adenovirus, cause inflammation of the pharyngeal mucosa by direct invasion of the mucosa or secondary to suprapharyngeal secretions.[9] Other viruses, such as rhinovirus, cause pain through stimulation of pain nerve endings by mediators, such as bradykinin.
- GABHS accounts for 15 to 30 percent of pharyngitis cases in children and up to 38 percent of cases of tonsillitis.
- GABHS releases exotoxins and proteases. Erythrogenic exotoxins are responsible for the development of the scarlatiniform exanthem (**Figure 29-2**).[10]

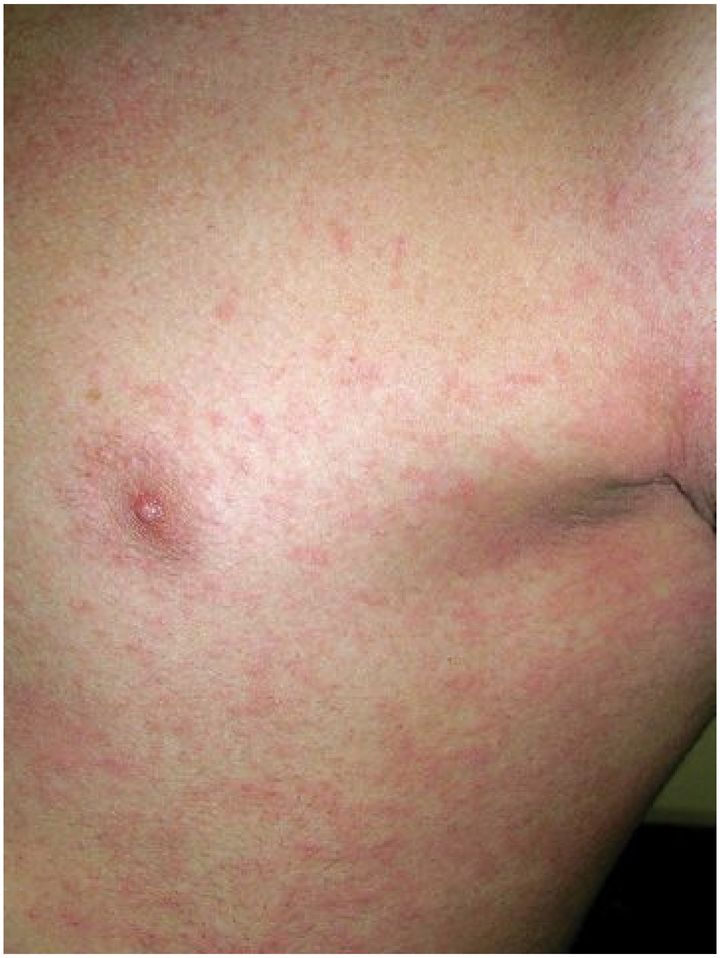

FIGURE 29-2 Scarlatiniform rash in scarlet fever. This 7-year-old boy has a typical sandpaper rash with his strep throat and fever. The erythema is particularly concentrated in the axillary area. (*Used with permission from Richard P. Usatine, MD.*)

- Secondary cross-reacting antibody formation during GABHS pharyngitis can result in rheumatic fever and valvular heart disease.[11] Antigen–antibody complexes can lead to acute poststreptococcal glomerulonephritis. These are the nonsuppurative complications of GABHS infection.
- GABHS pharyngitis can result in suppurative complications including bacteremia, otitis media, meningitis, mastoiditis, cervical lymphadenitis, endocarditis, pneumonia, or deep neck abscess formation (**Figure 29-3**).

RISK FACTORS

- Immune deficiency.

DIAGNOSIS

CLINICAL FEATURES

- Infants and young children with URI commonly manifest fever, nasal congestion, irritability, and rhinorrhea, which may be clear or purulent. Mild to moderate enlargement of the anterior cervical lymph nodes may be present.
- Older children and adolescents commonly manifest rhinorrhea, sore or scratchy throat, sneezing, sinus fullness, malaise, and hoarseness. Physical exam findings are minimal and may include mild erythema of the pharyngeal or nasal mucosa.
- Rapid onset of odynophagia, tonsillar exudates, anterior cervical lymphadenopathy, and fever are consistent with streptococcal pharyngitis. Headache and abdominal pain are common in children who have streptococcal pharyngitis.
- Not all tonsillar exudates are caused by streptococcal pharyngitis. Mononucleosis and other viral causes of pharyngitis commonly produce tonsillar exudates in children (**Figures 29-4** and **29-5**). The positive predictive value for tonsillar exudate in strep throat is only 31 percent; that is, 69 percent of patients with tonsillar exudate will have a nonstreptococcal cause.

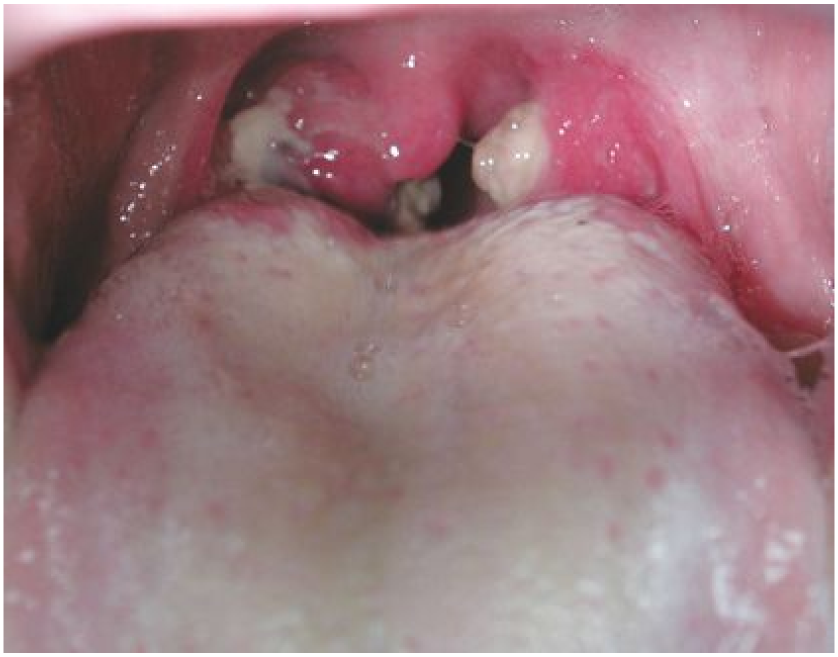

FIGURE 29-4 Mononucleosis with considerable tonsillar exudate. (*Used with permission from Tracey Cawthorn, MD.*)

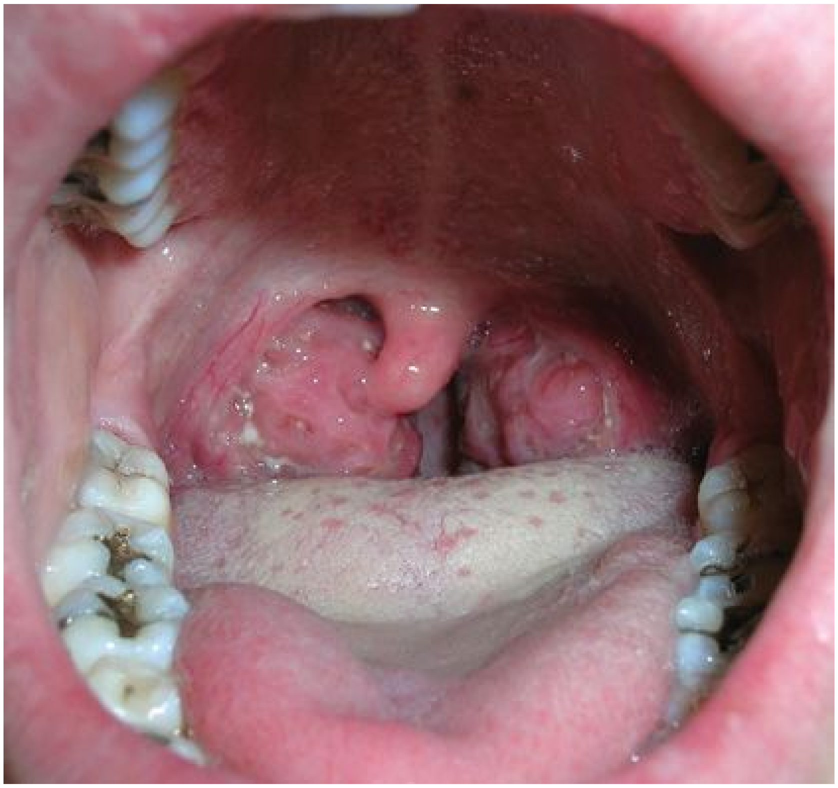

FIGURE 29-5 Viral pharyngitis showing enlarged cryptic tonsils with some erythema and exudate. (*Used with permission from Richard P. Usatine, MD.*)

- Para- and supratonsillar edema with medial and/or anterior displacement of the involved tonsil and uvular displacement to the contralateral side suggest peritonsillar abscess (**Figure 29-2**). Trismus and anterior cervical lymphadenopathy with severe tenderness to palpation are additional findings.
- Palatal petechiae can be seen in all types of pharyngitis (**Figures 29-1** and **29-6**).

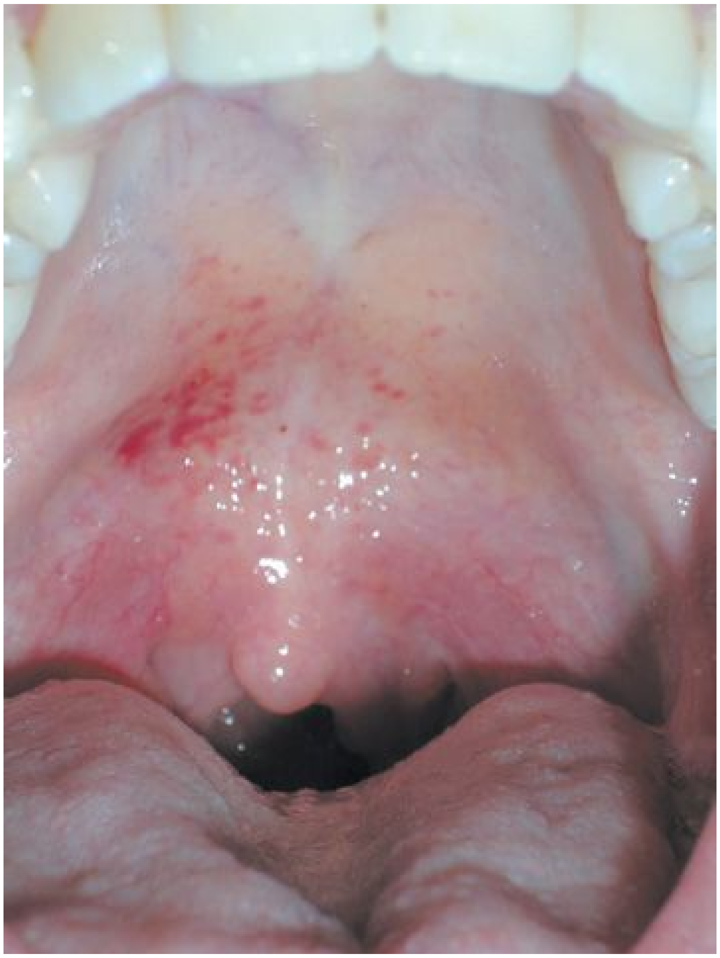

FIGURE 29-6 Viral pharyngitis with visible palatal petechiae. Palatal petechiae can be seen in all types of pharyngitis. (*Used with permission from Richard P. Usatine, MD*.)

- A sandpaper rash is suggestive of scarlet fever (**Figure 29-2**, and Chapter 28, Scarlet Fever and Strawberry Tongue). Strawberry tongue frequently accompanies scarlet fever (**Figure 28-4**).
- Lymphoid hyperplasia from viral infections, gastroesophageal reflux disease (GERD), or allergies can cause a cobblestone pattern on the posterior pharynx or palate (**Figure 29-7**). Although it usually is more suggestive of a viral infection or allergic rhinitis, lymphoid hyperplasia can be seen in strep pharyngitis (**Figure 29-8**).

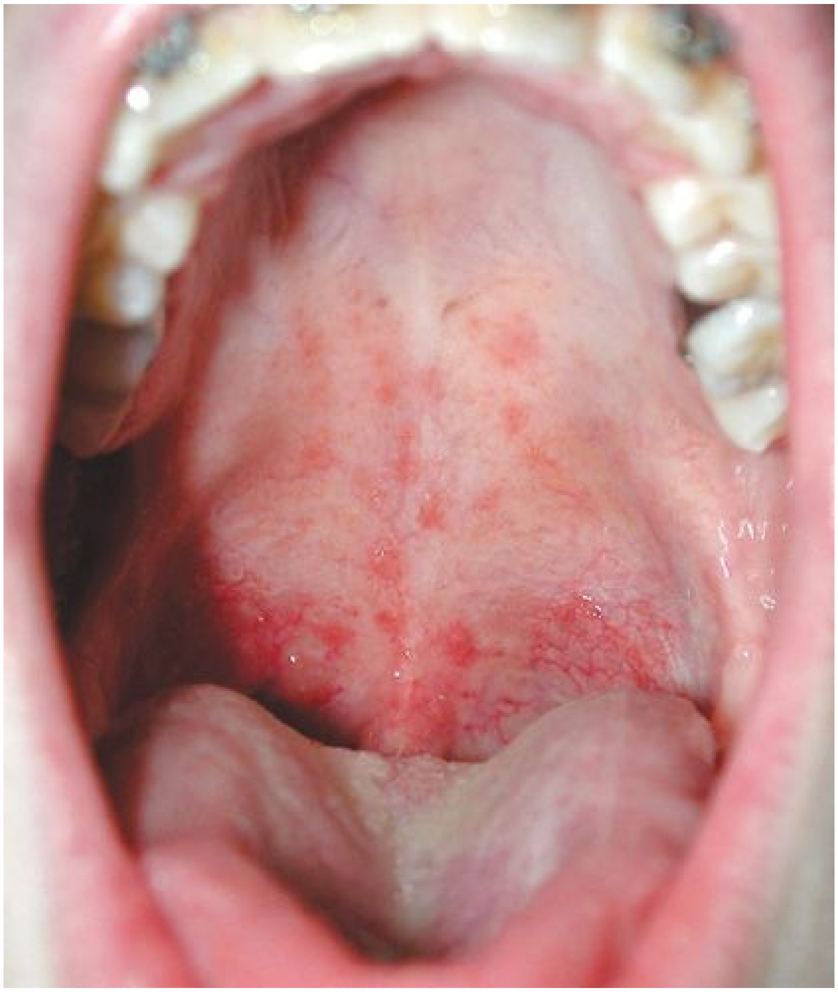

FIGURE 29-7 Viral pharyngitis with prominent vascular injection of the soft palate and lymphoid hyperplasia. (*Used with permission from Richard P. Usatine, MD*.)

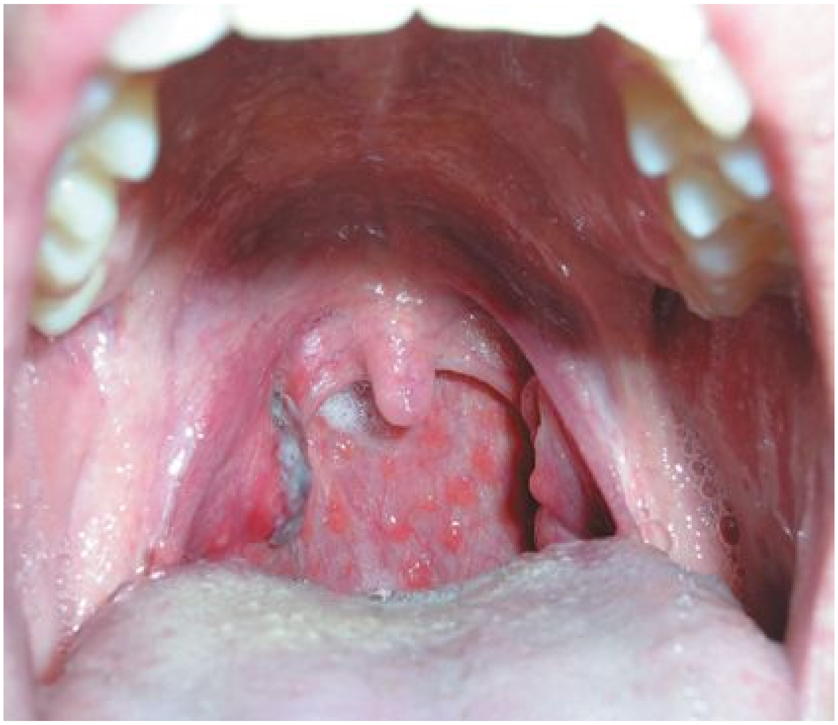

FIGURE 29-8 Strep pharyngitis with dark necrotic area on right tonsil and prominent lymphoid hyperplasia in a cobblestone pattern on the posterior pharynx. (*Used with permission from Richard P. Usatine, MD*.)

- The presence of rhinorrhea and nasal congestion indicate a viral URI infection and are not consistent with GABHS infection.

LABORATORY TESTS AND IMAGING

- The diagnosis of viral URI is made clinically; testing for specific viral etiologies is not indicated for most cases.
- Children who are at high risk for complications from viral URI (i.e., immunodeficient patients), or who require hospitalization, may benefit from having a specific viral etiology identified. In these cases, a nasopharyngeal swab or washing for respiratory viruses can be obtained. Direct fluorescent antibody tests, real-time polymerase chain reaction testing, or viral cultures are the most commonly used modes of viral detection in these settings.

- Swabbing the throat and testing for GABHS pharyngitis by rapid antigen detection test (RADT) and/or culture should be performed because the clinical features alone do not reliably discriminate between GABHS and viral pharyngitis. In children and adolescents, negative RADT should be backed up by a culture. A positive RADT does not require a backup culture.[12]
- Diagnostic studies for GABHS are not indicated in children <3 years of age because these infections are uncommon in this age group.[12]
- Diagnostic studies for GABHS are not indicated in children who have symptoms that are consistent with a viral URI, such as rhinorrhea, nasal congestion, and hoarseness.
- Test options for RADT include enzyme immunoassays, latex agglutination, liposomal method, and immunochromatography assays; the latter has the highest reported sensitivity (0.97), specificity (0.97), and positive (32.3) and negative (0.03) likelihood ratios.[12]
- False-positive tests for streptococcal infection can occur when the patient is colonized with GABHS but the bacteria are not the cause of the acute disease (carrier state). GABHS is part of the normal oropharyngeal flora in many school-aged children and the diagnosis of acute streptococcal pharyngitis must include both the clinical signs of acute infection and a positive throat culture. Distinguishing GABHS infection versus colonization can be challenging; the history and physical findings of pharyngitis should be used to determine whether a throat culture should be performed.
- False-negative tests for streptococcal infection can occur when poor sampling technique with the throat swab fails to recover the streptococcal organism despite being the cause of the acute infection.
- Laboratory testing helps confirm the diagnosis of infection with EBV with a differential blood count characteristically showing 50 percent lymphocytosis and 10 percent atypical lymphocytes. Serologic studies include a monospot and serum heterophil antibody titer. Testing may initially be negative and should be repeated in two weeks if clinical suspicion is high.[13]

- Viral cultures from vesicles can be obtained in Coxsackievirus and herpes infections, but the diagnosis is usually based on clinical suspicion and findings.
- Head-neck CT scan or ultrasonography can assist in the diagnosis and localization of peritonsillar abscess and should be obtained if further extension into the deeper neck is suspected such as a parapharyngeal or retropharyngeal abscess.[14]

DIFFERENTIAL DIAGNOSIS

- Allergic rhinitis—Can have similar clinical symptoms as URI but without constitutional symptoms; usually seasonal in nature and family history of allergies is common. Physical exam findings of allergic “shiners” and “nasal salute” can help in the diagnosis (see Chapter 215, Allergic Rhinitis).
- Acute bacterial sinusitis—May complicate URI and manifests as prolonged duration of URI symptoms (greater than 10 to 14 days) or severe symptoms of fever, purulent nasal congestion present for at least 3 to 4 consecutive days in a child who appears ill.
- Infectious mononucleosis—Nausea, anorexia without vomiting, uvular edema, generalized symmetric lymphadenopathy, and lethargy particularly in teenagers and young adults, is more suggestive of acute mononucleosis (Epstein-Barr virus [EBV]) although the pharyngeal examination has a similar appearance to GABHS (**Figure 29-4**). Tonsils often appear dirty-gray. Hepatosplenomegaly is indicative of EBV in this group. Management is symptomatic and recovery can take weeks. Upper airway obstruction can occur because of enlarged tonsils and adenoids and can be managed with a nasal trumpet and high-dose steroids. Children and adolescents should avoid any physical activity for 4 to 5 weeks because of the risk of splenic rupture[15] (see Chapter 184, Infectious Mononucleosis).
- Herpangina/Coxsackievirus infection—Oropharyngeal vesicles and ulcers indicate herpangina, which is caused by Coxsackievirus A16 in the majority of cases (**Figure 29-9**).

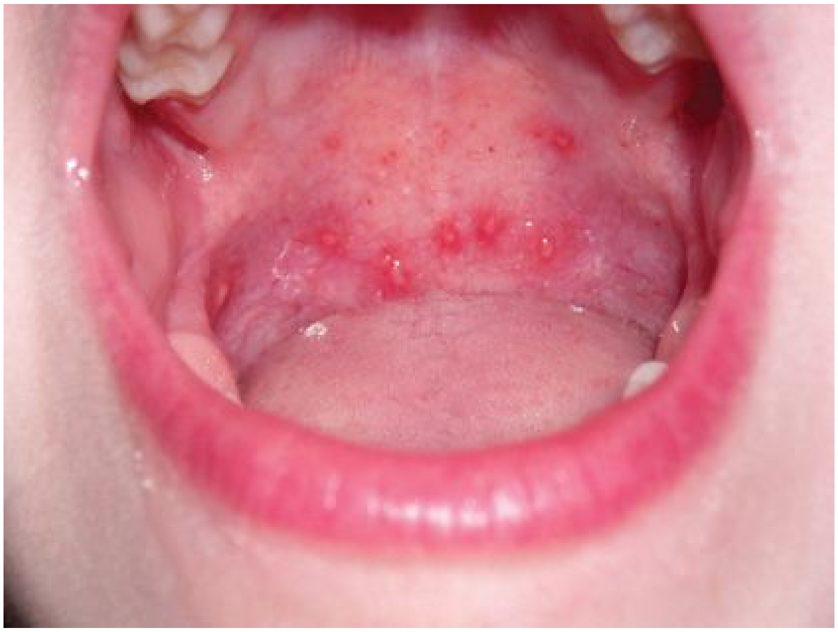

FIGURE 29-9 Herpangina caused by Coxsackievirus virus. (*Used with permission from Emily Scott, MD.*)

- Oral *Candida*—Whitish plaques of the oropharyngeal mucosa indicate oral *Candida*/thrush, which is mainly found in infants (see Chapter 121, Candidiasis). Risk factors include antibiotic use, immunodeficiency, and use of steroid inhalers.
- Sexually transmitted infections must be considered in the adolescent population—Primary human immunodeficiency virus, gonococcal and syphilitic pharyngitis can all present with the symptom of sore throat. *Neisseria gonorrhoeae* has been detected in 6 percent of adolescents with acute pharyngitis and can manifest with acute exudative tonsillitis.[16] Although uncommon, these diagnoses should be considered in high-risk populations.
- Primary herpes gingivostomatitis causes oral ulcers and pain in the mouth. The wide distribution of ulcers with the first case of herpes simplex virus (HSV)-1 distinguishes this infection from other types of pharyngitis (see Chapter 39, Herpes Simplex Virus Gingivostomatitis and 114, Herpes Simplex).
- *Cytomegalovirus* (CMV)—Primary CMV infection in the immunocompetent host is usually asymptomatic. In the

immunocompromised host, CMV can present with a mononucleosis-like syndrome clinically indistinguishable from EBV infection.

- Epiglottitis—Rapid-onset fever, malaise, sore throat, and drooling in the absence of coughing characterize acute epiglottitis, especially when presenting in children. Progression of the disease can lead to life-threatening airway obstruction. Fortunately, this is a rare condition because of the preventive effect of the *Haemophilus influenzae* type b (HIB) vaccine.
- Supraglottitis—Similar symptoms to epiglottitis, although typically seen in adults this can occur in children and adolescents. Sore throat and painful swallowing are the most common presenting symptoms, seen in more than 90 percent of cases. Muffled voice and drooling, dyspnea, stridor, and cough reported in less than 50 percent of cases. No definite organism is identified in the majority of cases. Unlike epiglottitis in children, HIB is responsible for less than 20 percent of supraglottitis cases but still accounts for the majority of positive cultures. Supraglottitis is currently more common than epiglottitis, because of HIB vaccine. Mortality rates have been reported up to 20 percent.
- Diphtheria—A rare condition in the US today, as most patients have been immunized. However, it needs to be considered, especially in unvaccinated and immigrant populations. Pharyngeal diphtheria presents with sore throat, low-grade fever, and malaise. The pharynx is erythematous with a grayish pseudomembrane that cannot be scraped off. Complications include myocarditis resulting in acute and severe congestive heart failure (CHF), endocarditis, and neuropathies.
- Other bacterial causes—Non–group A *Streptococcus*, *Fusobacterium necrophorum*, *Mycoplasma pneumoniae*, *Chlamydophila pneumoniae*, and *Arcanobacterium haemolyticum* have all been isolated as bacterial causes of pharyngitis.
- PFAPA syndrome—The association of periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis was first described by Marshall et al. in 1987.[17] The hallmark of this condition is the periodicity of its occurrence and abrupt onset high fevers lasting 3 to 7 days and recurring every 3 to 6 weeks. The fever cycle is associated with one or more of the following: aphthous stomatitis, pharyngitis, and cervical adenitis. PFAPA syndrome

can also be associated with rashes, headaches, abdominal pain, and arthralgias. Between episodes the child is asymptomatic. On physical exam, the child usually exhibits an erythematous pharynx or tonsils and culture is usually GABHS negative. Treatment with steroids has been used which does shorten the febrile cycle. However, the asymptomatic periods between fevers also shortens. Treatment is usually tonsillectomy; a recent case series showed resolution of symptoms in 99 of 102 patients undergoing this surgery.[18]

MANAGEMENT

NONPHARMACOLOGIC

- Hydration with plenty of liquids.
- Saltwater gargles.

MEDICATIONS

- Age-appropriate dosing of acetaminophen and ibuprofen can be used for symptomatic relief of discomfort, fever, and pain. Doses can be alternated as needed. Aspirin should be avoided in children.
- Antihistamines, decongestants, antitussives, and expectorants are not helpful for the treatment of URI in children and are not recommended.[2]
- Over-the-counter cold and cough medications should not be given to infants because of the risk of life-threatening adverse effects.
- Zinc gluconate has not been shown to be effective for the treatment of URI.[19]
- Steroids (e.g., dexamethasone single 10-mg injection) are recommended for children with infectious mononucleosis who have severe tonsillitis causing airway obstruction. SOR Ⓒ However, there is no strong evidence to recommend steroids for patients with infectious mononucleosis who do not have airway obstruction.[20]

- For suspected or proven GABHS, penicillin V, 250 mg two or three times daily in children weighing less than 27 kg and 500 mg two or three times daily for children and adolescents weighing greater than 27 kg is first-line therapy. Treatment in penicillin allergic individuals should consist of a 10-day course of a first generation cephalosporin if no history of anaphylaxis is noted, or 10 days of clindamycin or clarithromycin or 5 days of azithromycin.[12] In some cases, amoxicillin 50 mg/kg per day in divided doses every 12 hours is preferred over penicillin V because of palatability.
- Various regimens for peritonsillar abscess may be used including Penicillin G in combination with metronidazole, ampicillin-sulbactam, amoxicillin-clavulanate, and clindamycin. Route and duration of therapy varies according to severity, need for surgical drainage, and response to therapy.[21]

COMPLICATIONS

- Bacterial sinusitis and otitis media may complicate URI. New-onset fever and earache may be signs of bacterial otitis media, while persistent nasal symptoms or development of severe purulent nasal drainage for 3 to 4 consecutive days may indicate bacterial sinusitis.
- Viral URI can be an important trigger for an asthma exacerbation in a child with underlying reactive airway disease.
- Peritonsillar abscess—More commonly occurs in patients with recurrent or chronic tonsillitis that is inadequately treated. Infection from the tonsil spreads from the superior pole to the potential space between the tonsil and tonsillar capsule. These usually occur unilaterally and have a characteristic appearance of swelling superiolaterally to the tonsil and deviation of the uvula to the opposite side. Pain is usually severe and involves the ipsilateral ear. Dysphagia, odynophagia, trismus, and drooling are common. Treatment is drainage, usually via needle aspirate or open incision and drainage. If a patient has two or more occurrences, a tonsillectomy is recommended.[22]
- Deep neck infections—A cervical mass, poor range of motion of the neck, high fevers, and any displacement if the pharyngeal walls should raise suspicion. Associated shortness of breath may be a warning sign of

impending airway obstruction. Other complications include aspiration, thrombosis, mediastinitis, and septic shock.[14]

- Scarlet fever is secondary to acute streptococcal tonsillitis or pharyngitis with production of endotoxins by the bacteria.[23] An erythematous rash, sore throat, cervical lymphadenopathy, vomiting, headache, fever, erythematous tonsils, and pharynx sometimes associated with a yellow exudate and tachycardia are common manifestations. An enlarged, erythematous tongue with a rash and enlarged papillae is also a common sign (strawberry tongue; see Chapter 28, Scarlet Fever and Strawberry Tongue). Treatment is similar to the treatment of streptococcal pharyngitis.
- Post-streptococcal glomerulonephritis can be seen after pharyngeal or skin infections. The incidence is 24 percent after exposure to nephrogenic strains, but these strains account for less than 1 percent of pharyngeal strains.[23] The condition is due to the presence of a common antigen of the glomerulus with the streptococcus and occurs 2 weeks after the initial infection.
- Pediatric Autoimmune Neuropsychiatric Disorders associated with Streptococcal Infections (PANDAS)—This disorder is characterized by a tic disorder or obsessive-compulsive disorder postulated to be associated with GABHS infection during childhood. Children can also exhibit abnormal movements and other neurologic symptoms. It is postulated that this entity occurs from cross-reaction of antibodies to the basal ganglia, similar what is seen in rheumatic fever movement disorders. It is more common in boys and younger children. The association with GABHS has not been proven however, and antibiotics do not seem to be beneficial. Immunoglobulin, plasma exchange, and tonsillectomy have been proposed for treatment, but there is little evidence for their benefit.[24,25]

REFERRAL

- If signs of airway impairment are present, the patient should be immediately transported to an emergency department. Intubation can be extremely difficult and risky.
- Refer patients with peritonsillar abscess or deep neck abscess to ear, nose, and throat (ENT). Incision and drainage is the treatment of choice in

addition to using systemic antibiotics.

- Consider ENT referral for tonsillectomy in proven recurrent or chronic GABHS cases, or under certain other conditions (e.g., antibiotic allergies/intolerances) with recurrence.[26] However, there is no evidence to support tonsillectomy for isolated cases of GABHS.[27]

PREVENTION AND SCREENING

- Influenza vaccine is routinely recommended for all children 6 months and older.

PROGNOSIS

- URI and pharyngitis, regardless of the cause, is typically self-limiting. Typical symptoms last for 10 to 14 days in infants and children.
- Antibiotics shorten the duration of illness in GABHS infection by approximately one day and help to prevent transmission. Most importantly, antibiotic treatment for GABHS pharyngitis greatly reduces the risk of rheumatic fever.[21]

FOLLOW-UP

- Follow-up for new onset of symptoms following a URI may indicate a bacterial superinfection.
- There is no role for test of cure in asymptomatic children following treatment for streptococcal pharyngitis. This practice is likely to lead to identification of streptococcal carriage (which is benign and not associated with sequelae or transmission) rather than true infection.[28]

- Follow-up if clinically deteriorating, especially if swallowing or breathing becomes more difficult or severe headache develops.

PATIENT EDUCATION

- The treatment for most cases of URI and non-GABHS pharyngitis is education. Explain to patients or parents the difference between a viral and a bacterial infection to help them understand why antibiotics were prescribed or not prescribed. Antibiotic treatment for a patient with an obvious viral infection is inappropriate, despite patient or parental requests. Studies demonstrate that spending time to explain the disease process is associated with greater patient satisfaction than prescribing an antibiotic.[29,30]
- Rest, liquids, and analgesics should be encouraged.
- Patients receiving antibiotics should be reminded to complete the entire course, even if symptoms improve. Common antibiotic side effects, like rash, nausea, and diarrhea should be reviewed.
- Patients with mononucleosis and splenomegaly should be warned to avoid contact sports because of the risk of splenic rupture.

PATIENT RESOURCES

- **www.familydoctor.org/familydoctor/en/diseases-conditions/sore-throat.html**.
- **www.nlm.nih.gov/medlineplus/ency/article/000639.htm**.

PROVIDER RESOURCES

- Shulman ST, Bisno AL, Clegg HW, et al. Clinical practice guideline for the diagnosis and management of group A streptococcal pharyngitis:

2012 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2012;55(10):1279-1282.

- **www.aapredbook.aappublications.org/content/**.
- Modified Centor Score for Strep Pharyngitis. Estimates probability that pharyngitis is streptococcal in nature, and suggests management course —**www.mdcalc.com/modified-centor-score-for-strep-pharyngitis**.
- The Modified Centor criteria are:
    - History of fever or temperature of 38°C (100.4°F) (1 point).
    - Absence of cough (1 point).
    - Tender anterior cervical lymph nodes (1 point).
    - Tonsillar swelling or exudates (1 point).
    - Age:
        - <15 years (1 point).
        - 15 to 45 years (0 points).
        - >45 years (–1 point).

The probability of GABHS is approximately 1 percent with −1 to 0 points and approximately 51 percent with 4 to 5 points.[31] Although this scoring system does not adequately predict the presence of GABHS pharyngitis, it does predict the low likelihood of GABHS when the score is low. This may help determine the need for a throat culture or RADT test.

30 ACUTE UPPER AIRWAY OBSTRUCTION

Kshama Daphtary, MBBS, MD, FAAP

PATIENT STORY

A 9-month-old infant is brought to the emergency department because of a 1-hour history of a barky cough and difficulty breathing, which followed a 2-day history of rhinorrhea and low-grade fever. He does not appear toxic, but is tachypneic, and has inspiratory stridor and suprasternal retractions. He is not drooling and has no change in voice. A dose of nebulized epinephrine is administered while awaiting the results of his neck x-ray. The frontal view of an x-ray of the soft tissues of the neck shows narrowing of the subglottic space (Steeple sign) (**Figure 30-1**). A diagnosis of croup is made and the infant is given a dose of dexamethasone orally. Thirty minutes later, his stridor and retractions have resolved.

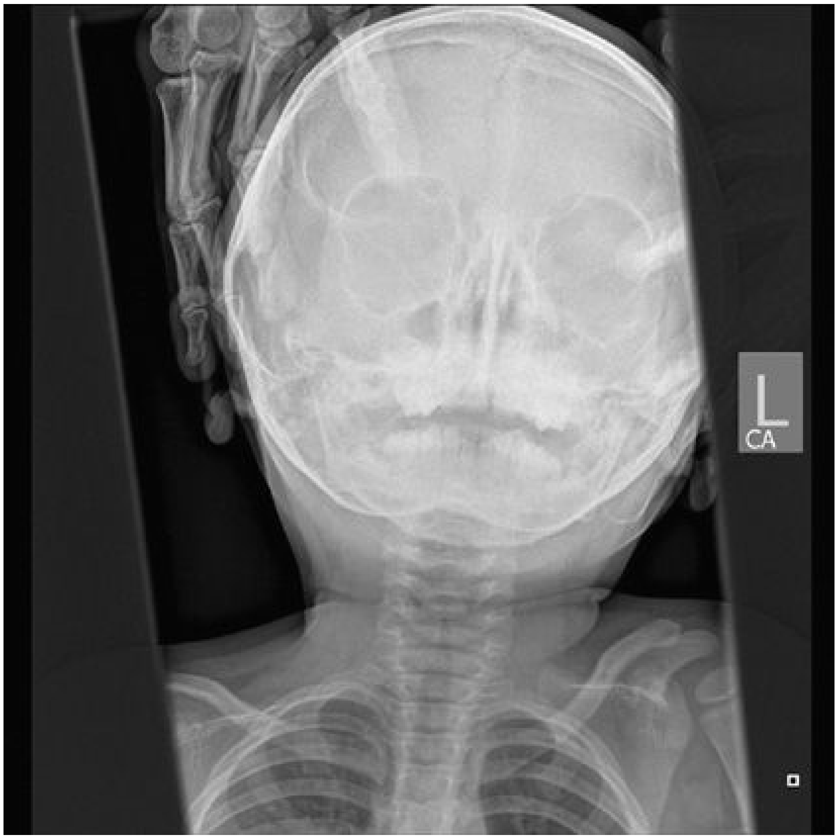

FIGURE 30-1 Subglottic narrowing (“steeple sign”) of croup on frontal x-ray of the neck. (*Used with permission from Kshama Daphtary, MBBS, MD.*)

INTRODUCTION

Upper airway obstruction refers to blockage of any portion of the airway above the thoracic inlet or the extrathoracic airway. It is one of the most daunting emergencies faced by a physician and, if not promptly diagnosed and managed, can progress to hypoxia and can lead to cardio-respiratory arrest and irreversible brain damage. Stridor, suprasternal retractions, and change of voice are the sentinel signs of upper airway obstruction.

SYNONYMS

- Upper airway obstruction is often referred to as extra-thoracic airway obstruction.
- Croup is also known as laryngotracheobronchitis.
- Epiglottitis is used synonymously with supraglottitis.
- Bacterial tracheitis is also known as bacterial laryngotracheobronchitis or pseudomembranous croup.

EPIDEMIOLOGY

- Upper airway obstruction is one of the most common life-threatening emergencies in children, accounting for up to 15 percent of visits to the emergency department.[1]
- Croup is the most common infection that causes acute upper airway obstruction and has an annual incidence of 18 per 1,000 children in the US; children between the ages of 6 months and 4 years are primarily affected, with a peak incidence of 60 per 1,000 among children 1 to 2 years of age. Although sporadic cases occur throughout the year, croup is epidemic in early fall and winter.[2]
- The incidence of epiglottitis has decreased dramatically, since the introduction of the conjugated *Haemophilus influenzae* type b vaccine, from 41 cases per 100,000 children in 1987 to 1.3 per 100,000 in 1997.[2,3]
- Bacterial tracheitis has an estimated incidence of approximately 0.1 cases per 100,000 children per year and has a peak incidence in fall and winter. Although it affects all age groups, it occurs more frequently in children between the ages of 6 months and 8 years. Retropharyngeal abscess is more common in young children, with the vast majority of cases occurring in patients younger than 6 years of age.[2]
- Peritonsillar abscess is usually a disease of older children and adolescents.
- Foreign body aspiration is a common pediatric problem that has the potential to cause partial or complete airway obstruction. The majority of

cases involve the toddler age group. Common foods aspirated are peanuts, popcorn, hotdog, candy, and grapes.

ETIOLOGY AND PATHOPHYSIOLOGY

- Although upper airway obstruction can occur at different levels of the airway, obstruction at the level of the larynx and subglottis assumes the greatest importance because the subglottis is the narrowest portion; therefore, even small lesions can become symptomatic.
- The subglottic region is completely encircled by the cricoid cartilage and cannot expand in diameter. Should inflammation and edema develop, the subglottic airway caliber is substantially reduced as it contains loosely attached connective tissue.
- Narrowing of the airway has an exponential effect on airflow. Poiseulle's law for laminar airflow states that $\Delta P = (Q)\ (8\ \eta l/\pi r^4)$ where ΔP is the pressure gradient between 2 ends of a tube (airway); Q is the volume of air passing through the tube per unit time (or velocity of flow); r is the radius; η is the viscosity of the medium; and l is the length. Rearranging this equation gives us the determinants of the resistance to laminar airflow, which is $\Delta P/Q = (8\ \eta l/\pi r^4)$. However, when airway diameter is reduced, airflow becomes turbulent and the resistance to turbulent flow is inversely proportional to the fifth power of the radius of the lumen of the airway. Thus, a small decrease in the radius of the airway results in a marked increase in resistance to airflow and work of breathing.
- (**Table 30-1**) shows the common causes of acute upper airway obstruction. The etiology of upper airway obstruction differs by age group with congenital abnormalities predominating in neonates, and infectious agents accounting for the majority of cases in infancy and early childhood.

TABLE 30-1 Common Causes of Acute Upper Airway Obstruction

Congenital

- Choanal atresia
- Pierre-Robin sequence
- Cystic hygroma
- Laryngeal web
- Vascular ring (**Figure 30-2**)
- Subglottic stenosis (**Figure 30-3**)

Infections

- Croup—Parainfluenza virus type 1 most common, although parainfluenza types 2 and 3, influenza A and B, respiratory syncytial virus, adenovirus, *Mycoplasma pneumoniae*, herpes simplex type 1, and other organisms have also been implicated.
- Bacterial tracheitis—*Staphylococcus aureus* is the most common cause, but *Streptococcus pyogenes*, *Streptococcus pneumoniae*, other alpha hemolytic streptococcal species, *Moraxella catarrhalis*, and anerobes are all possible causes.
- Epiglottitis—*Haemophilus influenzae* type b is the most common causative organism of epiglottitis, although many other agents have been reported, including *S pyogenes*, *S. pneumoniae*, *S. aureus*, *Klebsiella* sp, *Pseudomonas aeruginosa*, and *Candida* sp (**Figure 30-4**).
- Retropharyngeal abscess—Polymicrobial flora including *Staphylococcus aureus*, various streptococcal species, and anaerobes (**Figure 30-5**).
- Peritonsillar abscess—Most often caused by *S pyogenes* (**Figure 30-6**).
- Acute tonsillopharyngitis—Most commonly caused by *S pyogenes*. Polymicrobial infections and viral pathogens are also important sources of infection.
- Infectious mononucleosis—Epstein-Barr virus commonly. The differential diagnosis also includes cytomegalovirus.
- Ludwig's angina—*S aureus*, alpha-haemolytic streptococci, and anaerobes such as bacteroides, peptococci, and peptostreptococci.
- Laryngeal papillomatosis—Human papilloma virus (HPV), usually types 6 and 11 (**Figure 30-7**).

Foreign bodies

- Airway
- Esophageal (**Figure 30-8**).

Vocal cord paralysis

- Secondary to neurological disorders such as Chiari malformation.
- Following surgeries especially cardio-thoracic procedures such as ligation of patent ductus arteriosus and trachea-esophageal fistulas and thyroid surgeries.

Trauma

Burns, inhalational injury

Allergic

- Anaphylaxis
- Angioedema—Allergic, pseudoallergic (secondary to drugs); nonallergic (such as hereditary angioedema with C1 inhibitor deficiency), and idiopathic.

Neoplasms

- Hemangiomas
- Cysts (**Figures 30-9** and **30-10**).

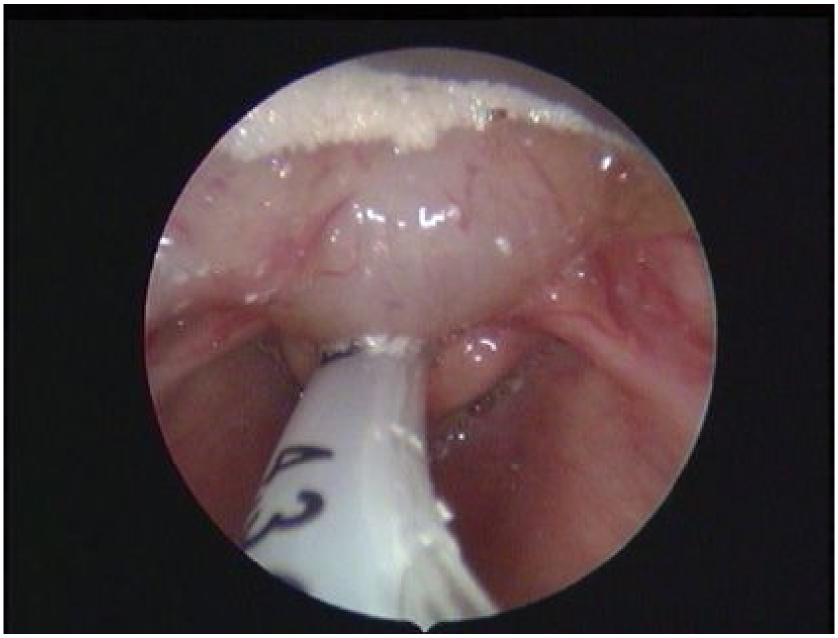

FIGURE 30-10 Vallecular cyst causing upper airway obstruction in an infant. (*Used with permission from Paul Krakovitz, MD*.)

RISK FACTORS

Acute symptomatic upper airway obstruction can affect a normal airway or one that has chronic but asymptomatic narrowing. Children with the following conditions are at higher risk for developing symptomatic upper airway obstruction:

- Craniofacial anomalies (maxillary hypoplasia, nasal septal deviation, micrognathia, retrognathia (**Figures 30-11** and **30-12**), platybasia, or macroglossia).

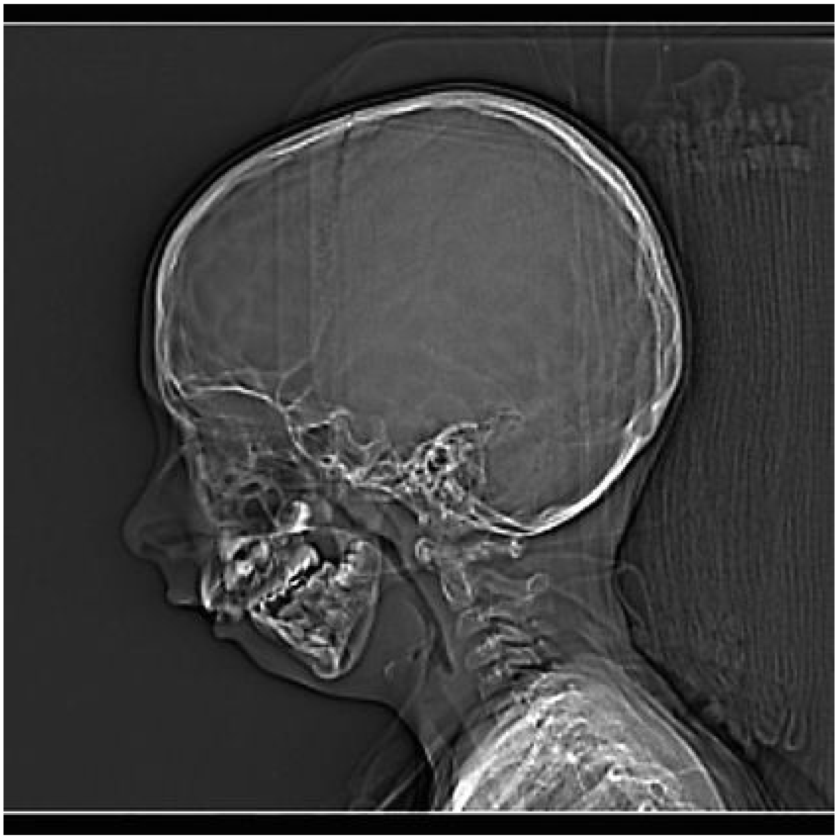

FIGURE 30-11 Retrognathia on scout CT scan. (*Used with permission from Kshama Daphtary, MBBS, MD*.)

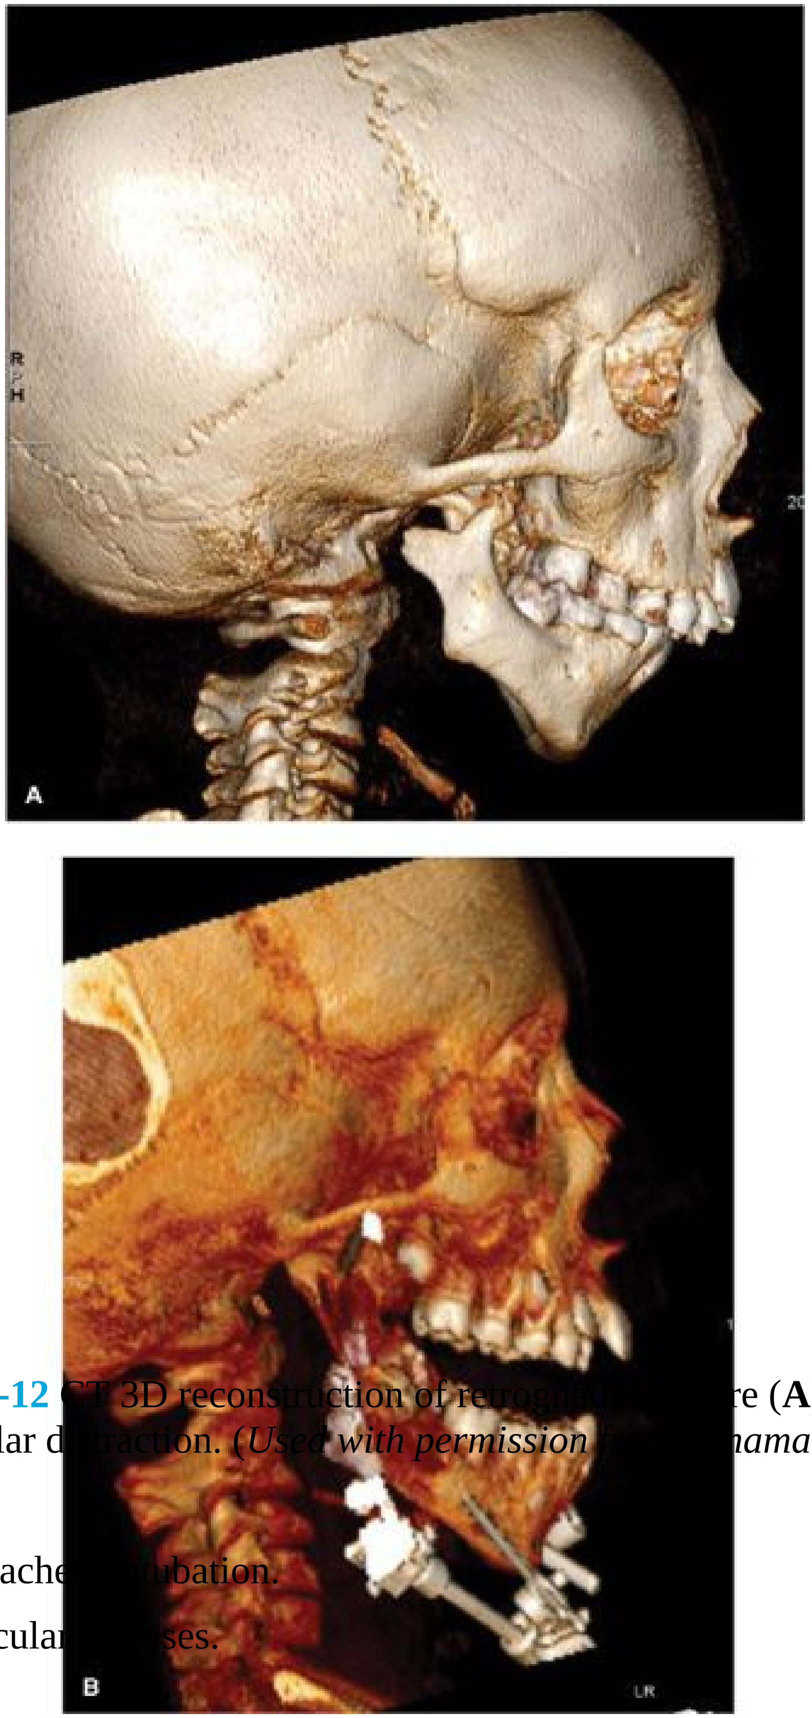

FIGURE 30-12 CT 3D reconstruction of retrognathia before (**A**) and after (**B**) mandibular distraction. (*Used with permission from* [illegible]*hama Daphtary, MBBS, MD*.)

- Previous tracheal intubation.
- Neuromuscular diseases.

DIAGNOSIS

CLINICAL FEATURES

Clinical presentation varies depending on the cause, but some features are common to all types of upper airway obstruction. A quick evaluation should be performed to determine the site and cause of obstruction, the severity of obstruction, and the need to establish an airway urgently.

- Patients with upper airway obstruction usually present with stridor, tachypnea, and increased work of breathing.
- A history of choking should be obtained to exclude foreign body aspiration.
- The physician should also enquire about a history of trauma.
- The pattern, severity and duration of fever, change in voice, inability to swallow, presence of drooling, exposure to allergens, and immunization history may offer clues about the etiology.
- Physical examination should be performed preferably with the child sitting on the parent's lap with the chest and neck exposed to minimize disturbing the patient.
- Key physical findings that help in determining the site and cause of obstruction include the physical appearance of the child, the position of comfort that the child assumes, the character of the noisy breathing, characteristics of the voice, the inability to handle secretions, presence of swelling over the face or neck, the use of accessory muscles of respiration, and craniofacial anomalies.
- Agitation, confusion, panic, altered state of consciousness, paradoxical breathing, sternal retractions, gasping respiration, and decrease in oxygen saturation are signs of impending respiratory arrest.
- Sudden total obstruction is not infrequent in patients with epiglottitis and foreign body aspiration, and may be precipitated by examination of the pharynx, the supine position or stressful procedures (e.g., intravenous

canula insertion). If these conditions are deemed to be unlikely, examination of the pharynx may be carried out.

- Direct visualization of the airway may be necessary and should only be performed by a skilled and experienced practitioner. Flexible fiberoptic nasopharyngolaryngoscopy can be done at the bedside. Alternatively, flexible or rigid laryngoscopy and bronchoscopy may be performed in the operating room and may also prove therapeutic (e.g., removal of a foreign body).
- In an unconscious patient, the first sign of airway obstruction is the inability to ventilate with a bag-valve mask or a jaw-thrust that does not open the airway.

LABORATORY TESTING

- No investigation is warranted until the airway is stabilized.
- Blood cultures are generally negative in patients with retropharyngeal abscesses, epiglottitis and bacterial tracheitis.
- Cultures of the affected area usually yield the causative organism.
- The white blood cell count, C-reactive protein and erythrocyte sedimentation rate may be elevated in patients with these infections.
- Blood gas analysis is rarely useful.
- Routine laboratory studies are not indicated in the evaluation of most patients with acute urticaria or angioedema. However, patients with recurrent angioedema without concomitant hives, including patients with angioedema associated with angiotensin-converting enzyme inhibitor should have assays of C4, C1 inhibitor antigen, and C1 inhibitor function. Serum C4 levels are reduced in patients with C1 inhibitor deficiency (hereditary angioedema).[4]

IMAGING

- Imaging should be postponed until the airway is secured in patients who are unstable.

- A physician who is competent in providing airway support should accompany stable patients to the radiology department.
- Plain films of the neck and chest may be useful to identify radio-opaque foreign bodies and to screen for infections that cause upper airway obstruction.
- Computed tomography is useful to diagnose abscesses, magnetic resonance imaging for vascular anomalies; these two tests and echocardiography have replaced barium swallow to diagnose vascular rings.
- The steeple sign or narrowing of the subglottic area on the frontal view of an x-ray of the neck or chest is the classic radiographic finding in croup (**Figure 30-1**).
- A round and thickened epiglottitis (thumb sign), loss of the vallecular air space, and thickening of the aryepiglottic folds are the classic findings on a lateral neck x-ray taken during inspiration with hyperextension of the neck (**Figure 30-4**).
- Bacterial tracheitis may be indistinguishable from croup on x-ray, but in some cases, the tracheal column appears hazy with multiple irregularities within the lumen.
- Increased thickness of the pre-vertebral soft tissue, with or without presence of gas or air-fluid levels and loss of normal cervical lordosis, in a lateral x-ray taken during inspiration with extension of the neck suggests a retropharyngeal abscess.
- Radio-opaque foreign bodies can be readily diagnosed on plain x-rays. Foreign bodies that are flat that are lodged in the esophagus usually assume a coronal orientation (**Figure 30-8**). Esophageal foreign bodies generally obstruct immediately distal to the pyriform sinus, at the level of the aortic arch or at the cardia.

DIFFERENTIAL DIAGNOSIS

Common causes of acute upper airway obstruction can be differentiated on the basis of age of the patient, onset of illness, prodrome, symptoms and signs (**Table 30-2**).

TABLE 30-2 Differential Diagnosis of Common Causes of Acute Upper Airway Obstruction

	Croup	Bacterial Tracheitis	Epiglottitis	Retropharyngeal Abscess	Foreign Body
Age	6 m – 4 y	6 m–8 y	6 m – 4 y	<6 y	Toddlers
Onset	Gradual	Intermediate	Rapid	Intermediate	Sudden
Fever	Usually low	Usually high	High	High	None
Prodrome	Upper respiratory	Upper respiratory	Usually none	Upper respiratory	Choking
Cough	Barking, brassy	Brassy	None	Unusual	Croupy
Appearance	Sick but nontoxic	Toxic	Toxic, assumes 'tripod' position	Sick, muffled voice, neck stiffness, trismus	Nontoxic
Drooling	No	No	Usually	Usually	Variable
Course	Usually benign	May acutely decompensate	Fulminant	Insidious	Occasionally life-threatening
Sore throat	None	Usually absent	Usually severe	Usually	None
Radiographic appearance	Narrowing of the subglottic space (steeple sign) on frontal view	Narrowing of subglottic space, tracheal air column may be hazy, intraluminal irregularities may be present	Round and thick epiglottis (thumb sign), loss of vallecular space, thickening of aryepiglottic folds on lateral view	Increase prevertebral soft tissue space	Flat objects assume coronal orientation when lodged in the esophagus

MANAGEMENT

- A child with a respiratory compromise should never be left unattended.

- Efforts should be taken to minimize disturbing the patient unless airway obstruction is life-threatening. Initial evaluation should be directed to making triage decisions about management and further evaluation.
- The unstable child must be evaluated and treated rapidly, with emergency stabilization of the airway receiving the highest priority.
- Patients with airway obstruction leading to respiratory arrest should promptly be ventilated with a combination of bag-valve-mask technique and proper head positioning (slight neck extension, chin lift and jaw thrust maneuvers). Oral and nasopharyngeal airways should be available for use in case of difficulty in bag-valve-mask ventilation.
- A patent airway should then be established under optimal conditions by the physician most experienced in handling difficult airways.
- The stable child with signs and symptoms of airway compromise should be carefully monitored and offered supplemental oxygen in a nonthreatening manner, keeping the patient as calm as possible while definitive treatment is instituted.
- Patients with epiglottitis, Ludwig’s angina, facial burns, and smoke inhalation should be intubated early in a controlled atmosphere by an experienced practitioner with a specialist capable of performing a tracheostomy present.

NONPHARMACOLOGICAL

Cool humidified oxygen or air

Cold humidified oxygen or air has been advocated for patients with croup. However, there is evidence showing that there is no benefit.[5–7] SOR Ⓐ

Heliox

- Heliox or helium-oxygen mixture reduces the work of breathing by decreasing airway resistance to turbulent flow across the obstructed airway.

- It has been used to provide temporary support and management in several conditions that cause airway obstruction including croup and post-extubation subglottic edema.[8] To be effective, the helium: oxygen ratio should be at least 60:40. SOR B

MEDICATIONS

Racemic epinephrine

- Nebulized epinephrine is effective in reducing airway edema due to its vasoconstrictive effect on the vasculature of the airway musculature.
- It leads to a rapid (within 30 minutes) but transient improvement in symptoms for croup.[9] SOR A

Corticosteroids

- Glucocorticoids have been used in the treatment of airway obstruction secondary to edema as a result of infection, allergy, and trauma.[10]
- Glucocorticoids are effective in relieving symptoms of croup within 6 hours.[11]
- The effect lasts about 12 hours and has been found to reduce the need for other drugs and decrease the length of hospital stay or return visits.[11] SOR A
- Glucocorticoids are commonly used to prevent or treat post-extubation stridor.[12] SOR B

Antibiotics

- Third-generation cephalosporins are the preferred agents for epiglottitis. SOR C
- A combination of a penicillin-beta-lactamase inhibitor, such as ampicillin-sulbactam, is the preferred agent for peritonsillar and retropharyngeal

abscess. Clindamycin or metronidazole, combined with a third-generation cephalosporin, are alternative therapies for such conditions. SOR Ⓒ

- Additional coverage against *S aureus* is often required for bacterial tracheitis. In these situations, clindamycin or a penicillinase-resistant penicillin (such as oxacillin or nafcillin) is often combined with a third generation cephalosporin. Vancomycin may be used in patients that appear toxic, have multiorgan involvement, or if methicillin-resistant *S. aureus* is prevalent in the community. In most cases, clinical improvement should be seen within 24 to 48 hours. SOR Ⓒ

Other

- Patients with angioedema should be treated with histamine blockers (H1 and H2), corticosteroids, and epinephrine if symptoms are severe.
- Drugs that may be responsible for angioedema, such as non-steroidal anti-inflammatory drugs and angiotensin-converting enzyme inhibitors, should be discontinued. Hereditary angioedema may be refractory to this treatment.
- For patients with hereditary angioedema, plasma-derived C1 esterase inhibitors should be administered.[13–15] Recombinant C1 esterase inhibitors, ecallantide and icatibant are recommended in adults but are not currently approved for use in children.[16] If no other treatment that has been proved to be effective is available, fresh frozen plasma should be used.[17] SOR Ⓒ
- Recurrent laryngeal papillomata are treated with laser or surgical resection. Adjuvant pharmacotherapy with interferon-alfa and antivirals given systemically or intralesional cidofovir may be considered.[18,19] Quadrivalent human papilloma virus vaccine has been used successfully in one patient.[20] SOR Ⓑ

SURGERY

- Cricothyroidotomy and tracheostomy may rarely be required to establish a secure airway.

- Patients with bacterial tracheitis often require a bronchoscopy for diagnostic and therapeutic purposes.
- Retropharyngeal and peritonsillar abscesses will require surgical drainage.
- Airway and esophageal bodies require removal in the operating room.
- Cysts, webs, hemangiomas, and papillomas will also require surgical intervention.

REFERRAL

- If epiglottitis or Ludwig’s angina are suspected, arrangements should be made for immediate evaluation by an anesthesiologist and otolaryngologist to secure the airway in the operating room.
- An otolaryngologist should also be consulted whenever retropharyngeal or peritonsillar abscesses, foreign bodies, subglottic stenosis, vocal cord palsy, or other causes of airway obstruction are suspected that need further evaluation and surgical intervention.
- An allergy and immunology specialist should be consulted whenever hereditary angioedema is suspected.
- A pediatric intensivist should be consulted for all patients with moderate to severe airway obstruction as they need to be monitored in the intensive care unit because of the potential for decompensation.

PREVENTION AND SCREENING

- Most infections can be prevented by maintain good hand hygiene such as frequent hand washing.
- Epiglottitis can be prevented by immunization with the *H. influenzae* type b vaccine.[3] SOR Ⓐ
- Patients with hereditary angioedema should be counseled and educated about their disease with attention to the identification and avoidance or elimination of precipitating factors that may trigger acute attacks such as

trauma, mental stress, infections, angiotensin converting enzyme inhibitors, and estrogen contraceptives.[14,16]

- Patients with hereditary angioedema may require short-term prophylaxis with a plasma-derived C1 inhibitor prior to undergoing a procedure likely to precipitate an attack.[14,16] SOR Ⓒ
- Regular therapy with plasma-derived C1 inhibitor is the preferred treatment for long-term prophylaxis in hereditary angioedema. Attenuated androgens may be used in children over 16 years of age. The antifibrinolytic drugs, ε-aminocaproic and tranexamic acid, although less effective, may offer some benefit.[16,21]
- Since recurrent respiratory papillomatosis is caused by human papilloma virus, most commonly types 6 and 11, and is transmitted from the mother to the child either in utero or at the time of birth, quadrivalent human papilloma virus vaccine holds promise for preventing recurrent respiratory papillomatosis.[22]

PROGNOSIS

- All patients with upper airway obstruction are at risk of developing pulmonary edema once the obstruction is relieved and should be carefully monitored.[23]
- Once the patient is past the acute phase, complete recovery is expected in most cases of upper airway obstruction.
- Most patients with croup have resolution of symptoms within 48 hours.
- One to eight percent of children with croup are hospitalized and less than 3 percent of the hospitalized patients are intubated.[1] Mortality is low.
- The mortality rate for bacterial tracheitis has been reported as high as 18 to 40 percent. Associated morbidity includes pneumonia, ARDS, septic shock, and multiple organ dysfunction syndrome.[24,25]
- Lemierre’s syndrome is an uncommon complication of pharyngo-tonsillar infections caused most commonly by *Fusobacterium necrophorum* and

characterized by ipsilateral internal jugular vein thrombosis and septic emboli most commonly affecting the lung and causing pulmonary abscesses.

- Patients with recurrent respiratory papillomatosis require repeated surgeries, often 20 procedures during their lifetimes.[19] The risk of malignant transformation is less than 1 percent.[26]

31 CHRONIC UPPER AIRWAY OBSTRUCTION—LARYNGOMALACIA

Anne Hseu, MD
Paul Krakovitz, MD

PATIENT STORY

A 4-month-old infant presents to your office with noisy breathing. His mother notes it began at a few weeks of life and has gradually worsened. The noise is described as a high-pitched wheeze with inspiration. It worsens when the baby is feeding, crying, or supine. Laryngoscopy confirms the diagnosis of laryngomalacia (**Figure 31-1**). The infant is treated with acid suppression therapy. The infant's symptoms resolve by 18 months of age.

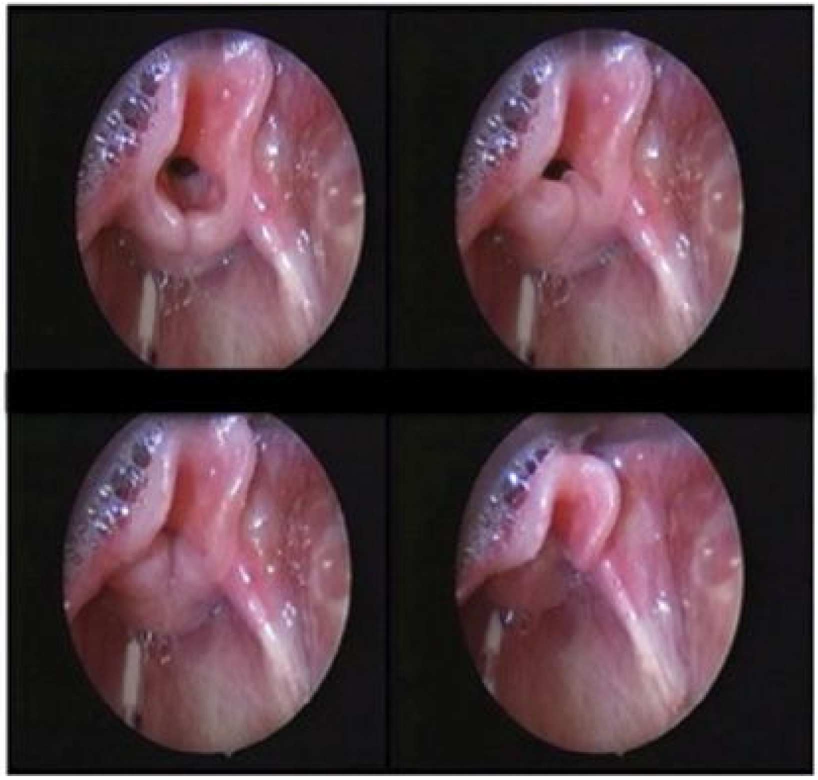

FIGURE 31-1 Multiple views of laryngomalacia in one infant. Note the omega-shaped epiglottis and prolapse of redundant supraglottictissue into the airway. (*Used with permission from Paul Krakovitz, MD*.)

INTRODUCTION

Laryngomalacia is a congenital abnormality of the larynx. It results in dynamic collapse of supraglottic structures leading to airway obstruction.

SYNONYMS

Laryngomalacias, Larynx chondromalacia.

EPIDEMIOLOGY

- Most common cause of stridor in newborns, affecting 45 to 75 percent of all infants with congenital stridor.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Exact etiology of laryngomalacia is unknown.
- Theories include anatomic displacement of flaccid tissue, immaturity of cartilage, neurologic underdevelopment affecting laryngeal function, and tone.[1]

RISK FACTORS

- Gastroesophageal and laryngopharyngeal reflux.
- Neurologic disease.
- Secondary airway lesions.
- Congenital heart disease.
- Congenital abnormalities/genetic disorders.

DIAGNOSIS

CLINICAL FEATURES

- Presents with inspiratory stridor that typically worsens with feeding, crying, supine, or positioning.

- Symptoms begin within first few weeks of life, peak at 6 to 8 months, and usually resolve by 12 to 24 months.
- Common associated symptoms include regurgitation, coughing, choking, and slow feeding.
- Less common symptoms include respiratory distress, cyanosis, pectus excavatum, and failure to thrive.

PROCEDURES

- Diagnosis suspected by clinical history and confirmed by awake dynamic flexible laryngoscopy.
- Typical features include supraglottic tissue prolapse during inspiration, omega-shaped epiglottis, retroflexed epiglottis, foreshortened aryepiglottic folds, and redundant arytenoid tissue (**Figure 31-1**).
- Based on history, patients may need to be screened for secondary, synchronous airway lesions.

LABORATORY TESTING AND IMAGING

- Usually not indicated. If there is concern for a synchronous airway lesion, may consider bronchoscopy or imaging.

DIFFERENTIAL DIAGNOSIS

- Subglottic stenosis—Congenital or acquired narrowing of the subglottic airway (**Figure 31-2**).

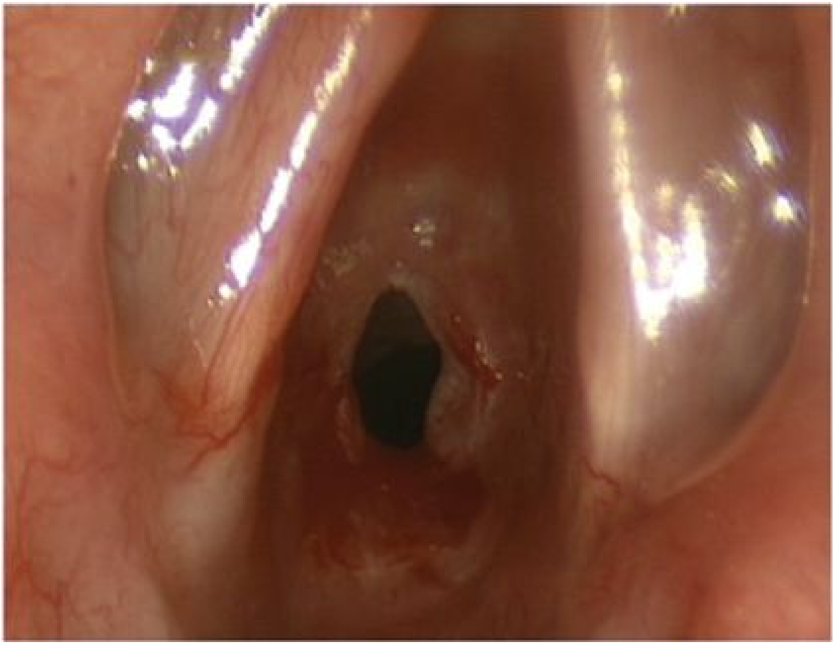

FIGURE 31-2 Subglottic stenosis. Note the true vocal cords laterally and the area of airway narrowing seen just distally in the subglottis. (*Used with permission from Paul Krakovitz, MD*.)

- Tracheomalacia—Flaccidity of tracheal cartilage leading to tracheal collapse especially with increased airflow (**Figure 31-3**).

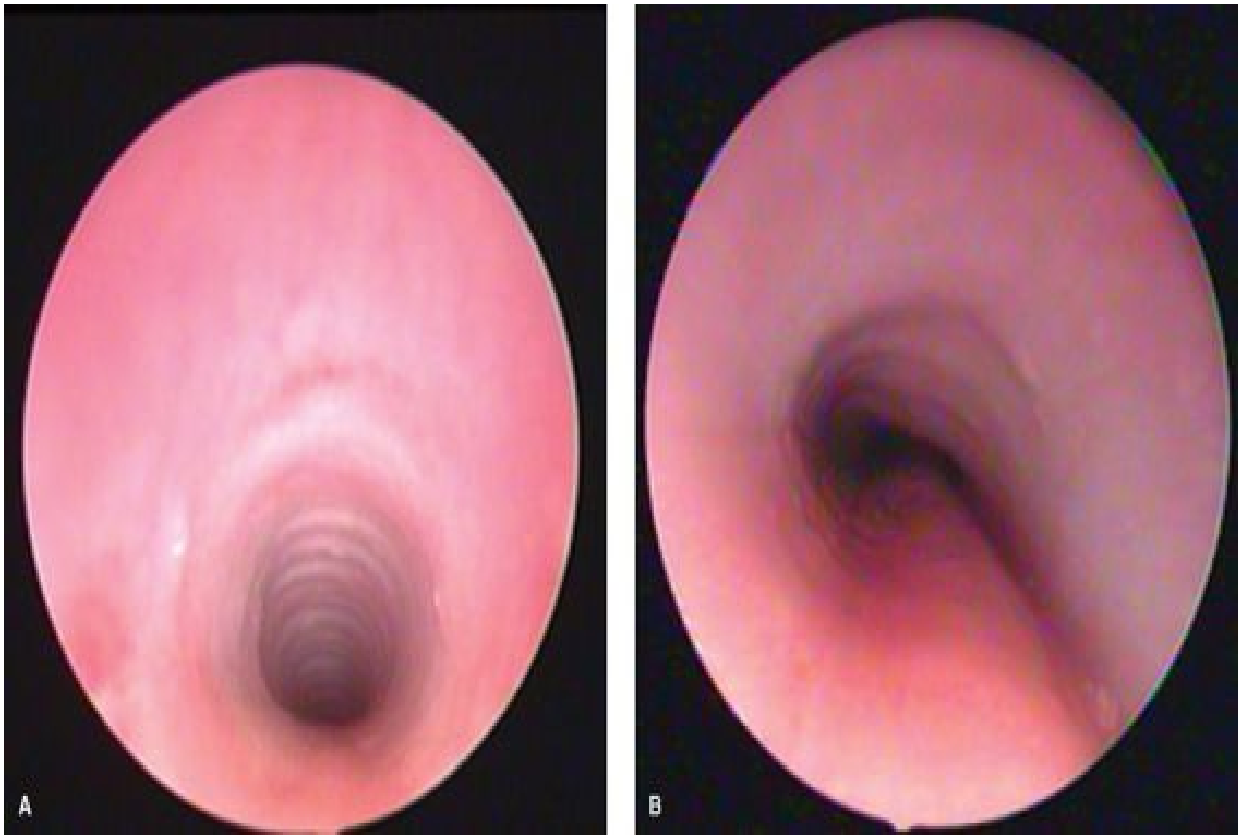

FIGURE 31-3 **A.** Endoscopic view of a normal trachea. **B.** Endoscopic view of tracheomalacia. Note the anterior-posterior collapse of the trachea seen just above the carina. (*Used with permission from Paul Krakovitz, MD*.)

- Vocal cord paresis or paralysis—Weakness or immobility of one or both vocal cords (**Figure 31-4**).

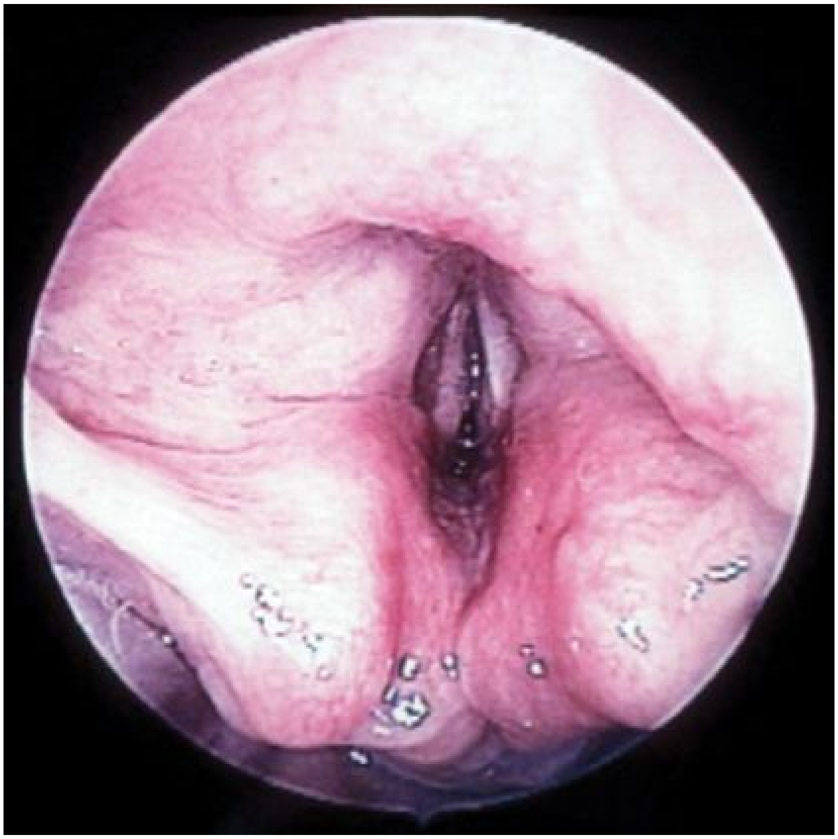

FIGURE 31-4 Bilateral vocal cord paralysis with right and left true vocal cords sitting in a paramedian position. (*Used with permission from Paul Krakovitz, MD*.)

MANAGEMENT

Management depends on categorization of mild, moderate, or severe disease. This is based on associated feeding and obstructive symptoms, not severity of stridor. Factors that are associated with disease severity and progression include APGAR scores, number of medical co-morbidities, presence of secondary airway lesions, and baseline resting oxygen saturation average. Gestational age at birth, birth weight, gender, and race have not been found to influence disease severity.[2]

NONPHARMACOLOGIC

- At the time of disease presentation, approximately 40 percent of infants will have mild disease.[1]
- Seventy percent of these patients will have self-limiting disease and can be managed expectantly.

MEDICATIONS

- Infants with moderate disease are often described as fussy and difficult to feed. Treatment with acid suppression therapy may improve symptoms and shorten the duration of laryngomalacia’s natural course.[3] SOR Ⓒ
- Acid suppressive therapy options include H2 blockers such as ranitidine or proton pump inhibitors such as omeprazole.

SURGERY

- Approximately 5 to 20 percent of infants with laryngomalacia present with severe disease and require surgical intervention.[4,5]
- Indications for surgery include recurrent cyanosis, obstructive apneas, aspiration or feeding difficulties, failure to thrive, and cor pulmonale.[4] SOR Ⓐ
- Surgical treatment includes supraglottoplasty where obstructive tissue is removed endoscopically (**Figure 31-5**). Surgery should also include a thorough airway assessment to rule out secondary airway pathology.

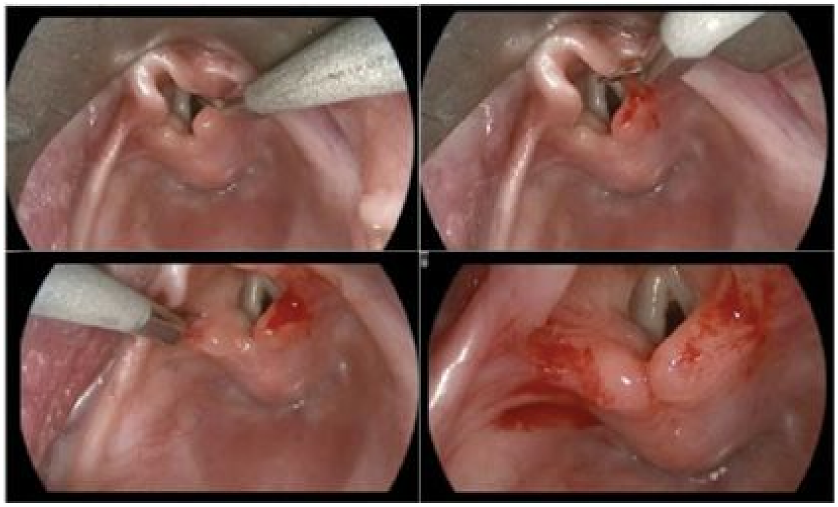

FIGURE 31-5 Supraglottoplasty. Foreshortened aryepiglottic folds are divided bilaterally. (*Used with permission from Soham Roy, MD*.)

- Tracheotomy is usually reserved for supraglottoplasty failures and patients with multiple medical comorbidities. SOR C

REFERRAL

- Pediatric otolaryngology consultation for patients who are thought to have moderate to severe disease.

PREVENTION AND SCREENING

- Identify patient factors and symptoms associated with moderate and severe disease that may warrant otolaryngology consultation.

FOLLOW-UP

- Patients with risk factors for severe symptoms and progression warrant close follow-up with otolaryngology.

PATIENT EDUCATION

- Infants with noisy breathing should have a medical evaluation.

32 THYROGLOSSAL DUCT CYST AND OTHER HEAD AND NECK MASSES

Karthik Rajasekaran, MD
Peter Revenaugh, MD
Paul Krakovitz, MD

PATIENT STORY

A 6-year-old boy is brought to his pediatrician with a 2-day history of fevers and cough. During the exam, the pediatrician notes a mass in the neck. His father first noticed it this morning. The mass is approximately 2 × 2 cm in size and located at the level of the hyoid in the midline of his neck (**Figure 32-1**). It is well circumscribed, with erythematous, and tender overlying skin. The mass moves when the boy swallows. The pediatrician suspects a thyroglossal duct cyst and refers to pediatric otolaryngology. The surgeon recommends complete excision to the father. After the upper respiratory infection has resolved, the thyroglossal duct cyst is removed completely under general anesthesia with no complications. The boy recovers completely.

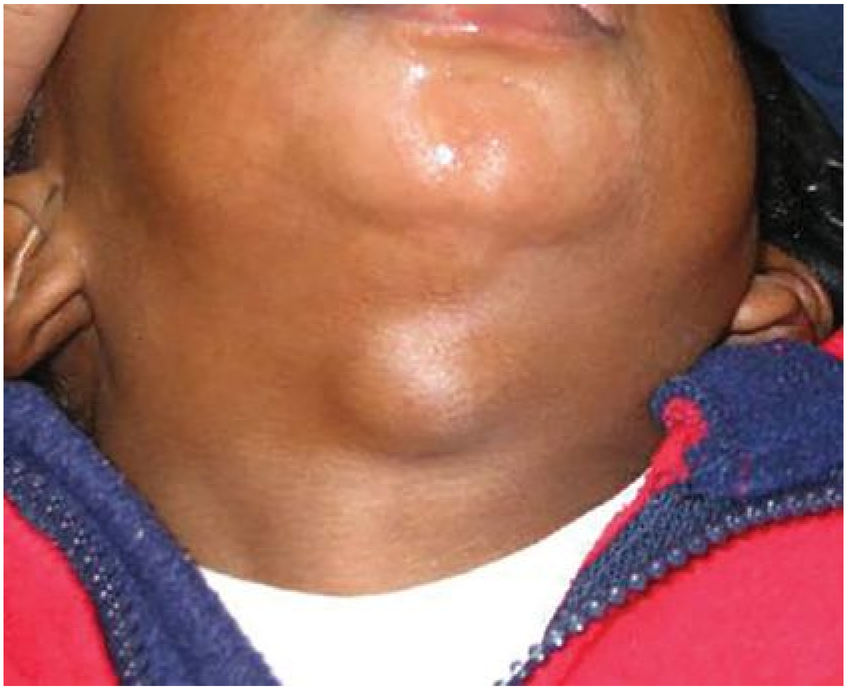

FIGURE 32-1 Thyroglossal duct cyst in a 6-year-old boy. The mass is in central portion of the neck. (*Used with permission from Paul Krakovitz, MD*.)

INTRODUCTION

Thyroglossal duct cyst is a congenital neck mass that occurs during development, as the thyroid descends from the base of the tongue to its paratracheal location.

SYNONYMS

Ectopic cervical thyroid.

EPIDEMIOLOGY

- It is reported that 7 percent of the population have thyroglossal duct cysts.[1]
- The most common congenital anomaly of the neck in children, representing more than 75 percent of congenital midline neck masses.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Between the 3rd and 4th week of gestation, the thyroid gland descends from the base of tongue to its paratracheal location and remains connected by the thyroglossal duct, which involutes between the 7th and 10th week. Failure to involute results in persistence of a portion of this duct, which is known as a thyroglossal duct cyst.
- Thyroglossal duct anomalies commonly present when they become acutely infected as a tender mass in the midline neck near the level of the hyoid. It is postulated that lymphoid tissue of the neck close to the thyroglossal structures reacts to repeated upper respiratory infections and this infectious irritation may stimulate epithelial remnants to undergo cystic change.[3]

RISK FACTORS

- There are no risk factors identified that predispose a child to acquiring this mass.

DIAGNOSIS

A good history of the present illness is paramount in the diagnosis and management of a neck mass. Important details include age that the mass was first noted, clinical signs, rate of growth and constitutional symptoms, recent travel outside of the US, and cat exposure.

CLINICAL FEATURES

- Typically presents after an upper respiratory infection as a painful, erythematous, and tender midline neck mass (**Figures 32-1** and **32-2**).

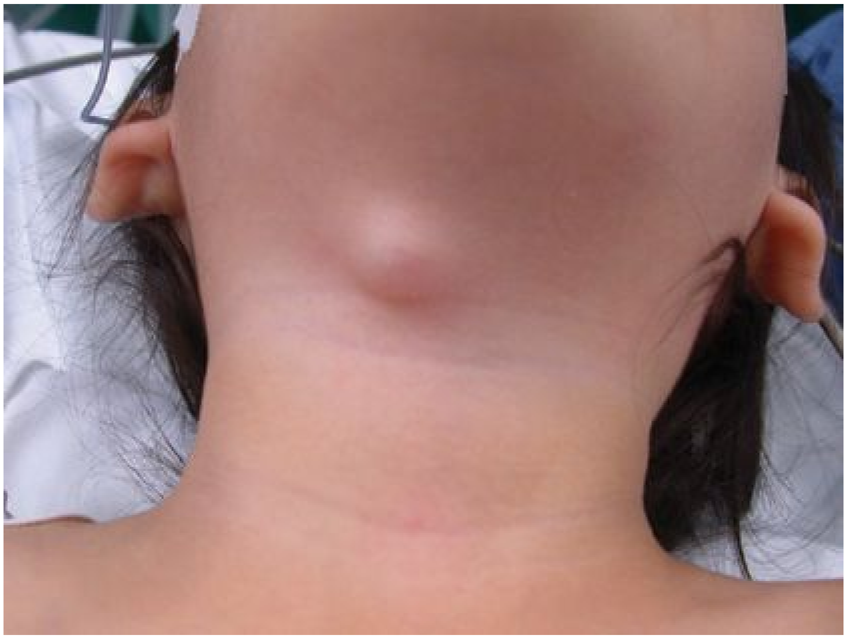

FIGURE 32-2 A thyroglossal duct cyst in a young girl. Note how it is close to the midline. These will move up with swallowing. (*Used with permission from Frank Miller, MD, and Usatine R. Dermatologic and Cosmetic Procedures in Office Practice. Elsevier, 2012*.)

- It can also appear as a mobile, painless mass in the midline of the neck.
- Associated symptoms that may develop include fever, dysphagia, dysphonia, and/or a discharging sinus.
- Average size is 2 to 4 cm in diameter.
- Movement of the cyst with swallowing is often cited as a reliable diagnostic sign because of the thyroglossal duct's close association with

the hyoid bone and foramen cecum.[4]

LABORATORY TESTING

- A complete blood count may be useful in identifying an infectious etiology.
- Other laboratory tests that are not particularly required for the evaluation of a midline neck mass but may be helpful in the work-up of other pediatric neck masses are:
  - *Bartonella* titers—To rule out cat scratch disease.
  - *Toxoplasma* titers.
  - Cytomegalovirus (CMV) titers.
  - Epstein-Barr virus (EBV) titers.
  - Monospot.

IMAGING

- Ultrasonography is the investigation of choice for a clinically suspected thyroglossal duct cyst (**Figure 32-3**). It is helpful prior to removal of the cyst to ensure that there is normal thyroid tissue and that the cyst does not represent an ectopic thyroid.

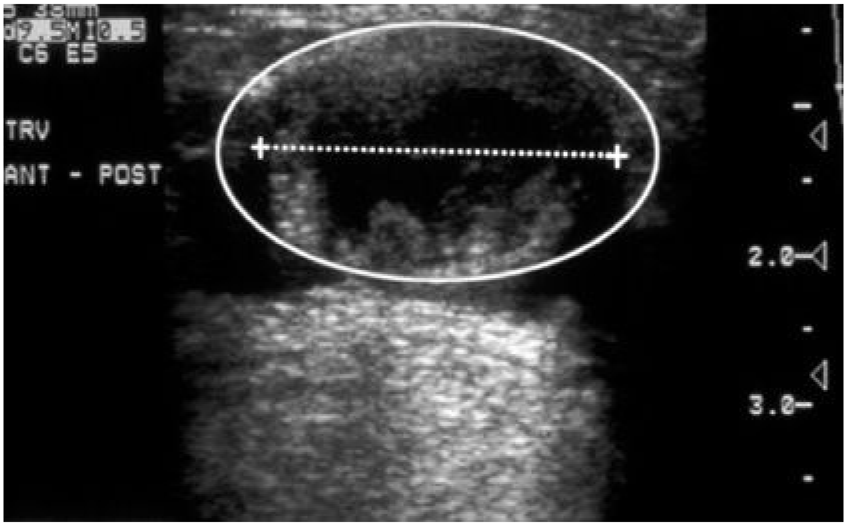

FIGURE 32-3 Thyroglossal duct cyst on ultrasound of the neck. (*Used with permission from Camille Sabella, MD.*)

- CT and MRI play a supplementary role to more accurately delineate the anatomy of large cysts, and MRI may be utilized to define a residual sinus tract in cases of recurrent disease.

DIFFERENTIAL DIAGNOSIS

- Mass location may help determine the diagnosis:
  - Midline neck mass.
    - Dermoid—Epithelium entrapped in tissue during embryogenesis. Dermoids are usually attached to the skin.
  - Lateral neck mass.
    - Branchial cyst—Second most common congenital neck mass, which arise from incomplete obliteration of the pharyngeal pouches and clefts during embryogenesis (**Figure 32-4**).

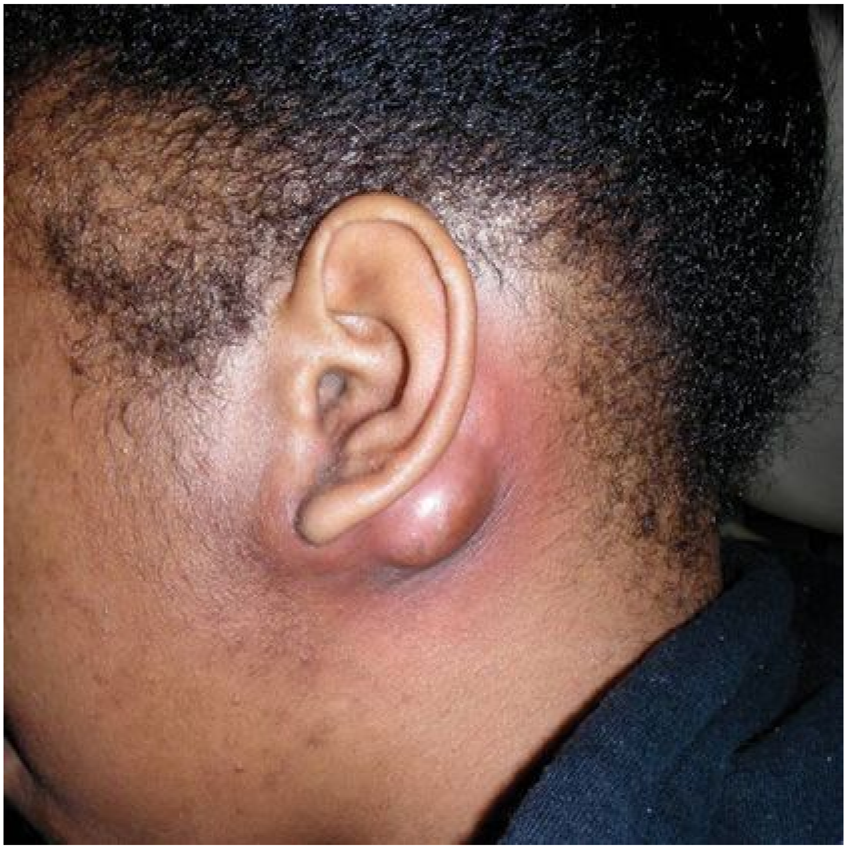

FIGURE 32-4 Type I branchial cleft cyst in the post-auricular area of this child. Typically, these occur in a peri-auricular pattern, more commonly anterior and inferior and down to the jaw line. Differential diagnosis for this location includes lymphovascular anomalies, mastoiditis, dermoid, or epidermal inclusion cysts. The recurrent nature of the abscesses and imaging on this child pointed to the diagnosis of a branchial cleft cyst. (*Used with permission from Paul Krakovitz, MD*.)

- Represents 20 percent of congenital pediatric head and neck masses.[5]
- Similar clinical presentation as thyroglossal duct cyst—Usually presents after an upper respiratory infection as a painful, erythematous neck mass.
- Imaging and diagnostic work up similar to thyroglossal duct cyst.
- Treatment is complete surgical excision (**Figure 32-5**).

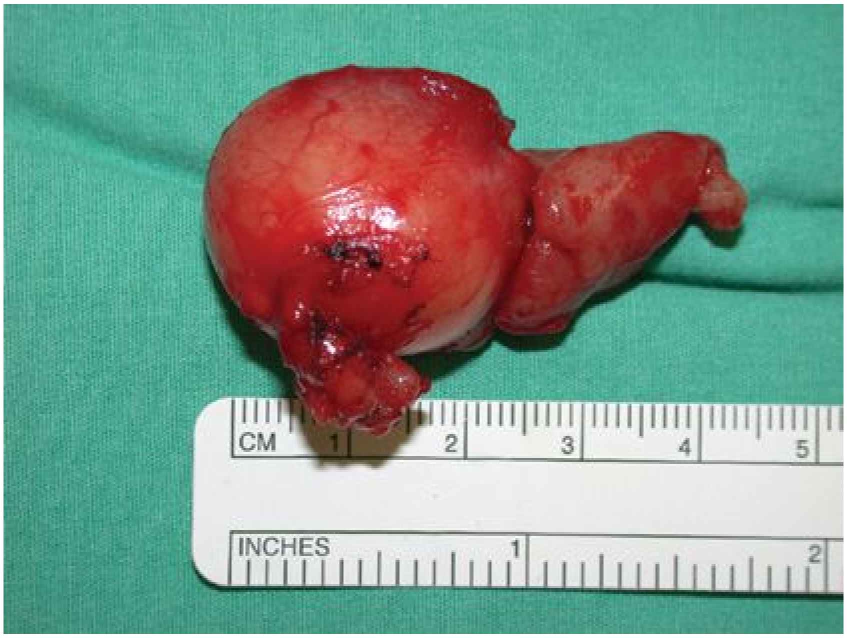

FIGURE 32-5 A branchial cleft cyst after removal. (*Used with permission from Frank Miller, MD and Usatine R. Dermatologic and Cosmetic Procedures in Office Practice. Elsevier, 2012.*)

- Cystic lymphangioma:
    - Most common lymphatic malformation, usually soft, and fluctuant (**Figure 32-6**).

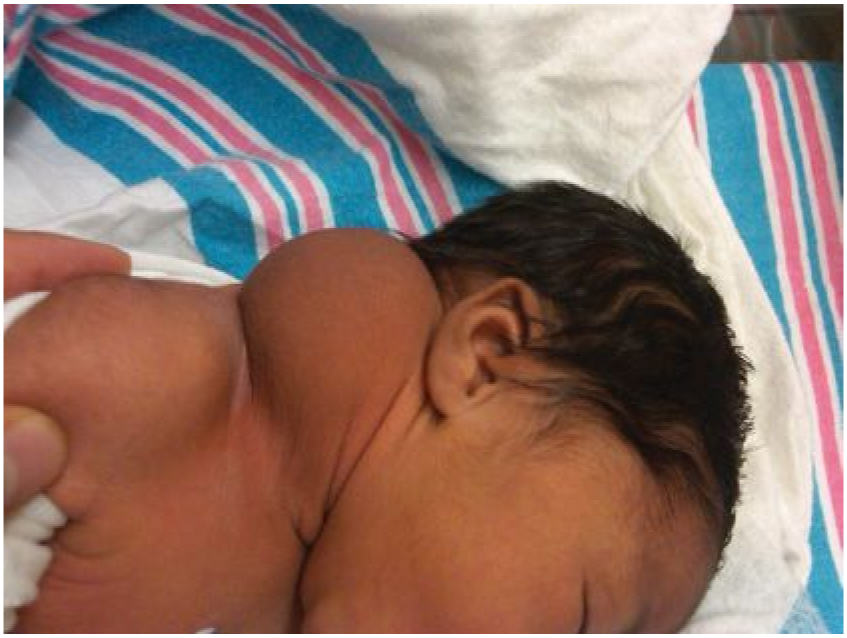

FIGURE 32-6 Cystic lymphangioma in an infant. Note the soft and fluctuant appearance. (*Used with permission from Federico Seifarth, MD*.)

  - Represents a congenital hamartomatous malformation of the lymphatic system that typically presents during infancy, and has a tendency to grow unless it is completely excised.
  - About 75 percent of all cases are localized in the neck region.[6]
  - Imaging and diagnostic work up similar to thyroglossal duct cyst.
  - Treatment of choice is complete surgical excision.

- Entire neck.
  - Hemangioma—Represents the majority of vascular tumors and present as red or bluish soft multi-locular masses (**Figure 32-7**).

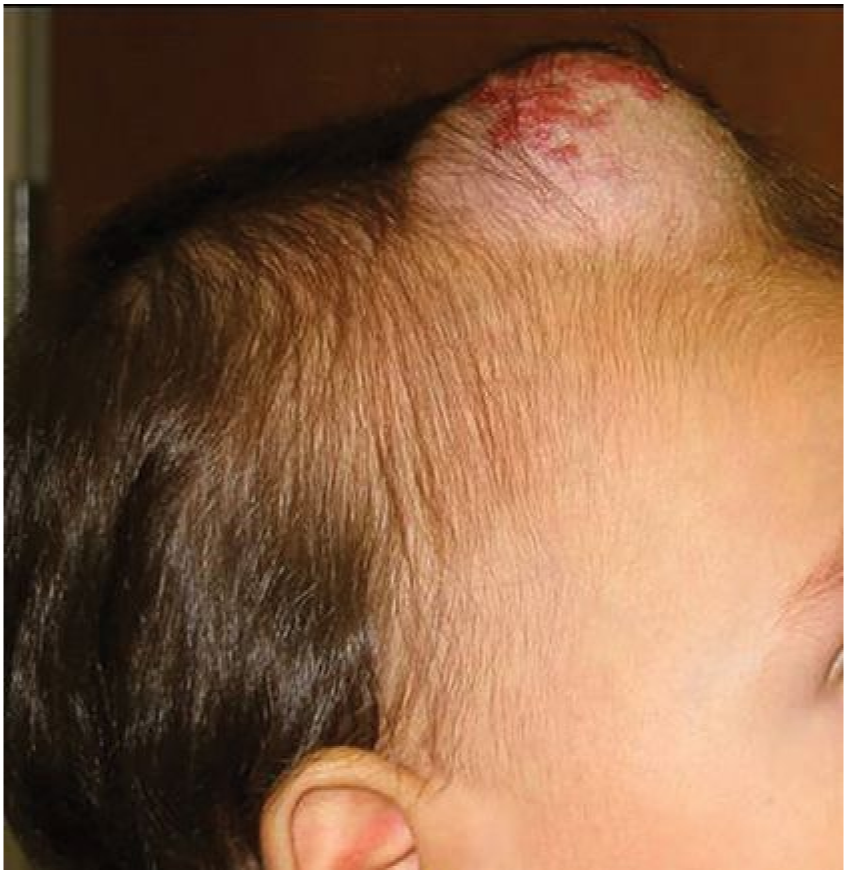

FIGURE 32-7 Classic hemangioma with erythematous cutaneous plaques on a soft tissue mass. (*Used with permission from Paul Krakovitz, MD*.)

- Venous Malformation—Lesion that is made up of dilated veins in a disorganized fashion, which readily expand in a dependent position and with raised venous pressure (**Figure 32-8**).

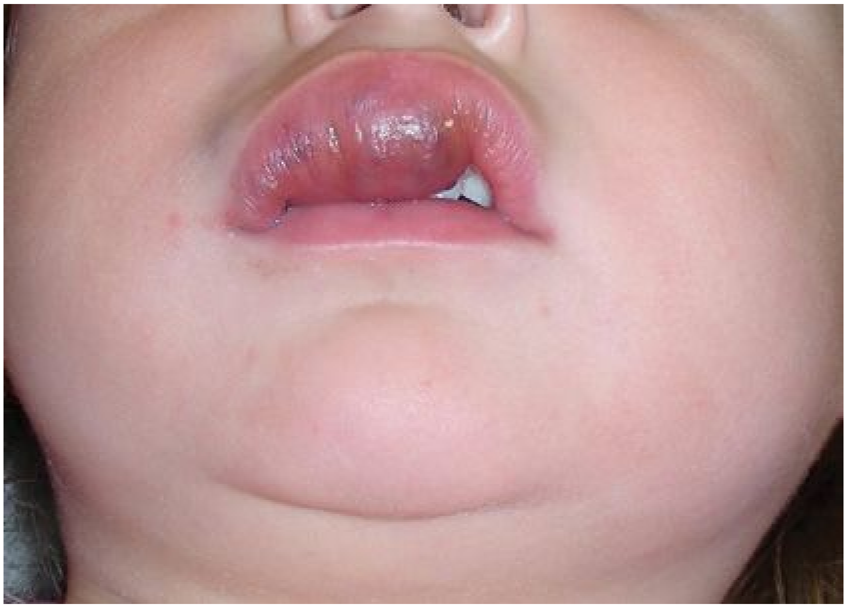

FIGURE 32-8 Venous malformation. Appearance can be similar to hemangioma. However, they have different characteristics on imaging and do not “regress” like a hemangioma. (*Used with permission from Paul Krakovitz, MD*.)

- Inflammatory adenopathy: most common cause of pediatric cervical adenopathy that comprises a wide variety of clinical conditions (see Chapter 33, Lymphadenopathy).

MANAGEMENT

NONPHARMACOLOGIC

- At the time of presentation, treatment of any acute infection, basic lab work, and possibly imaging would be appropriate first steps.
- Once the infection has resolved, imaging, if not already obtained, can be acquired.

MEDICATIONS

- There are no medications that can treat a thyroglossal duct cyst. However, medical treatment of an infection prior to surgical resection is reported to help decrease the rates of post-surgical recurrence.[7] SOR Ⓑ

SURGERY

- Complete excision is the treatment of choice. Removal of the entire cyst including the central portion of the hyoid bone and focused tongue base excision of the foramen cecum (commonly known as the Sistrunk procedure) is necessary.[4] SOR Ⓑ

REFERRAL

- Referral to Pediatric otolaryngology is advised when the diagnosis is made or suspected.
- Neck masses that have not resolved with antibiotics may warrant otolaryngology consultation.

PROGNOSIS

- Following complete excision of the thyroglossal duct cyst with the Sistrunk procedure, patients frequently do very well.
- Recurrences after Sistrunk operation are reported to occur in 0 to 12.2 percent of patients, in the most recent literature.[8,9]
- Failure to surgically excise the thyroglossal duct cyst can lead to repeated infections, dysphagia, dysphonia, and/or draining sinus.

FOLLOW-UP

- Only routine follow-up is needed following surgery, provided there is no further evidence of infection or clinical evidence of recurrence.

SECTION 4 NECK

33 LYMPHADENOPATHY

Samantha Anne, MD, MS
David Mandell, MD

PATIENT STORY

A 2-year-old girl presented to her pediatrician with a one month history of swollen glands in her neck and under her arms. Physical examination revealed non-tender firm lymphadenopathy in the anterior and posterior lymph node chains bilaterally (**Figure 33-1**). Work-up revealed anemia, neutropenia and thrombocytopenia. Biopsy of the lymph nodes and bone marrow biopsy showed acute lymphoblastic leukemia. She underwent induction chemotherapy and has responded well.

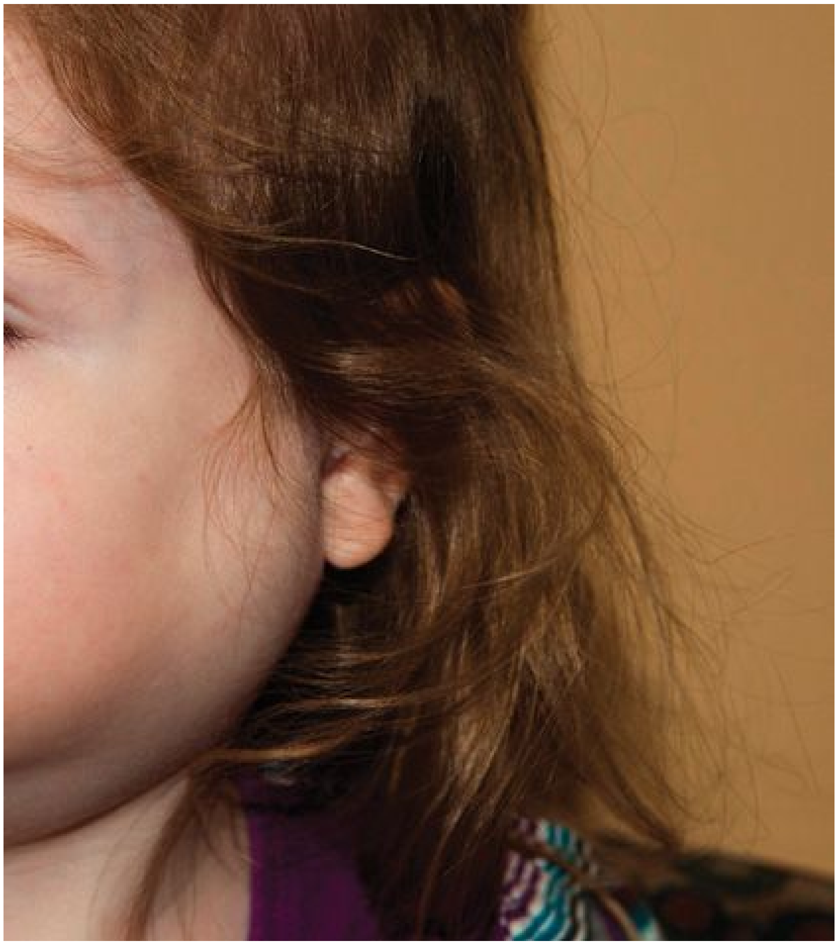

FIGURE 33-1 Firm, nontender pre-auricular and posterior cervical lymphadenopathy in a 2-year-old girl. This, along with pancytopenia, were the presenting features of acute leukemia. (*Used with permission from Camille Sabella, MD*.)

INTRODUCTION

Lymphadenopathy refers to nodes that are abnormal in either size, consistency, or number. In children, causes of lymphadenopathy can be divided into two large groups-inflammatory versus malignant. Cervical adenopathy due to inflammatory causes is by far the most common. Malignancy is less common but must be considered in the differential diagnosis based on certain concerning features in the history and physical exam.

SYNONYMS

Lymphadenitis, lymph node enlargement.

EPIDEMIOLOGY

- Almost all children develop lymphadenopathy at some point during childhood with nearly 2/3 of them developing enlarged nodes within infancy.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Lymph nodes are organized centers of immune cells that filter antigenic material such as infectious agents from lymphatics draining from areas of inflammation.
- When activated due to infection or antigenic stimulation, the nodes enlarge in size largely due to proliferation of cells intrinsic to the node such as plasma cells, macrophages, and others.
- Enlargement of nodes can also occur due to infiltration of malignant cells.[2]

RISK FACTORS

- Risk factors for inflammatory causes of lymphadenopathy are most commonly associated with exposure to pathogens.
- Viral illnesses that lead to lymphadenopathy are common in childcare centers.

- Parasitic and atypical infections can occur from a variety of exposures, including *Bartonella henselae* infection from a cat scratch and toxoplasmosis from exposure to cat feces.
- Lymphadenopathy associated with human immunodeficiency virus (HIV) infection can result from perinatal exposure, exposure to intravenous drug use, or unprotected sexual behavior.
- Certain infectious etiologies of lymphadenopathy can be regional in nature, such as exposure to coccidiomycosis in the southwest US and histoplasmosis exposure in the southeastern or central US.
- Medications, such as phenytoin or penicillin, can be associated with the development of lymphadenopathy.
- Odontogenic infections may cause a lymphadenopathy adjacent to the site of the infection.
- Risk factors for malignant causes of lymphadenopathy include exposures to Epstein-Barr virus (EBV) in cases of lymphoma or nasopharyngeal carcinoma.

DIAGNOSIS

CLINICAL FEATURES

- Localized lymphadenopathy occurs in 75 percent of the cases and generalized lymphadenopathy in the rest of the cases.
- Of all the locations that localized lymphadenopathy can occur, head and neck manifestation occurs in 55 percent of the cases.[1]
- Acute unilateral adenopathy is most likely due to streptococcal, staphylococcal, or viral infections (**Figures 33-2** and **33-3**).

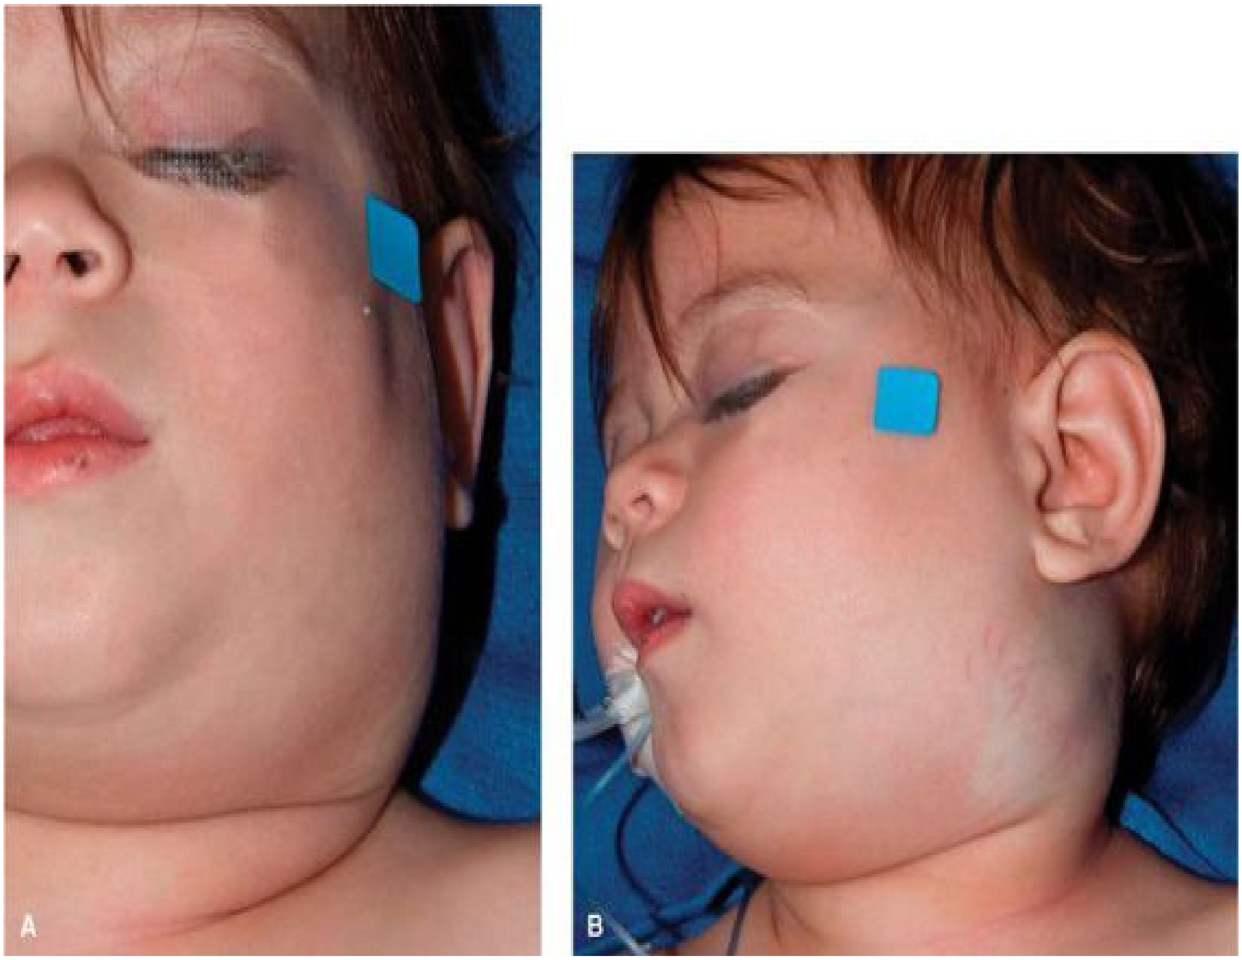

FIGURE 33-2 Unilateral left-sided fullness with confirmed abscess formation in a child about to undergo drainage procedure (**A**). Note the skin blanching due to underlying abscess formation (**B**). (*Used with permission from Prashant Malhotra MD*.)

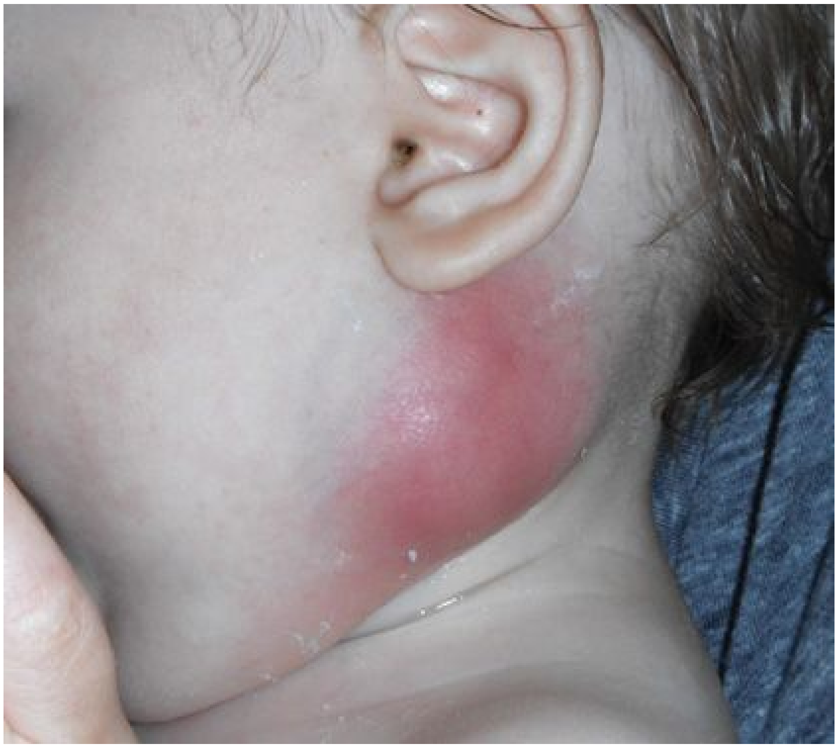

FIGURE 33-3 Acute lymphadenitis and abscess in a 9-month-old infant. (*Used with permission from Emily Scott, MD.*)

- Acute bilateral adenopathy tends to be due to systemic infections, such as infectious mononucleosis or viral upper respiratory infections (**Figure 33-4**).

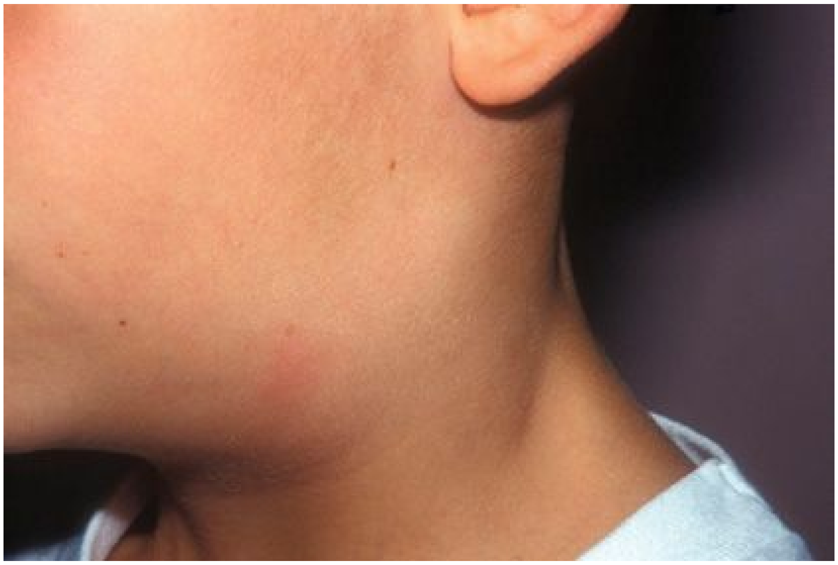

FIGURE 33-4 Anterior and posterior cervical lymphadenopathy in a school-aged child. This is most commonly of viral etiology. (*Used with permission from Johanna Goldfarb, MD*.)

- Subacute or chronic lymphadenopathy usually occurs due to slow-growing bacterial or viral infections such as cat-scratch disease or nontuberculous mycobacterial infection (**Figures 33-5** and **33-6**).

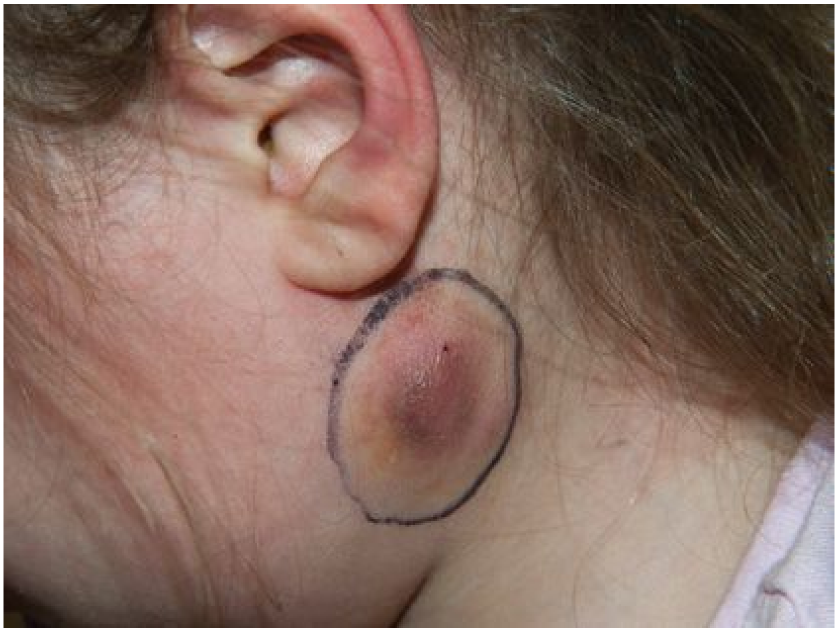

FIGURE 33-5 Subacute, cervical lymphadenopathy in a 3-year-old girl. Note the discoloration and proximity of the lymph node to the skin. This can be caused by cat scratch disease or nontuberculous mycobacteria. (*Used with permission from Camille Sabella, MD*.)

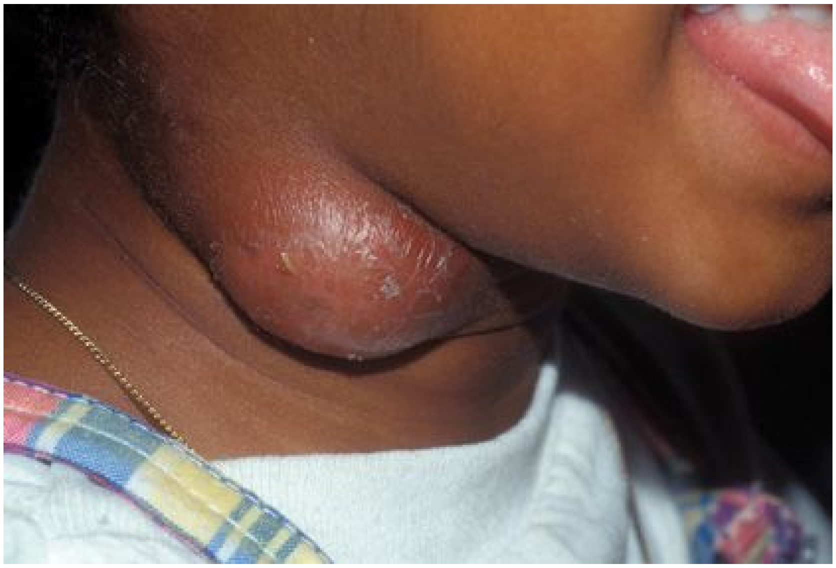

FIGURE 33-6 Nontuberculous mycobacterial adenitis in a young girl. Note the discoloration and the close proximity of the node to the skin. (*Used with permission from Johanna Goldfarb, MD*.)

- Inflammatory masses are generally tender and mobile. Exceptions include some of the causes of subacute or chronic lymphadenopathy, such as nontuberculous mycobacterial infection, which is usually a nontender lymphadenopathy with fixation of the node to the skin (see **Figure 33-5** and **33-6**).
- Features that may raise concern for the possible presence of malignancy include persistent nontender adenopathy with a size greater than 2 cm, constitutional symptoms such as fevers, night sweats, or weight loss, and adenopathy in certain unusual locations such as the supraclavicular region and in some cases, the posterior neck.[3]
- In addition, firm, rapidly enlarging, fixed nodes should alert concern for malignancy (**Figure 33-7**).

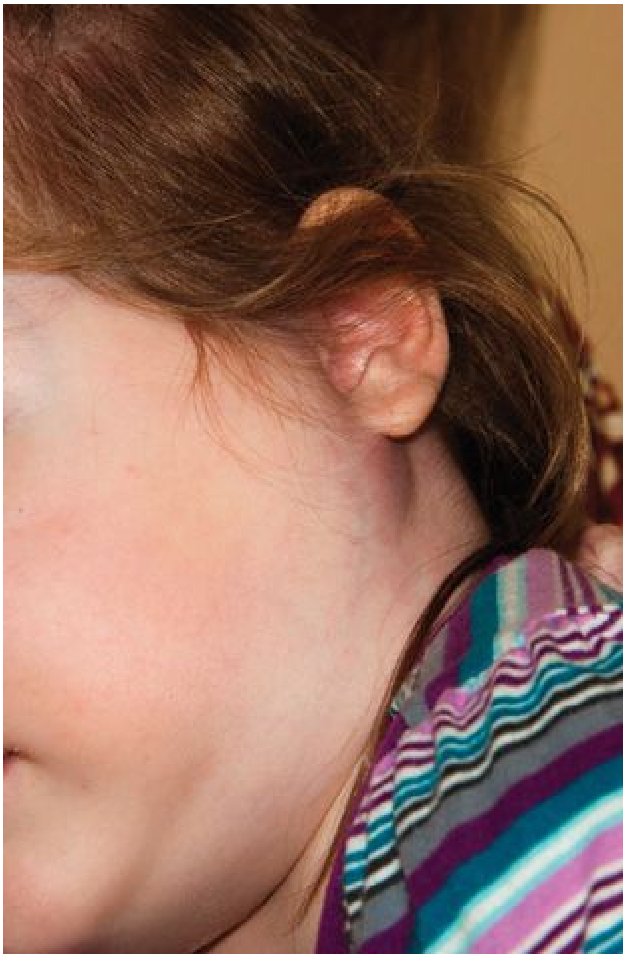

FIGURE 33-7 Rapidly enlarging lymph nodes in the same girl as in **Figure 33-1**. Note the discoloration, likely due to stasis from large matted lymphadenopathy. (*Used with permission from Camille Sabella, MD*.)

DISTRIBUTION

- Lymphadenopathy can be divided into level I including submental and submandibular nodes; level II, III, and IV, which include superior, middle, and inferior internal jugular nodes, respectively; level V, which is the posterior triangle, level VI which are the jutavisceral nodes; and, finally, level VII, which are nodes in the tracheoesophageal groove.
- Supraclavicular nodes have traditionally been felt to have a higher incidence of malignancy than other more common cervical locations and further evaluation should be considered even if the size is less than 2 centimeters.

LABORATORY TESTING

- Complete Blood Count with differential, serologic testing for EBV, CMV, cat-scratch disease, toxoplasmosis, HIV, and syphilis can be attained based on clinical suspicion.
- Cultures of infected tissue would be helpful in choosing appropriate medications.
- In addition, serum Lactate Dehydrogenase (LDH) can be attained in evaluation for lymphoma and urine VMA when there is concern for neuroblastoma.
- Pathology of the incised lymph node is helpful in ascertaining a definitive diagnosis, especially when malignancy needs to be excluded.

IMAGING

- Chest x-ray is helpful in the evaluation of malignancies, tuberculosis, HIV, and sarcoidosis.
- Computed tomography (CT) of the neck can be attained for infections to differentiate lymphadenitis and cellulitis from suppuration and abscess formation.
- Ultrasound can also make this differentiation and can be a less expensive alternative to CT. The attainment and interpretation of ultrasound results can be significantly operator-dependent (**Figure 33-8**).

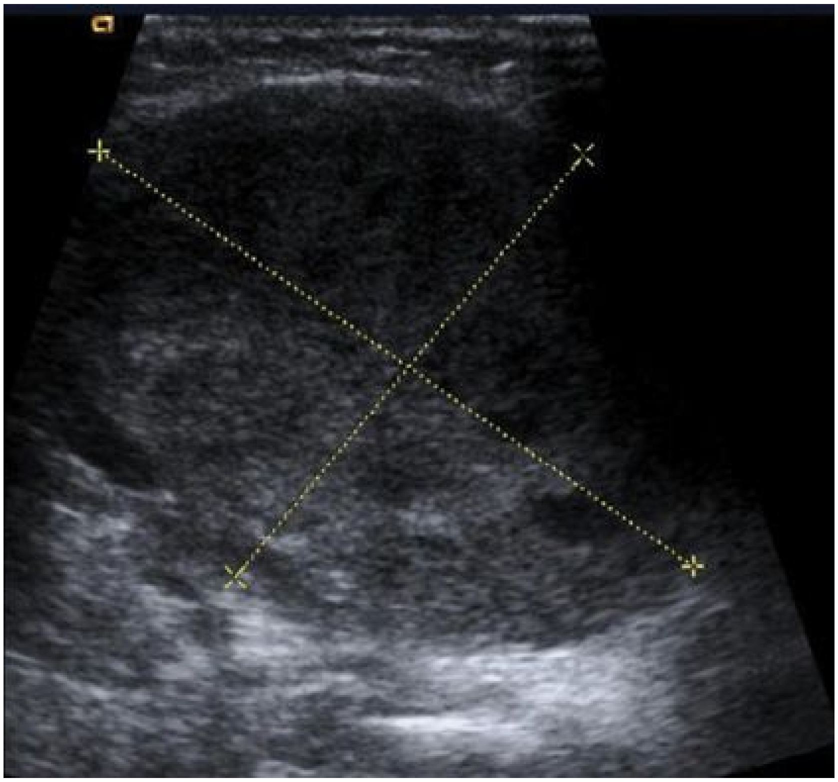

FIGURE 33-8 Heterogeneous enlarged lymph node between the left parotid and submandibular glands on ultrasound in a child with non-tuberculous mycobacterial infection. (*Used with permission from Camille Sabella, MD.*)

DIFFERENTIAL DIAGNOSIS

- Differential diagnosis of lymphadenopathy is extensive but can be differentiated into inflammatory versus malignant causes.
- The most common inflammatory causes are due to viral infections, which commonly cause nonspecific, reactive lymphadenopathy and infections with cytomegalovirus (CMV) or EBV or Varicella-zoster virus (VZV).
- The most common bacterial causes of adenopathy are streptococcal or staphylococcal upper respiratory infections, mycobacterial or atypical mycobacterial, cat scratch disease, and bacterial adenitis.
- Fungal infections, especially tinea capitis, can cause lymphadenopathy (**Figure 33-9**).

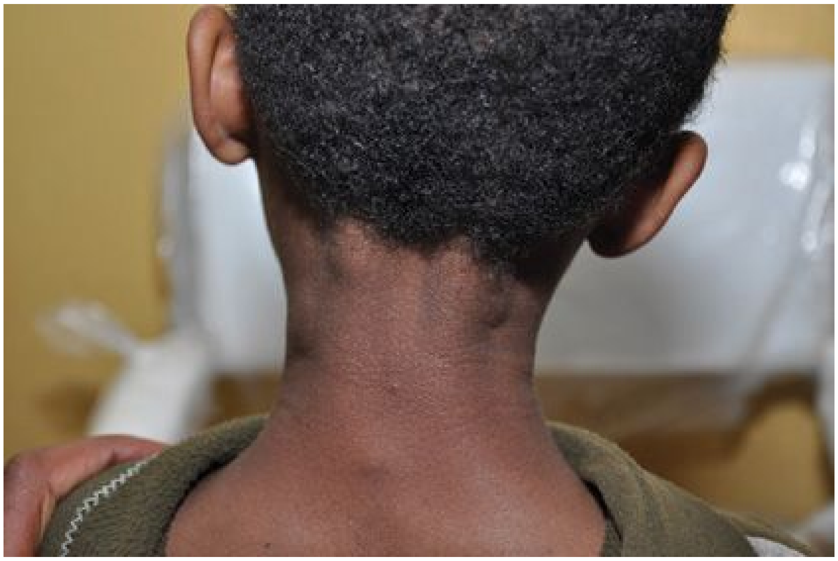

FIGURE 33-9 Occipital lymphadenopathy secondary to tinea capitis. (*Used with permission from Richard Usatine, MD*.)

- Non-infectious inflammatory causes include Kawasaki disease (see Chapter 177, Kawasaki Disease), Kimura disease, histiocytosis, and PFAPA syndrome (see Chapter 176, Periodic Fever Syndromes).[2]
- The most common malignant causes include lymphoma, leukemia, rhabdomyosarcoma, neuroblastoma, and nasopharyngeal carcinoma.

MANAGEMENT

- Treatment in general is directed toward underlying etiology.
- Early biopsy should be considered when there is involvement of supraclavicular nodes, systemic symptoms, fixation or hard masses, abnormal chest x-ray findings, or rapid enlargement or increase in adenopathy in the absence of obvious infection.[2] SOR Ⓒ

NONPHARMACOLOGICAL

- Observation and conservative management including rest, hydration, and pain control is reasonable in acute adenopathy from viral causes and with no concerning features in the history and physical exam.
- Reassurance is important to family members since the majority of cases of acute lymphadenopathy, especially in children, are due to transient, self-limited diseases, such as viral upper respiratory infections, that resolve within 4 to 6 weeks without sequelae.

MEDICATIONS

- Treatment of viral lymphadenitis ranges from observation to antiviral medication, depending on the type of virus, the severity of the symptoms, and the immune status of the host.
- Treatment of bacterial lymphadenitis often requires antibiotics, and sometimes surgical drainage.
- Subacute infections, including atypical mycobacterial infection, cat-scratch disease, protozoan and fungal infections, as well as sexually transmitted diseases, may be treated medically and occasionally surgically, depending on the infecting organism, the severity of the symptoms, and the immune status of the patient.
- Autoimmune disorders and malignancies are managed according to current treatment protocols specific for each disease.

SURGERY

- Options include needle aspiration, incision and drainage, incision and curettage, and excision/excisional biopsy (**Figure 33-10**).

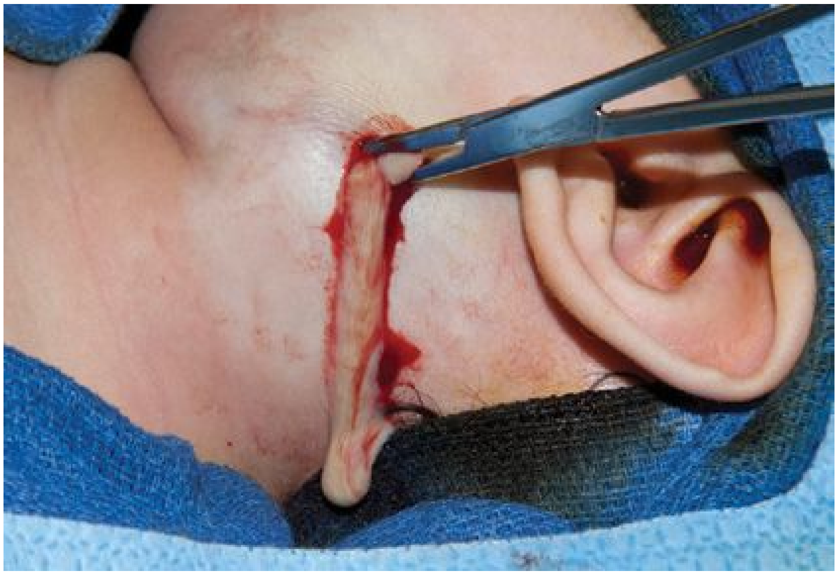

FIGURE 33-10 Abscess of the child in **Figures 33-2**, surgically incised with resultant copious purulent drainage elicited. (*Used with permission from Prashant Malhotra MD*.)

- Small unilocular abscesses can resolve with needle aspiration itself followed by antimicrobial/antifungal therapy based on culture results.
- Larger abscesses or abscesses associated with airway compromise, impending complications, or severe systemic illnesses should undergo incision and drainage.[2] SOR Ⓑ
- Excision of nodes or excisional biopsies should be considered in cases of nontuberculous mycobacterial adenopathy due to incidence of sinus tracts and development of chronic drainage whenever there is concern for malignancy.[2,4] SOR Ⓑ

REFERRAL

- For head and neck lymphadenopathy, early consult to otolaryngology is important to determine need for surgical intervention and to aid in attaining cultures.
- If concern for malignancy is present, hematology/oncology consultation is important.

PREVENTION AND SCREENING

- Avoiding sick contacts (including in childcare centers) may reduce the incidence of benign reactive lymphadenitis in children.
- Appropriately timed vaccinations can prevent childhood illnesses associated with lymphadenopathy such as rubella, rubeola, and varicella.

PROGNOSIS

- Complications of poorly managed infectious causes of lymphadenopathy can result in progression of illness resulting in systemic toxicity, suppuration, vascular complications such as venous thrombosis, and/or airway compromise.
- Delay in diagnosis of malignancy can result in progression in stage and worsened prognosis.

FOLLOW-UP

- The type of treatment used, whether surgical or medical, and response to treatment will determine the timing of follow-up and need for further testing.

PATIENT EDUCATION

- Patients (and parents) should be advised to notify their physician with increasing size and number of lymph nodes, development of constitutional symptoms in addition to lymphadenopathy, and with persistence of enlarged lymph nodes.

34 CONGENITAL ANOMALIES OF THE HEAD AND NECK

Karen Hawley, MD
Kyra Osborne, MD
Prashant Malhotra, MD, FAAP

PATIENT STORY

A newborn male, day of life 0, presented with respiratory distress requiring intubation. He was noted to have low set ears, micrognathia, and a cleft palate. Upon closer examination, he was also noted to have a right-sided complete aural atresia and the left canal is stenotic. His midface appeared hypoplastic and he was noted to have a cleft palate. A genetics consult was obtained and the patient was diagnosed with Treacher Collins syndrome (**Figure 34-1**). Surgical repair of palate was performed at 10 months of age, and a softband bone conduction device was provided in infancy for hearing habilitation. The family was counseled regarding ultimate options for reconstruction of microtia and aural atresia.

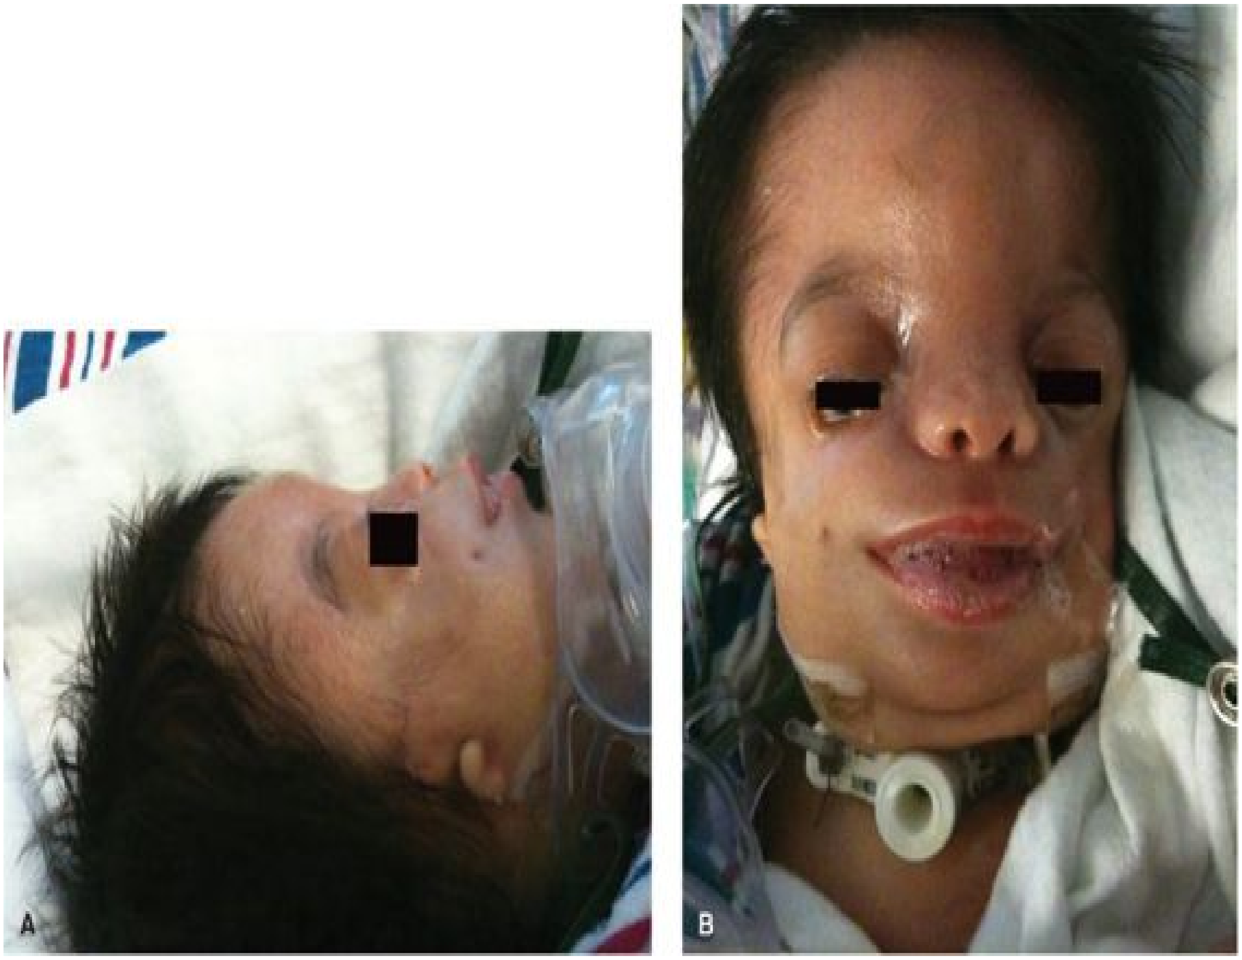

FIGURE 34-1 Treacher Collins syndrome in an infant with severe manifestations, as seen on lateral (**A**) and frontal (**B**) views. Note the microtia (underdeveloped pinna) and aural atresia. Severe maxillary and zygomatic hypoplasia leads to downsloping lateral canthi. This infant also has a facial pit and cleft palate. (*Used with permission from Prashant Malhotra, MD.*)

INTRODUCTION

Congenital anomalies in the head and neck are numerous and varied. In this chapter, we provide a general approach to the diagnosis and management of children with these anomalies and then outline an anatomic approach to considering these abnormalities using some illustrative photographs of those commonly encountered or unique entities.

Consensus terminology is critical for discussion. An anomaly is a structural or functional defect, which is present at the time of birth. A malformation is a major defect that is the result of incorrect morphogenesis. A sequence is a series of defects that occur in a nonrandom fashion. A single event then leads to a series of malformations. Pierre-Robin sequence is an example of a sequence. An association is encountered when there is a tendency of some malformations to occur together more commonly than would be expected by chance, but are not considered to be a part of an established malformation syndrome. An example is the CHARGE association, which includes coloboma, heart anomaly, choanal atresia, retarded growth, genital, or ear anomalies.[1]

DIAGNOSIS

CLINICAL FEATURES

- Congenital anomalies in the head and neck are common and a thorough head and neck examination is recommended.
- An initial airway evaluation for signs of distress or obstruction is essential. This includes observation of retractions and desaturations, listening for stridor, stertor, as well as evaluation of the voice. Stridor is generally a higher pitched sound and can occur during inspiration, expiration, or both. Stertor sounds more like snoring and occurs on inspiration, and is more indicative of obstruction in the nasal cavity, nasopharynx, or oropharynx. A hoarse, quiet, or raspy cry may indicate vocal cord pathology such as cord immobility or mass.
- Noting abnormalities in the general appearance of the infant such as facial asymmetry, low set ears, or down-slanting palpebrae may help to identify syndromic pathology. Skin changes such as skin tags, sinuses, and vascular malformations should be noted.
- The ear exam should include not only evaluation of the pinnae, but also assessment of canal patency for atresia. Routine examination of the

tympanic membrane and middle ear is also critical. A newborn hearing screen with consideration of both auditory brainstem responses and otoacoustic emissions testing should be discussed with an audiologist or neonatologist if appropriate.

- External nasal examination should include evaluation for pits or central hair, which could be indicative of a nasal dermoid. Anterior nasal rhinoscopy can be performed using an otoscope to assess for nasal mass or lesion. If there is suspicion for nasal obstruction, a 5 or 6 French catheter should be passed. If resistance is met, this may indicate intranasal obstruction. The need for nasal endoscopy can be determined by referral to a pediatric otolaryngologist.
- An oral exam should include visual inspection of the whole oral cavity and posterior oropharynx as well as bimanual palpation of the floor of mouth and assessment of the infant’s lip and palate.
- The neck should be evaluated for masses, pits, or draining sinuses.
- As several craniofacial syndromes are associated with ocular abnormalities, routine exam of the eyes should be performed and ophthalmology consultation obtained if needed.
- Any infant with suspected upper airway anomaly should be examined by a pediatric otolaryngologist. In the patient who is awake, a bedside flexible nasolaryngoscopy allows for a dynamic airway exam. If warranted, a complete airway evaluation in the operating room includes a direct laryngoscopy with rigid and/or flexible bronchoscopy. The need for such an exam depends on the clinical scenario and is a decision to be made by the consulting otolaryngologist.

LABORATORY DATA

- Various laboratory data and genetic testing may be obtained depending upon the identified anomaly. This is tailored to the patient and made in conjunction with neonatology, genetics, and other specialty team members.

MANAGEMENT

- The management of congenital abnormalities is specific to each pathologic process.
- A genetics consultation should be initiated if multiple anomalies are identified or if a syndrome is otherwise suspected.
- The appropriate consultations to an otolaryngologist, ophthalmologist, plastic surgeon, or other pediatric specialists will guide nonsurgical and surgical management.
- While cosmetic concerns may be most immediately apparent, functional anomalies related to airway, feeding, vision, and hearing should be prioritized.

HEAD AND NECK ANOMALIES BY ANATOMIC SITE

The more common head and neck anomalies will be discussed by anatomic site. A tabular summary will include basic epidemiology, evaluation, and management.

Congenital Nasal Anomalies (**Table 34-1**; **Figures 34-2** to **34-4**)

TABLE 34-1 Congenital Nasal Anomalies[2]

Anomaly	Epidemiology	Presentation	Evaluation	Treatment
Pyriform Aperture Stenosis Narrowing of anterior bony openings to nasal passages from overgrowth of nasal processes of maxilla (**Figure 34-2**)	• Rare; case reports and series	• Respiratory distress • Cyclical cyanosis • Apnea • Poor feeding • Narrow anterior nasal openings • Central solitary central maxillary incisor (SCMI)	• CT scan • Look for solitary central maxillary incisor (SCMI) • If SCMI present, MRI to r/o holoprosencephaly or other midline defects • Pediatric ENT consult • Consider genetics consult	• Conservative (oral airway, decongestants) vs. surgical opening of pyriform aperture
Choanal Atresia Failure of bucconasal membrane to degenerate, with failure to develop choanal openings in posterior nasal cavity (**Figure 34-3**)	• 1:8000 births • 50 percent have associated congenital anomalies • 2/3 are unilateral	• Respiratory distress • Cyclical cyanosis • Apnea • Poor feeding • May be normal in unilateral atresia • Failure to pass 5 or 6 Fr catheter	• Endoscopic evaluation • CT scan to see bony/membranous • Pediatric ENT consult • Genetics consult to evaluate for CHARGE or other associated syndrome	• Unilateral may be able to be managed conservatively • Bilateral usually requires intubation and early surgical opening of choanae vs. tracheostomy
Nasolacrimal Duct Cyst Cyst formation from distal nasolacrimal duct obstruction – commonly from an imperforate nasolacrimal duct opening	• 8:10,000 • F > M	• Respiratory distress • Cyclical cyanosis • Canthal swelling • Bluish mass • Epiphora	• Endoscopic evaluation • CT scan • Pediatric ENT consult	• Can managed conservative, usually surgical especially when bilateral
Nasal Dermoid Cyst formation from failure of involution of dural diverticulum, with trapping of epithelial remnants (including glands and hair) (**Figure 34-4**)	• 1:20,000–1:40,000 newborns	• Nasal obstruction • Visible mass – can be from glabella to columella • Midline pit +/– hair • Not pulsatile, does not transilluminate	• CT scan • MRI to r/o intracranial extension and differentiate glioma/encephalocele • Pediatric ENT consult • Possible neurosurgery consultation	• Surgical excision

FIGURE 34-2 Pyriform Aperture Stenosis seen on axial (**A**), and coronal (**B**) CT scan in a 2-week-old infant who presented with neonatal respiratory distress and feeding difficulty. A solitary central maxillary incisor seen on axial CT (**C**). (*Used with permission from Prashant Malhotra, MD.*)

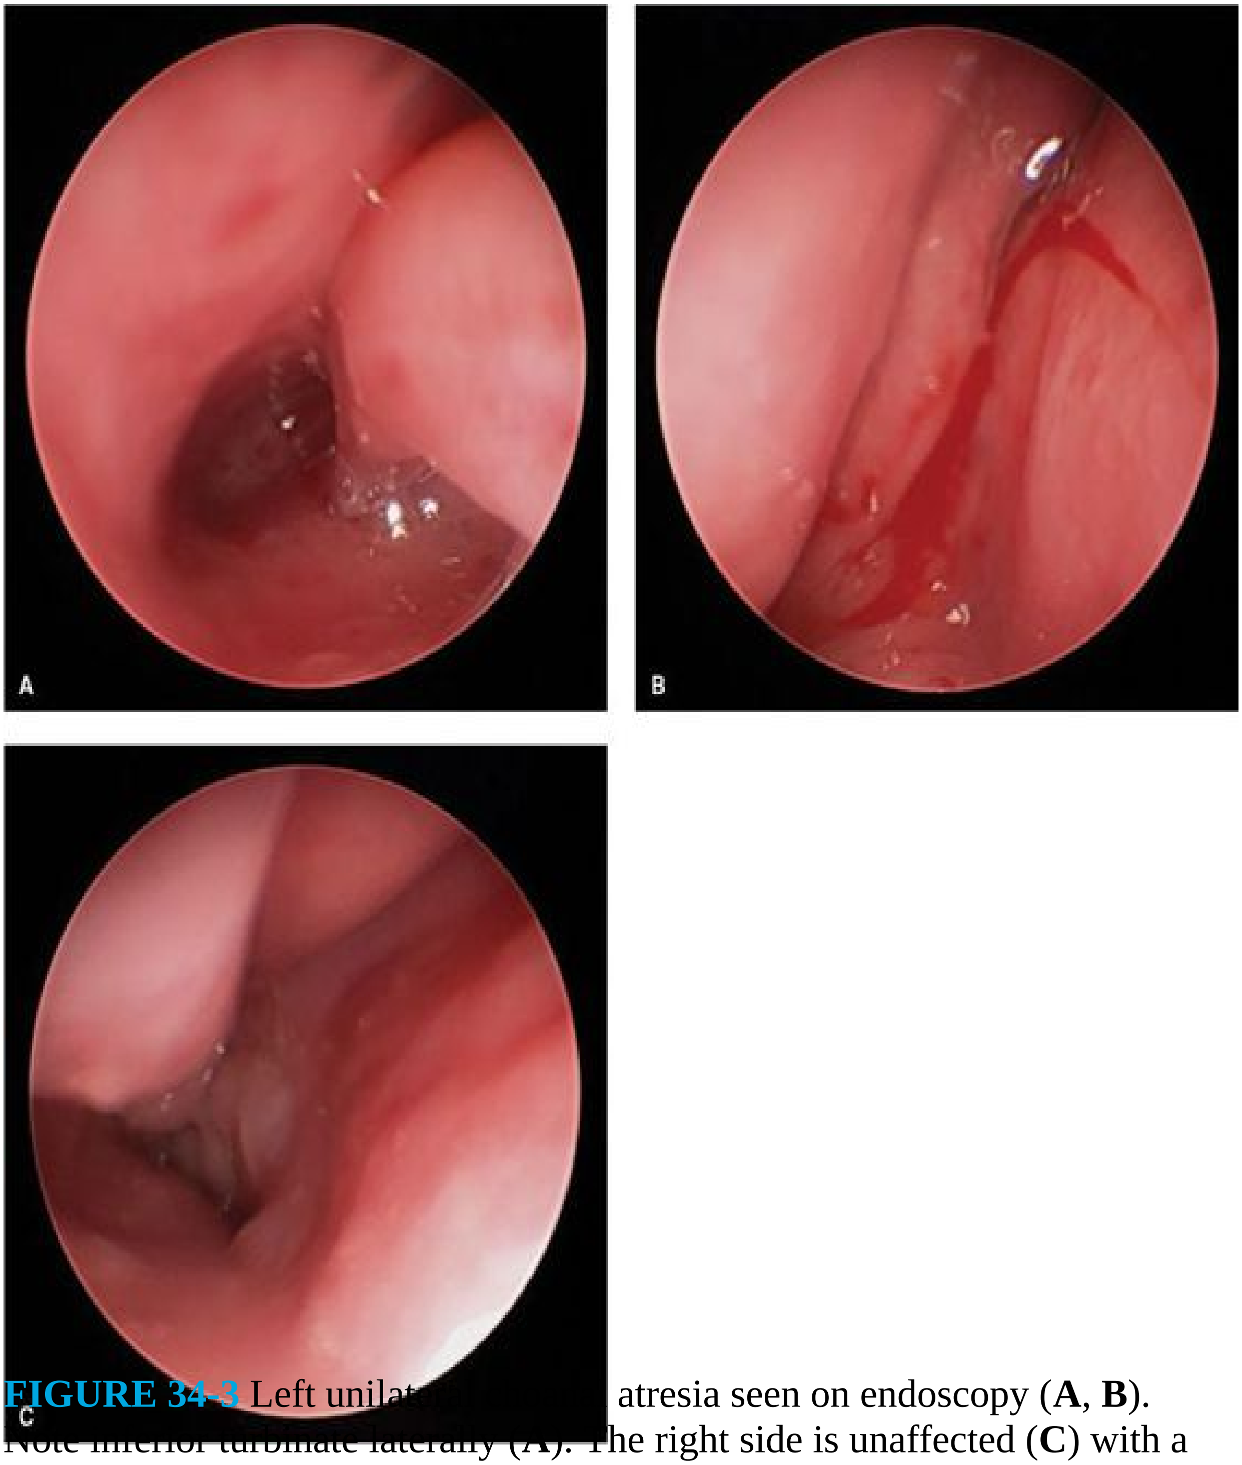

FIGURE 34-3 Left unilat[illegible] atresia seen on endoscopy (**A**, **B**). Note inferior turbinate laterally (**A**). The right side is unaffected (**C**) with a patent choanal opening seen behind the turbinate. (*Used with permission from Prashant Malhotra, MD*.)

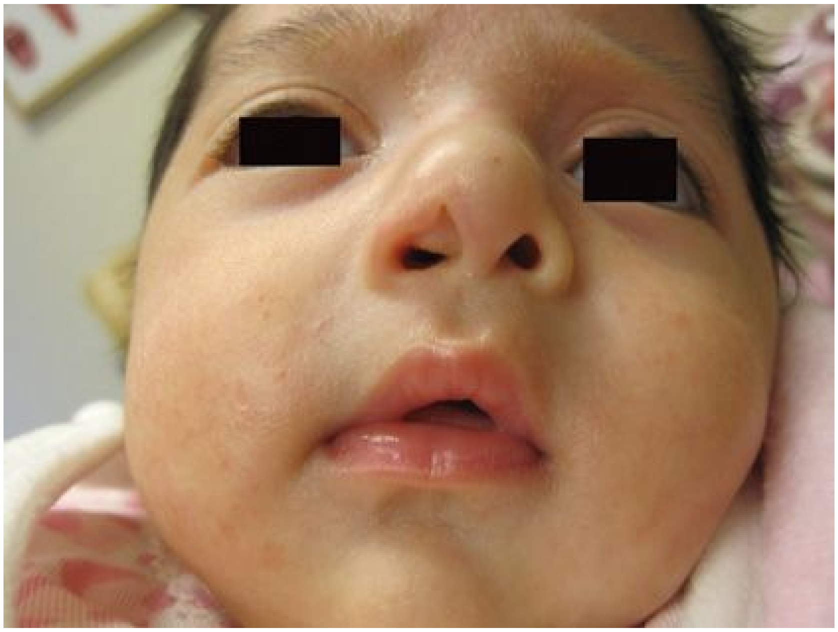

FIGURE 34-4 Predominantly nasal dermoid in an infant causing unilateral nasal obstruction. No intracranial extension was noted. Note the small dimple on nasal tip. (*Used with permission from Prashant Malhotra, MD.*)

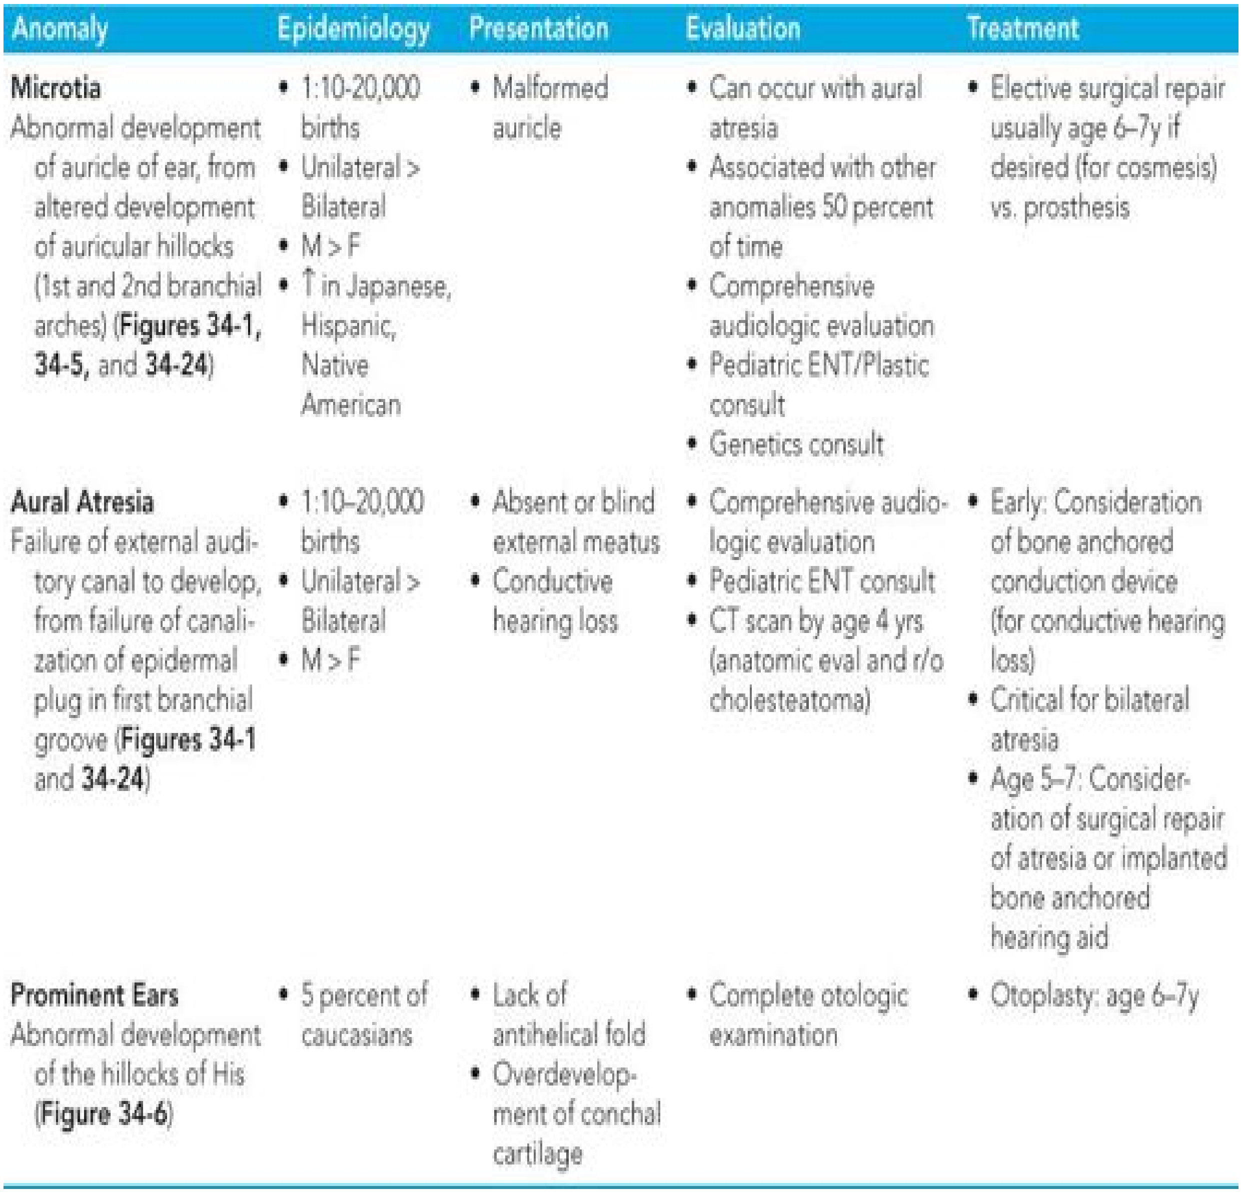
- **Embryology**—At approximately 3 weeks of gestation, the nasal placodes develop as invaginations of neural crest cells from the frontal prominence into nasal pits. These deepen to eventually create medial and lateral nasal prominences. Posteriorly, the nasobuccal membrane forms to separate the nasal and oral cavity. Failure of this membrane to degenerate causes choanal atresia.[2–4]
- The medial nasal prominence will fuse in the midline forming the columella, philtrum, and primary palate. The maxillary prominences fuse in the midline posteriorly creating the secondary palate (posterior to the incisive foramen) and to the medial nasal prominences anteriorly forming the upper lateral lip. Failure of all three fusions to occur (medial nasal prominence to maxillary prominences, left and right, and maxillary prominences in the midline) will create a bilateral complete cleft lip and palate.[2–4]
- Between the superior aspect of the nasal bone and the inferior aspect of the frontal bone there is a transient fontanelle. A pyramidal shaped extension of dura extends inferiorly toward the osseocartilaginous junction of the nasal bridge. This is temporarily congruent with the epidermal elements of

the nasal dorsum and protrudes through the skull base at the foramen cecum. Failure of these layers to separate can cause a variety of midline nasal masses such as dermoids and neurogenic nasal deformities.[3,5]

Congenital Ear Anomalies (**Table 34-2**; **Figures 34-5** and **34-6**)

TABLE 34-2 Congenital Ear Anomalies[6]



Anomaly	Epidemiology	Presentation	Evaluation	Treatment
Microtia Abnormal development of auricle of ear, from altered development of auricular hillocks (1st and 2nd branchial arches) (**Figures 34-1, 34-5,** and **34-24**)	• 1:10-20,000 births • Unilateral > Bilateral • M > F • ↑ in Japanese, Hispanic, Native American	• Malformed auricle	• Can occur with aural atresia • Associated with other anomalies 50 percent of time • Comprehensive audiologic evaluation • Pediatric ENT/Plastic consult • Genetics consult	• Elective surgical repair usually age 6–7y if desired (for cosmesis) vs. prosthesis
Aural Atresia Failure of external auditory canal to develop, from failure of canalization of epidermal plug in first branchial groove (**Figures 34-1** and **34-24**)	• 1:10–20,000 births • Unilateral > Bilateral • M > F	• Absent or blind external meatus • Conductive hearing loss	• Comprehensive audiologic evaluation • Pediatric ENT consult • CT scan by age 4 yrs (anatomic eval and r/o cholesteatoma)	• Early: Consideration of bone anchored conduction device (for conductive hearing loss) • Critical for bilateral atresia • Age 5–7: Consideration of surgical repair of atresia or implanted bone anchored hearing aid
Prominent Ears Abnormal development of the hillocks of His (**Figure 34-6**)	• 5 percent of caucasians	• Lack of antihelical fold • Overdevelopment of conchal cartilage	• Complete otologic examination	• Otoplasty: age 6–7y

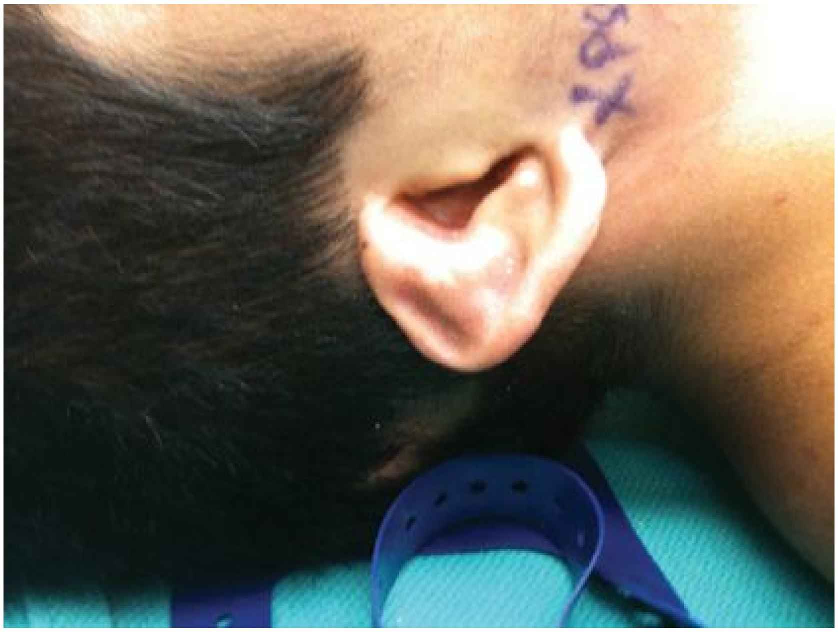


FIGURE 34-5 Microtia (underdeveloped pinna) in a child. (*Used with permission from Prashant Malhotra, MD*.)

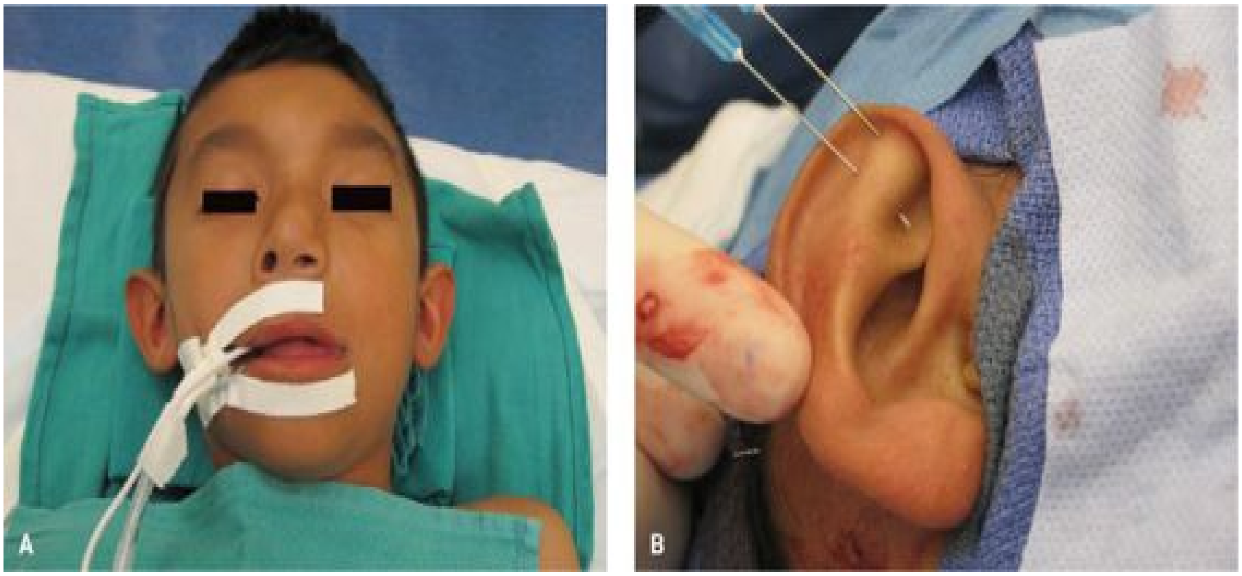

FIGURE 34-6 Prominent, protruding ears (**A**) in a child presenting for elective bilateral otoplasty (**B**). Protrusion typically results from absence of antihelical fold and excessive conchal bowl cartilage. Otoplasty involves intraoperative creation of an antihelical fold, to be secured with sutures. (*Used with permission from Prashant Malhotra, MD*.)

- **Embryology**—The otic placode is present at the third week of gestation. The auricle is derived from the six hillocks of His, from the first and second branchial arches, that are present by the sixth week of gestation. These form the tragus, antitragus, antihelix, helix, lobule, and the helical crus. The hillocks have fused by week 12. Cartilage formation begins in the 7th week of gestation.[6]

Congenital Oral/Oropharyngeal Anomalies (**Table 34-3**; **Figures 34-7** through **34-13**)

TABLE 34-3 Congenital Oral/Oropharyngeal Anomalies[7]

Anomaly	Epidemiology	Presentation	Evaluation	Treatment
Micrognathia Small mandible (**Figures 34-7** and **34-8**)	• Can occur in isolation or as part of syndrome • Pierre Robin Sequence (PRS) occurs in about 1/8,500 births	• Most are asymptomatic, but can present with significant airway obstruction if associated with Pierre-Robin sequence	• Monitor airway • Monitor weight gain • Pediatric ENT and craniofacial surgery consults	• Conservative—prone positioning or nasal airways • Surgical treatment: tongue-lip adhesion, tracheostomy or mandibular distraction osteogenesis
Ankyloglossia Short, fibrous lingual frenulum or a highly attached genioglossus muscle (**Figure 34-9**)	• Incidence 0.04–0.1 percent • Equal female to male ratio	• "Tongue-tie" • Feeding difficulties • Speech articulation difficulties • Tongue cannot contact the hard palate • Cannot protrude more than 1–2 mm past the teeth	• Consider speech therapy evaluation	• Speech therapy • Surgical treatment includes division of the frenulum (timing debated)
Macroglossia Enlargement of the tongue	Associated with: • vascular malformations, • congenital hypothyroidism • Beckwith-Wiedemann syndrome, • Down syndrome	• Difficulty feeding, stridor, airway obstruction • Diffuse enlargement of the tongue	• Consider ultrasound (evaluate floor of mouth for mass)	• Depends on severity • Surgical reduction may be indicated in severe cases.
Lingual thyroid Failure of the thyroid to descend from the foramen cecum[8]	• 1:4–10,000 • Female:Male = 4:1	• Presents in early childhood, adolescence or menopause • Airway obstruction • Pink, firm mass at base of tongue • Dysphagia, dysphonia or dyspnea	• U/S to assess for other areas of ectopic thyroid (In 75% of patients, this is the only functioning gland) • CT, MRI and technetium Tc-99m can also be used • Thyroid function tests; 50 percent of patients will be hypothyroid	• Debated - some authors argue for excision due to malignant potential. • If asymptomatic, may choose to follow clinically • Treat hormone dysfunction medically, as needed

Anomaly	Epidemiology	Presentation	Evaluation	Treatment
Natal Teeth Infant is born with a tooth or teeth[9]	• 1:3000 births	• Neonate will have normal appearing tooth • Function and structure of the tooth may not be normal • Can be either early eruption or supernumerary	• Referral to dentist • Monitor for any oral mucosa or tongue ulceration from the tooth	• Possible extraction if supernumerary or if concern for aspiration from highly mobile tooth
Congenital Epulis Granular cell tumor of the gingiva; benign mesenchymal tumor[9,10] (**Figure 34-10**)	• Female:Male = 8:1 • 5–16 percent exist in multiple sites	• Firm, mucosal covered lesion, more commonly along the maxillary gingival • Airway obstruction • Maxillary to mandibular ratio is 3:1	• CT demonstrates regular, prominent margins without associated bony tissue • Consult to pediatric ENT or oral surgeon	• Surgical excision
Dermoid Cystic lesion of the floor of mouth comprised of skin appendages with a squamous epithelial lining[11] (**Figure 34-11**)	• 7 percent of dermoids occur in the head and neck • 11.5 percent of dermoids in the head and neck are in the floor of mouth	• Midline slow growing mass • Cystic lesion of the floor of the mouth, rarely in the tongue • Can occur superior or inferior to the mylohyoid muscle	• CT scan or ultrasound • Consult pediatric ENT	• Medical management +/– incision and drainage in the setting of an acute infection • 5 percent risk of malignant transformation • Surgical excision

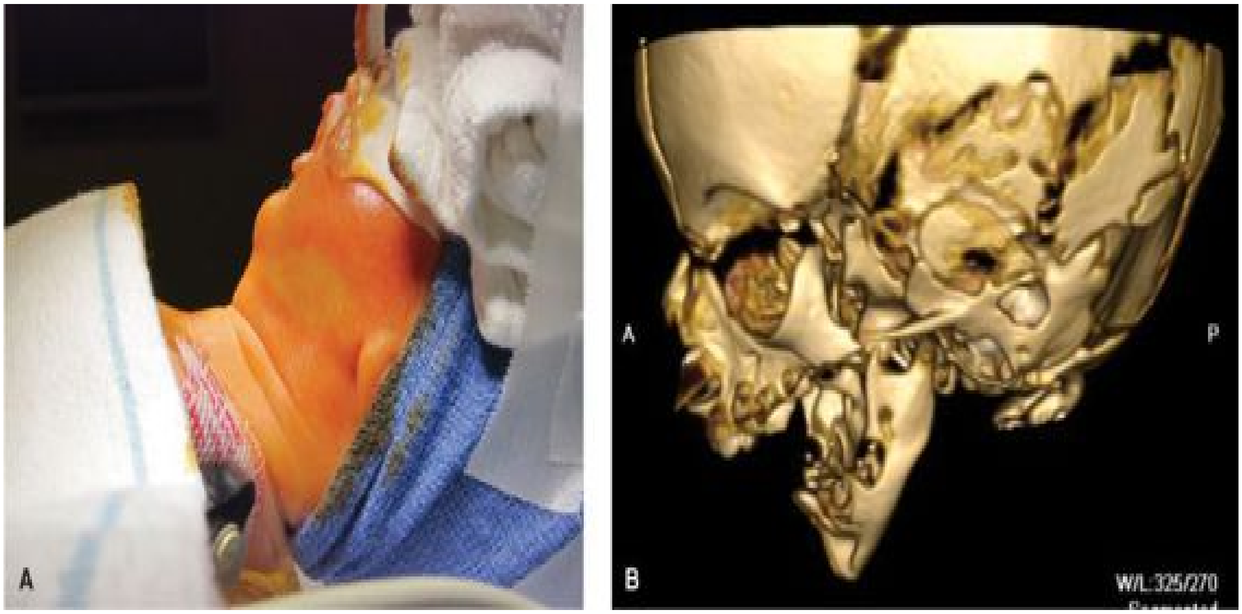

FIGURE 34-7 3 week old infant with severe micrognathia and upper airway obstruction, prior to mandibular distraction, on preoperative, profile view (**A**) and on CT scan with 3D reconstruction (**B**). (*Used with permission from Jonathan Grischkan, MD*)

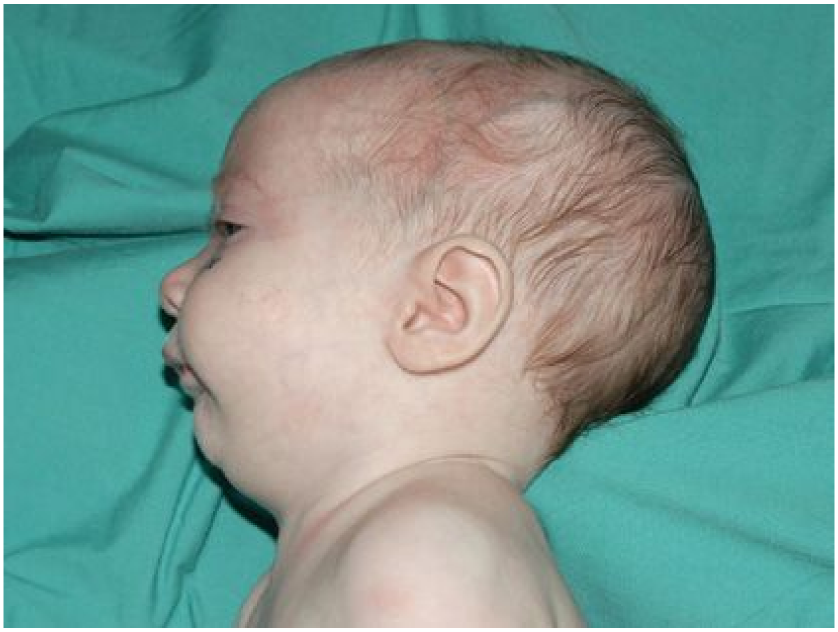

FIGURE 34-8 Micrognathia in an infant, which ultimately required mandibular distraction for persistent respiratory distress and poor growth. (*Used with permission from Prashant Malhotra, MD*.)

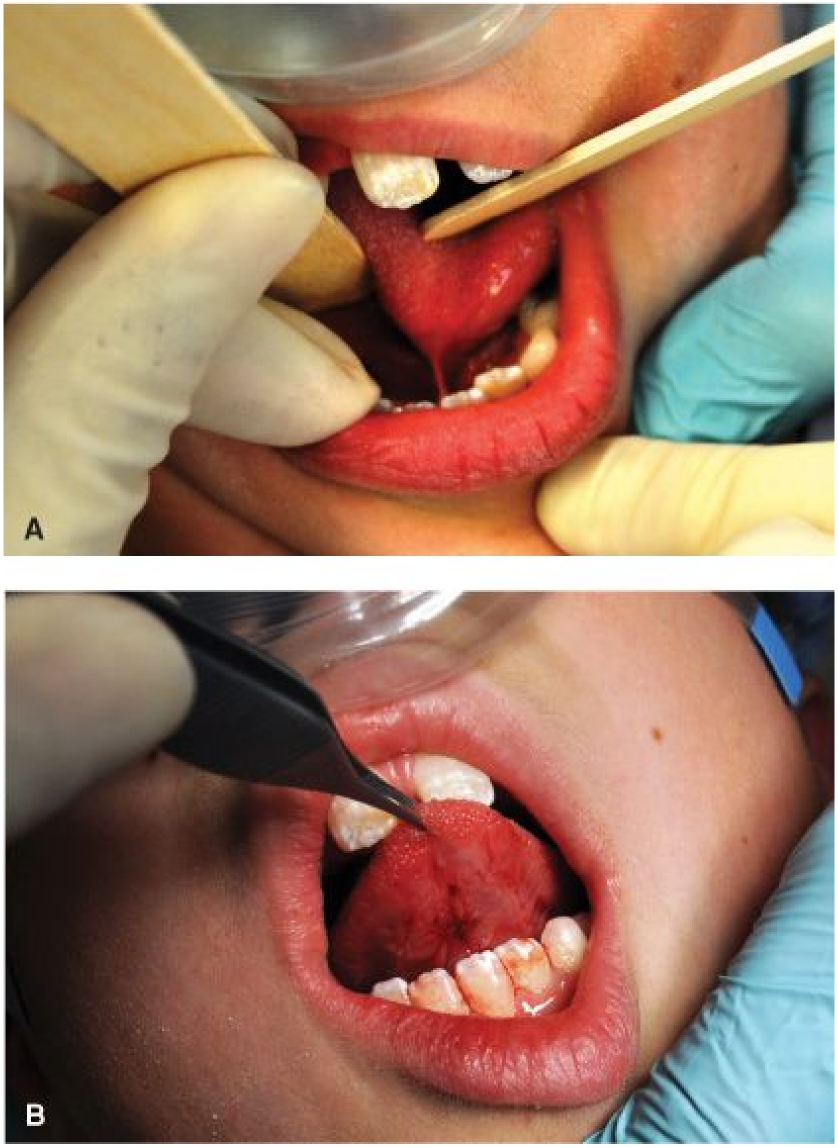

FIGURE 34-9 Ankyloglossia in an 8-year-old boy with speech articulation disorder and membranous ankyloglossia, preoperatively (**A**). Patient was unable to pass tongue tip beyond mandibular teeth. Note the extent of the release after frenuloplasty (**B**). Patient is also able to now protrude tongue tip well past mandibular teeth. (*Used with permission from Prashant Malhotra, MD*.)

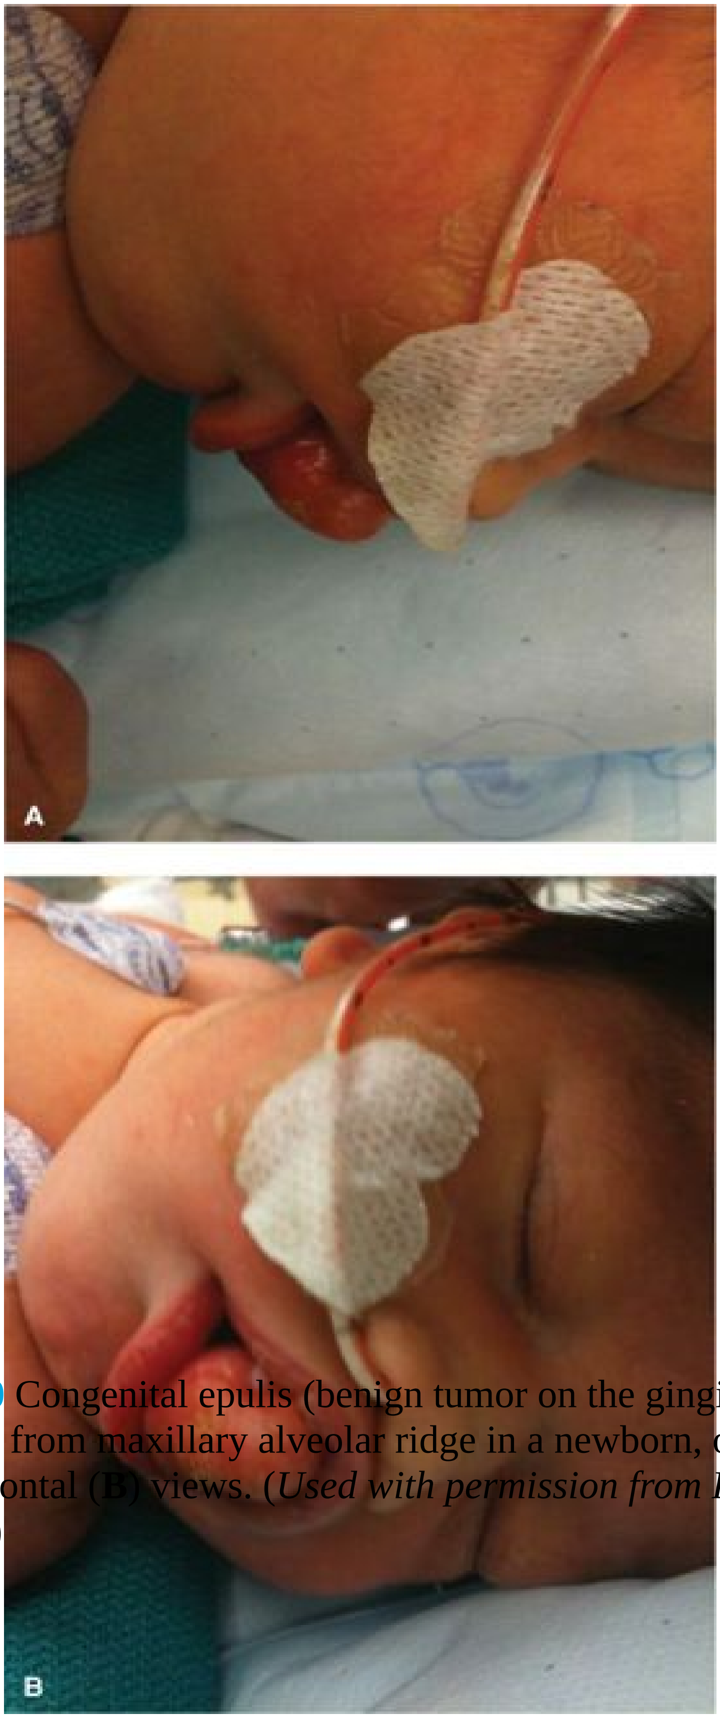

FIGURE 34-10 Congenital epulis (benign tumor on the gingival or alveolar mucosa) arising from maxillary alveolar ridge in a newborn, on lateral (**A**) and primarily frontal (**B**) views. (*Used with permission from Prashant Malhotra, MD*.)

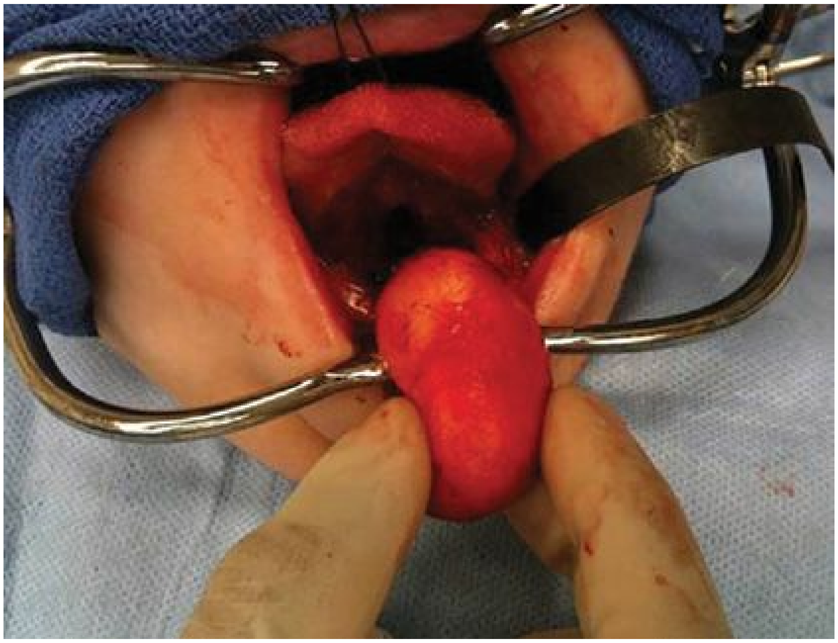

FIGURE 34-11 Oral dermoid cyst in a 2-year-old child being surgically excised from the floor of the mouth. (*Used with permission from Prashant Malhotra, MD.*)

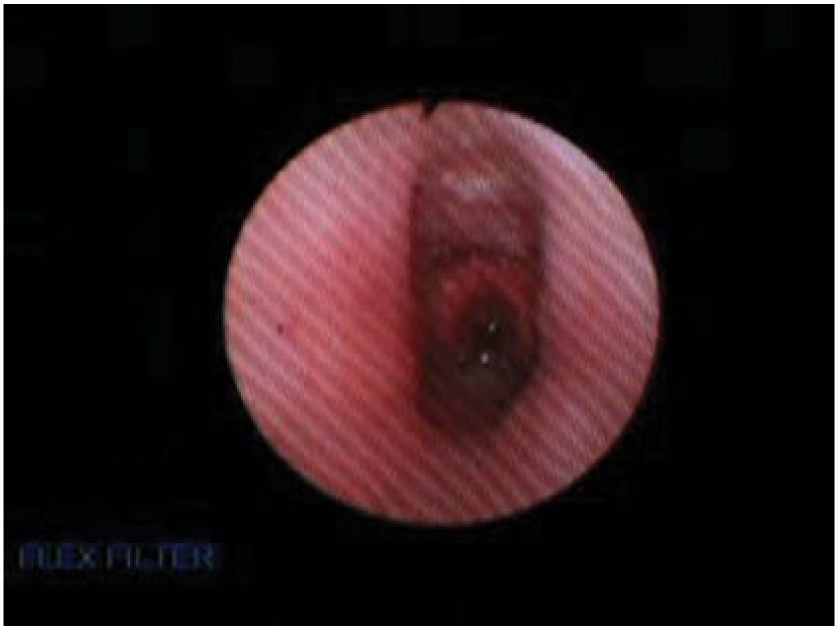

FIGURE 34-12 Naso-oropharyngeal soft tissue stenosis in a young child with Mobius syndrome. Endoscopic view with flexible scope shows narrowed caliber, normal larynx in the distance. (*Used with permission from Prashant Malhotra, MD.*)

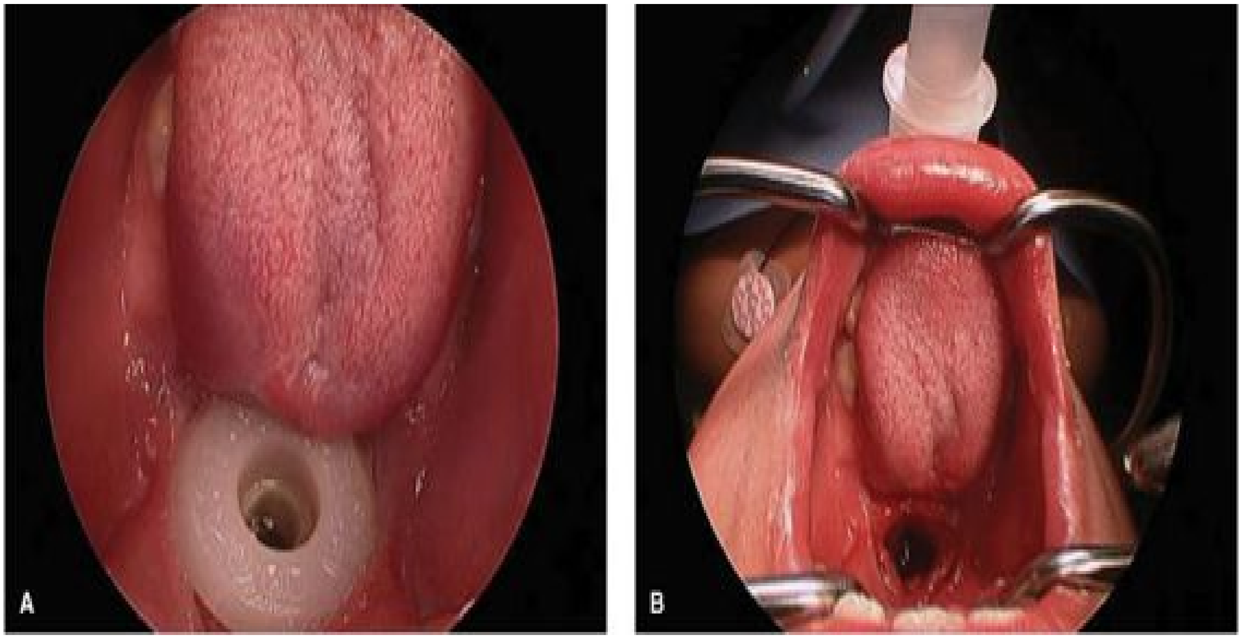

FIGURE 34-13 Pharyngeal aplasia with (**A**) and without (**B**) a stent in place. There was no oropharyngeal opening until created surgically. Oropharyngeal stent in place through surgically created opening. Soft tissue was serially resected/ablated with ultimate restoration of patency. (*Used with permission from Prashant Malhotra, MD*.)

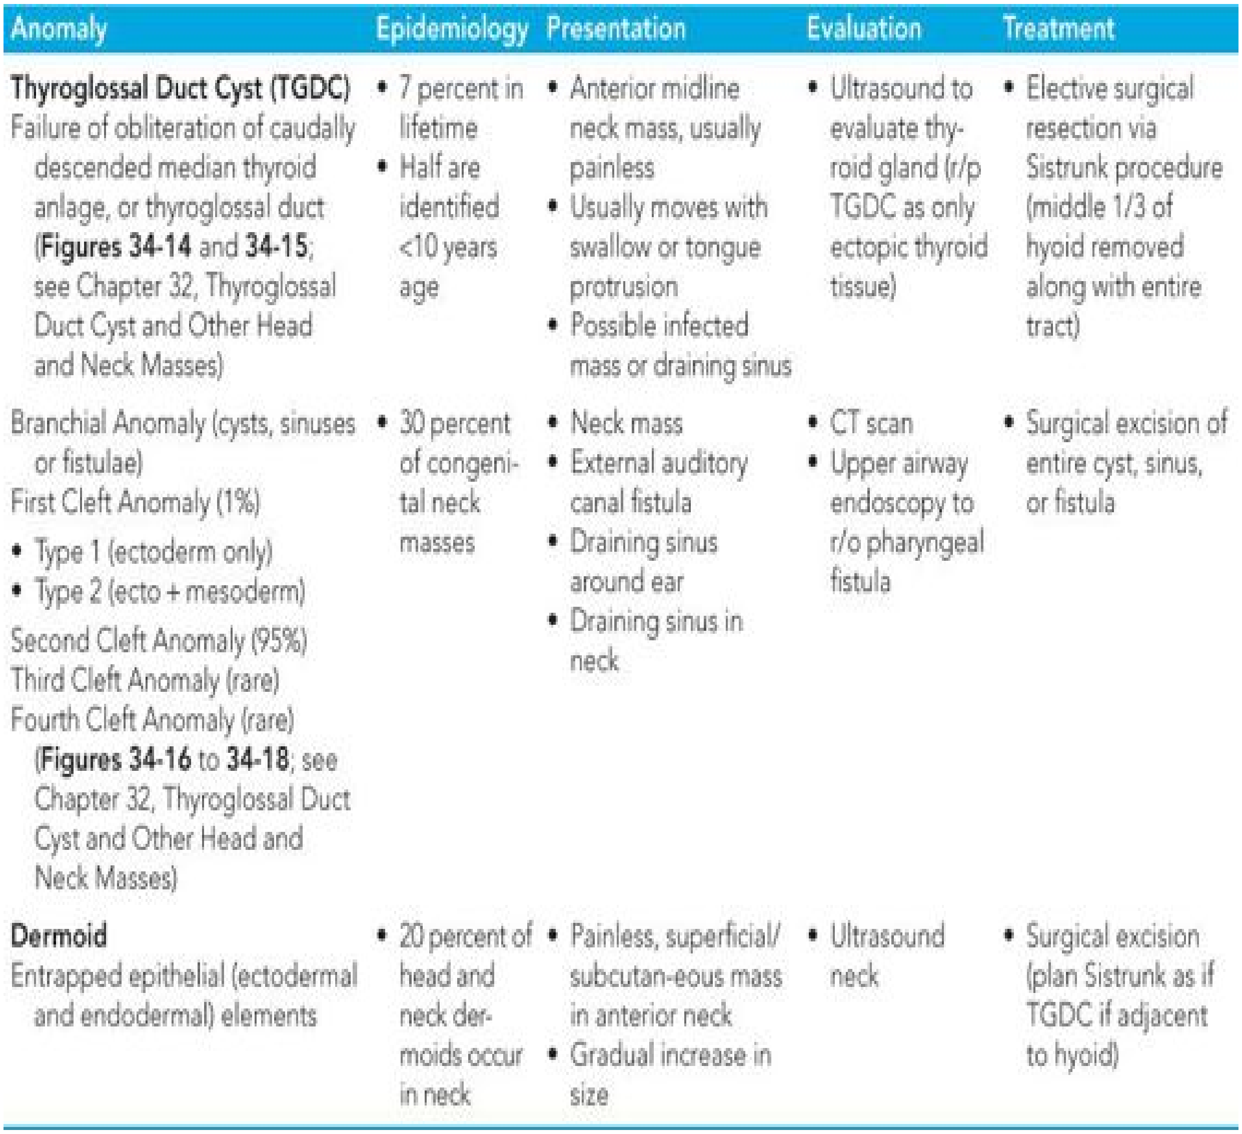
- **Embryology**—The mandible is derived from Meckel's cartilage, which is the lower portion of the first branchial arch. Development takes place from the 4th to 10th week of gestation. The tongue is actually derived from branchial arches 1 to 4 as well as occipital stomites (masses of mesoderm along sides of neural tube). The tongue originally forms in the nasal cavity and as the palatine shelves join in the midline, the tongue is pushed inferiorly into the oral cavity. See the preceding nasal/oral embryology for more detail. In the setting of Pierre Robin Sequence, it is hypothesized that relative macroglossia prevents the palatine shelves of the maxillary prominences from fusing, creating a midline cleft palate.[12]

Congenital Cervical Anomalies (**Table 34-4**; **Figures 34-14** through **34-18**)

TABLE 34-4 Congenital Cervical Anomalies[13]



Anomaly	Epidemiology	Presentation	Evaluation	Treatment
Thyroglossal Duct Cyst (TGDC) Failure of obliteration of caudally descended median thyroid anlage, or thyroglossal duct (**Figures 34-14** and **34-15**; see Chapter 32, Thyroglossal Duct Cyst and Other Head and Neck Masses)	• 7 percent in lifetime • Half are identified <10 years age	• Anterior midline neck mass, usually painless • Usually moves with swallow or tongue protrusion • Possible infected mass or draining sinus	• Ultrasound to evaluate thyroid gland (r/p TGDC as only ectopic thyroid tissue)	• Elective surgical resection via Sistrunk procedure (middle 1/3 of hyoid removed along with entire tract)
Branchial Anomaly (cysts, sinuses or fistulae) First Cleft Anomaly (1%) • Type 1 (ectoderm only) • Type 2 (ecto + mesoderm) Second Cleft Anomaly (95%) Third Cleft Anomaly (rare) Fourth Cleft Anomaly (rare) (**Figures 34-16** to **34-18**; see Chapter 32, Thyroglossal Duct Cyst and Other Head and Neck Masses)	• 30 percent of congenital neck masses	• Neck mass • External auditory canal fistula • Draining sinus around ear • Draining sinus in neck	• CT scan • Upper airway endoscopy to r/o pharyngeal fistula	• Surgical excision of entire cyst, sinus, or fistula
Dermoid Entrapped epithelial (ectodermal and endodermal) elements	• 20 percent of head and neck dermoids occur in neck	• Painless, superficial/subcutan-eous mass in anterior neck • Gradual increase in size	• Ultrasound neck	• Surgical excision (plan Sistrunk as if TGDC if adjacent to hyoid)

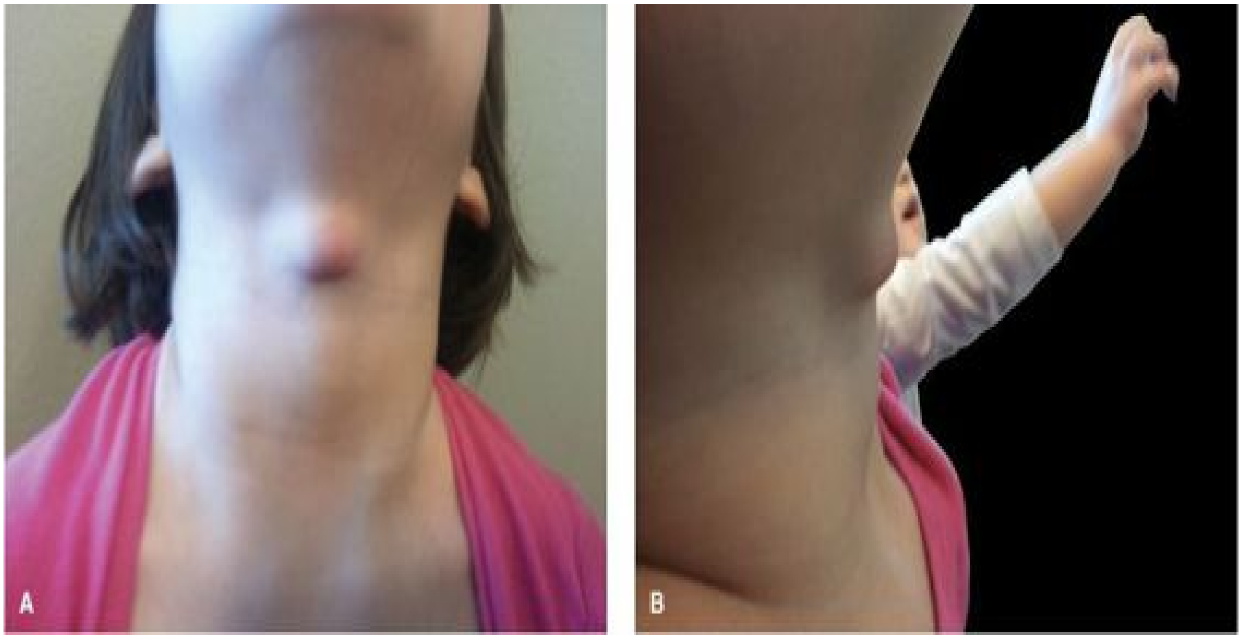


FIGURE 34-14 Thyroglossal duct cyst in a 2-year-old girl, as seen on frontal (**A**) and lateral (**B**) views. (*Used with permission from Prashant Malhotra, MD*.)

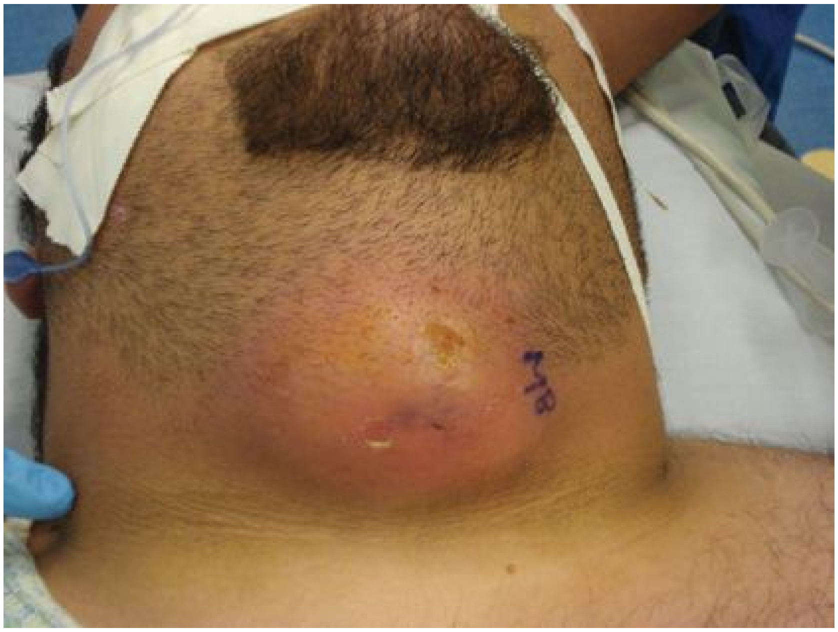

FIGURE 34-15 Acutely infected thyroglossal duct cyst in a teenager. This required incision and drainage prior to definitive Sistrunk procedure (excision of cyst with tract and middle third of hyoid bone). (*Used with permission from Prashant Malhotra, MD*.)

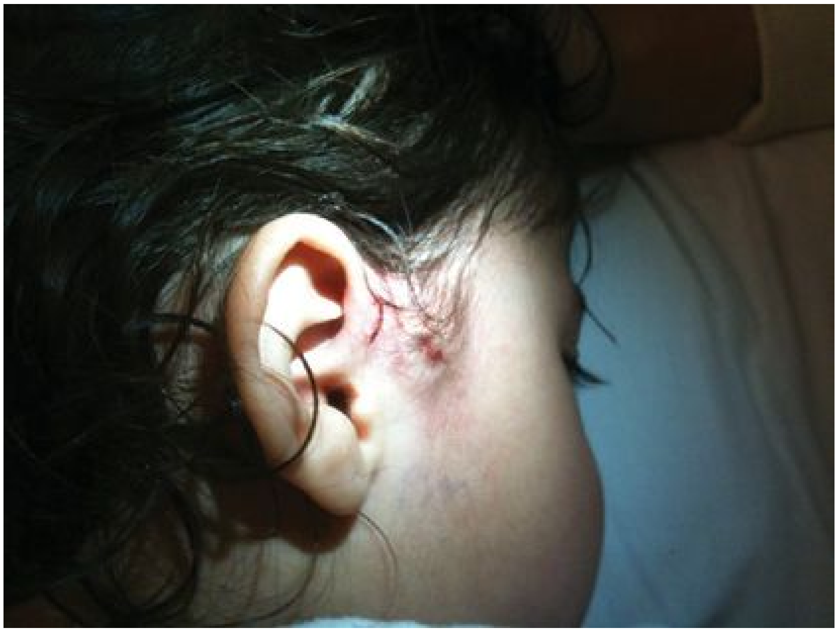

FIGURE 34-16 Infected right preauricular sinus with abscess in a young girl. (*Used with permission from Prashant Malhotra, MD.*)

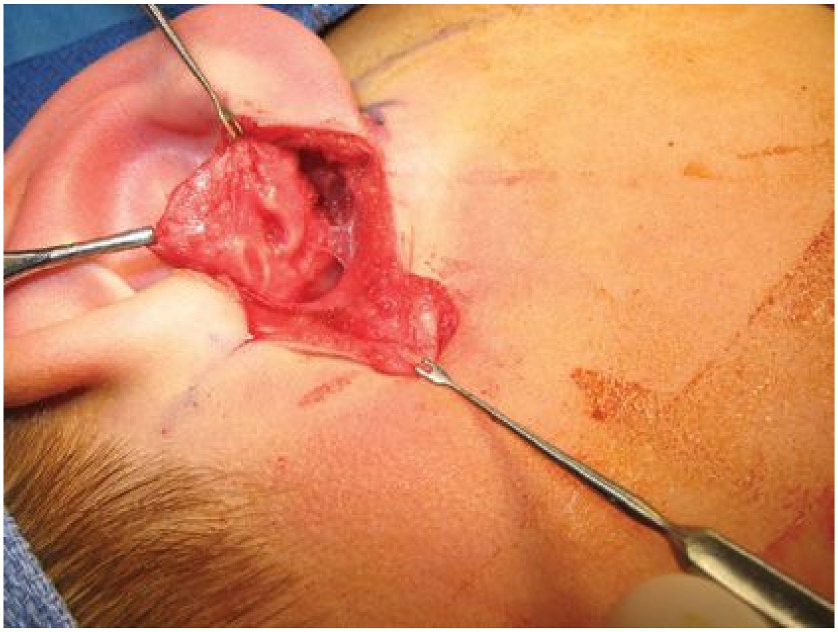

FIGURE 34-17 First Branchial Anomaly. Intraoperative view of Type 1 first branchial anomaly with duplicated cartilage and sinus. This was excised along with small cyst and external canal reconstructed. (*Used with permission from Prashant Malhotra, MD.*)

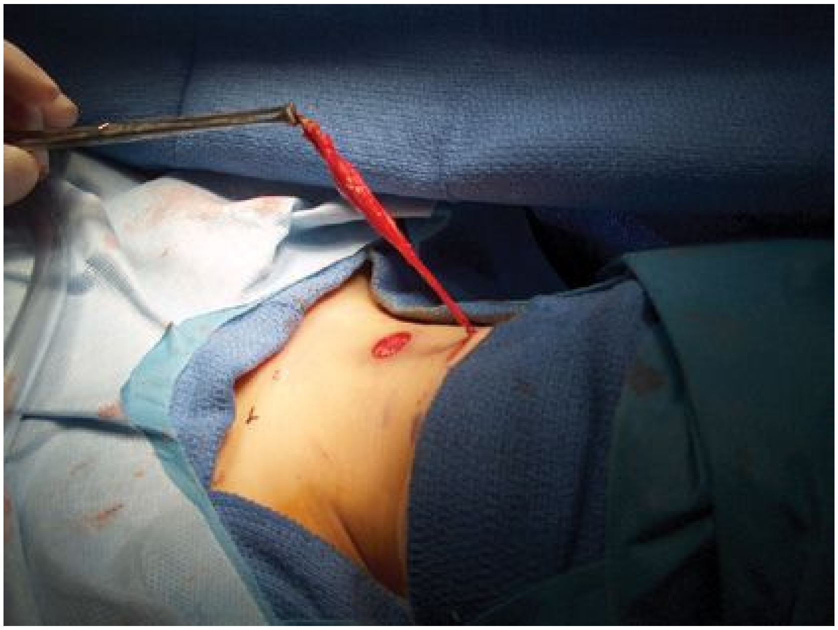

FIGURE 34-18 Stairstepping horizontal incisions demonstrate characteristic tract of 2nd branchial anomaly as it traverses between the carotid bifurcation, superficial to CN IX and toward the tonsillar fossa. (*Used with permission from Prashant Malhotra, MD*.)

- **Embryology**—The thyroid gland forms from a diverticulum arising between the anterior 2/3 and posterior 1/3 muscle tongue. This descends caudally, anterior to the hyoid, and fuses with fourth and fifth branchial pouches to form the thyroid.[13] The branchial arches are responsible for much of the musculoskeletal and neural development of the head and neck. Branchial anomalies result from incomplete obliteration of the clefts and pouches, and are classified by the cleft or pouch of origin. The origin affects the location of associated fistulae and relationship to nerves, arteries, and muscles. This has clear relevance for surgical resection. Branchio-oto-renal syndrome is a classic example of a genetic cause for congenital branchial arch abnormalities.
- Branchial anomalies can present as cysts, sinuses, or fistulae. Cysts have no external opening, sinuses open to the skin, and fistulae have a skin opening and an opening into the pharynx.

Other Anomalies and Syndromes

- **Cleft lip/palate**—Orofacial clefting occurs in approximately 1/700 live births with a higher prevalence in Native Americans and Asians, and a lower prevalence in African Americans. It is the second most common birth deformity (second to club foot) and 2/3 of these children have other associated abnormalities.[14] Cleft lip is associated with cleft palate in 68 to 86 percent of cases and a unilateral cleft is more common than bilateral.[4] Management is best orchestrated in the context of a multidisciplinary Cleft-Craniofacial team (**Figures 34-19** and **34-20**).

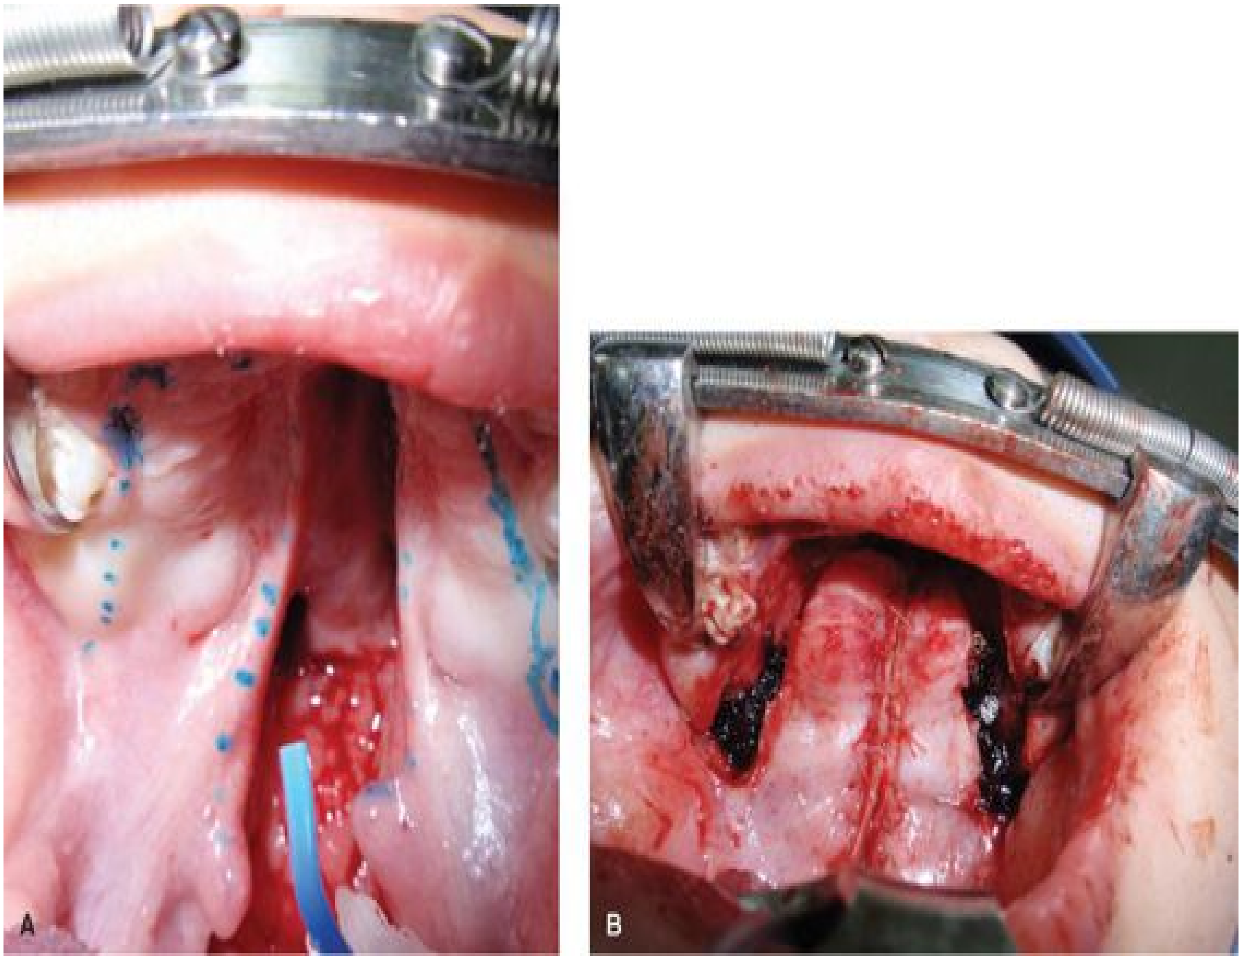

FIGURE 34-19 Cleft palate as seen intraoperatively prior to repair (**A**) and immediately after repair (**B**). (*Used with permission from Prashant Malhotra, MD.*)

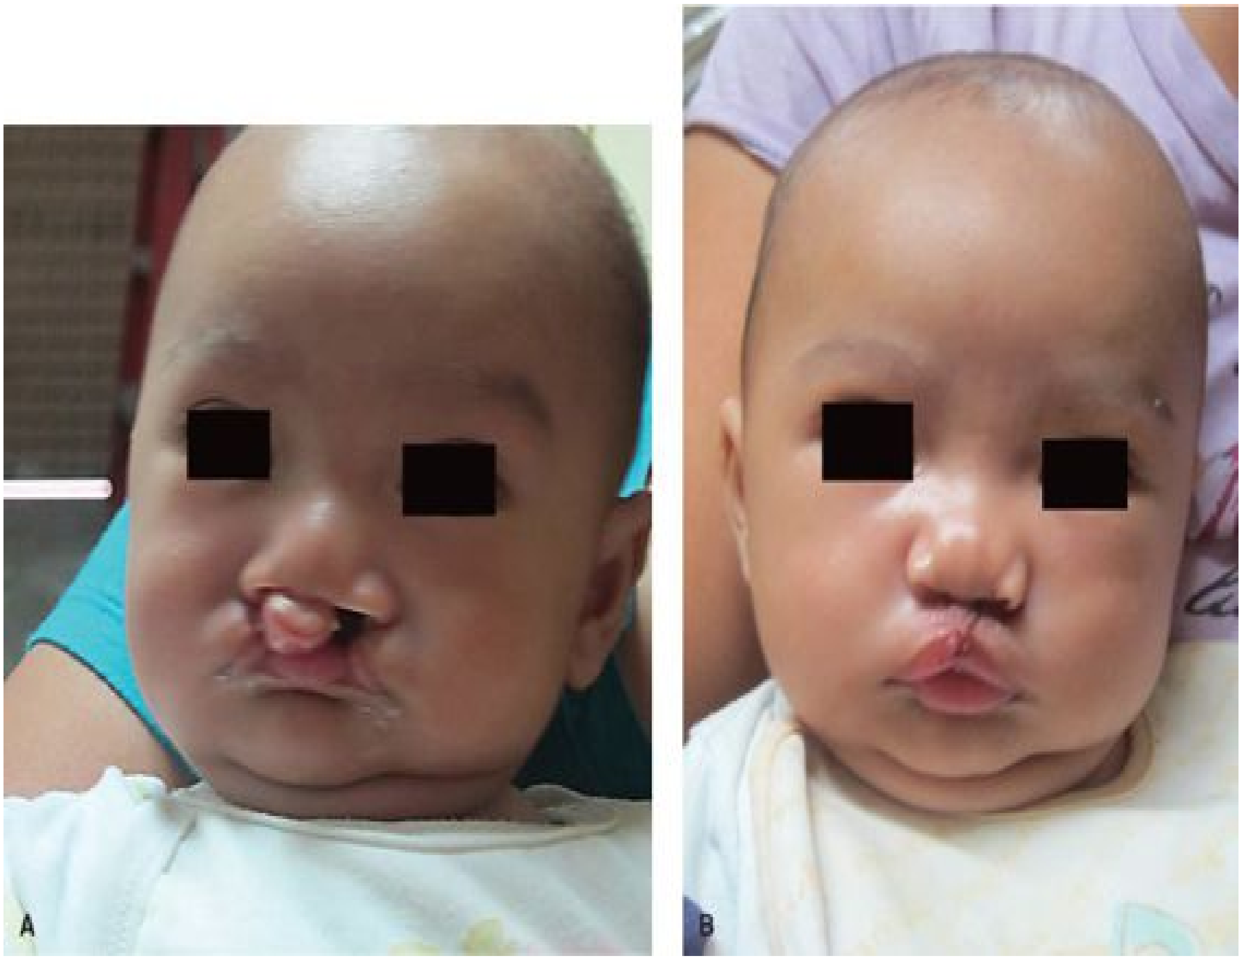

FIGURE 34-20 Bilateral cleft lip with prominent premaxilla, prior to repair (**A**) and 1 week after repair (**B**). (*Used with permission from Prashant Malhotra, MD.*)

- **Vascular anomalies**—These include vascular tumors such as hemangiomas as well as malformations such as capillary and venous malformations, arteriovenous malformations (AVM), and lymphatic malformations. Other than focal hemangiomas, they are best managed by a multidisciplinary vascular anomalies team, consisting of dermatology, plastic surgery, otolaryngology, radiology, and other specialists. A brief discussion follows for selected lesions.
  - Hemangiomas: These common benign neoplasms are composed of proliferating endothelial type cells, and affect the head and neck in 60 percent of cases. They typically develop after birth and have a characteristic proliferate phase, plateau phase, and subsequent involutional phase. They have varied presentations and treatment is

individually tailored. If they have no complications (ulceration or bleeding) or a threat to function (vision, airway, cosmesis, etc.), they may be observed. First line medical therapy previously consisted of systemic corticosteroids, but the use of propranolol has supplanted this. Surgery has a role for aggressive proliferative or function threatening lesions, or after incomplete involution.[15]

- Venous Malformations (VMs)—VMs are benign malformations made up of ectatic veins. They differ from hemangiomas, as they are present at birth, grow proportionally with the child, and are not proliferative lesions. MRI can help confirm diagnosis and determine extent of lesion. They are low-flow lesions that are isointense to muscle on T1-weighted images and enhance brightly on T2. Conservative management, injection sclerotherapy, and laser therapy are usually first line options, with surgery reserved for persistent symptomatic disease (**Figure 34-21**).[16]

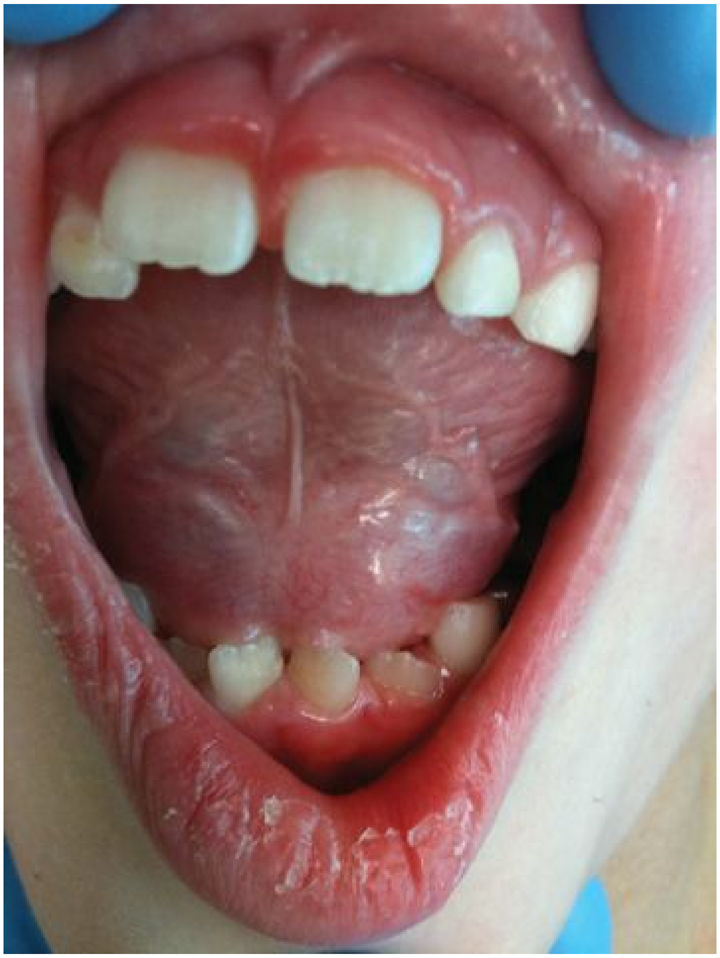

FIGURE 34-21 Venolymphatic Malformation in a 10-year-old with bilateral, symmetric, floor of mouth fullness. Imaging and pathology after excision demonstrated combined venous and lymphatic (venolymphatic) malformation. (*Used with permission from Prashant Malhotra, MD*.)

- Lymphatic Malformations (LMs, previously known as cystic hygroma or lymphangioma)—These are rare vascular anomalies, common in the head and neck, from aberrant formation of peripheral lymphatic vessels or fusion with venous structures, occurring in 1 to 4/10,000 births. They are categorized as macrocystic, microcystic, or combined lesions depending on the size of the fluid filled compartments. They present as asymptomatic masses or with functional difficulties such as dysphagia or airway difficulties. MRI is imaging modality of choice, typically with low signal intensity on T1-weighted images, high signal intensity with well demarcated margins on T2-weighted images. LMs may be identified on antenatal ultrasound and appropriate airway planning should be anticipated. LMs are difficult to treat. Medical therapy with antibiotics and anti-inflammatory may be used if they acutely worsen. Definitive treatment varies based on de Serres staging, affected site and type of lesion, and is individualized. Observation, surgery, and injection sclerotherapy are options for macrocystic lesions. These same options exist for microcystic lesions, which are more difficult to treat (**Figures 34-22** and **34-23**).[17]

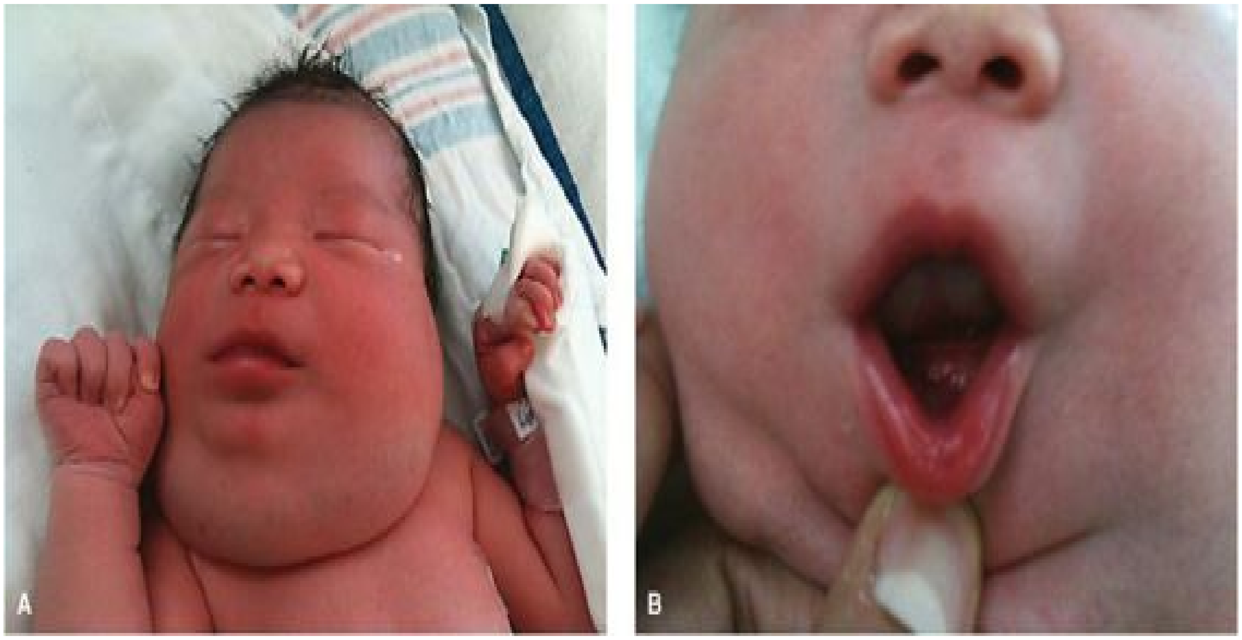

FIGURE 34-22 Massive Lymphatic Malformation (LM) in a 1-day-old newborn involving suprahyoid and infrahyoid spaces, floor of mouth, tongue, pharynx, supraglottic larynx, and into mediastinum (**A**). LM was combined microcystic and macrocystic. Note the tense floor of mouth and tongue involvement (**B**), with mouth pushed upwards to palate. (*Used with permission from Prashant Malhotra, MD*.)

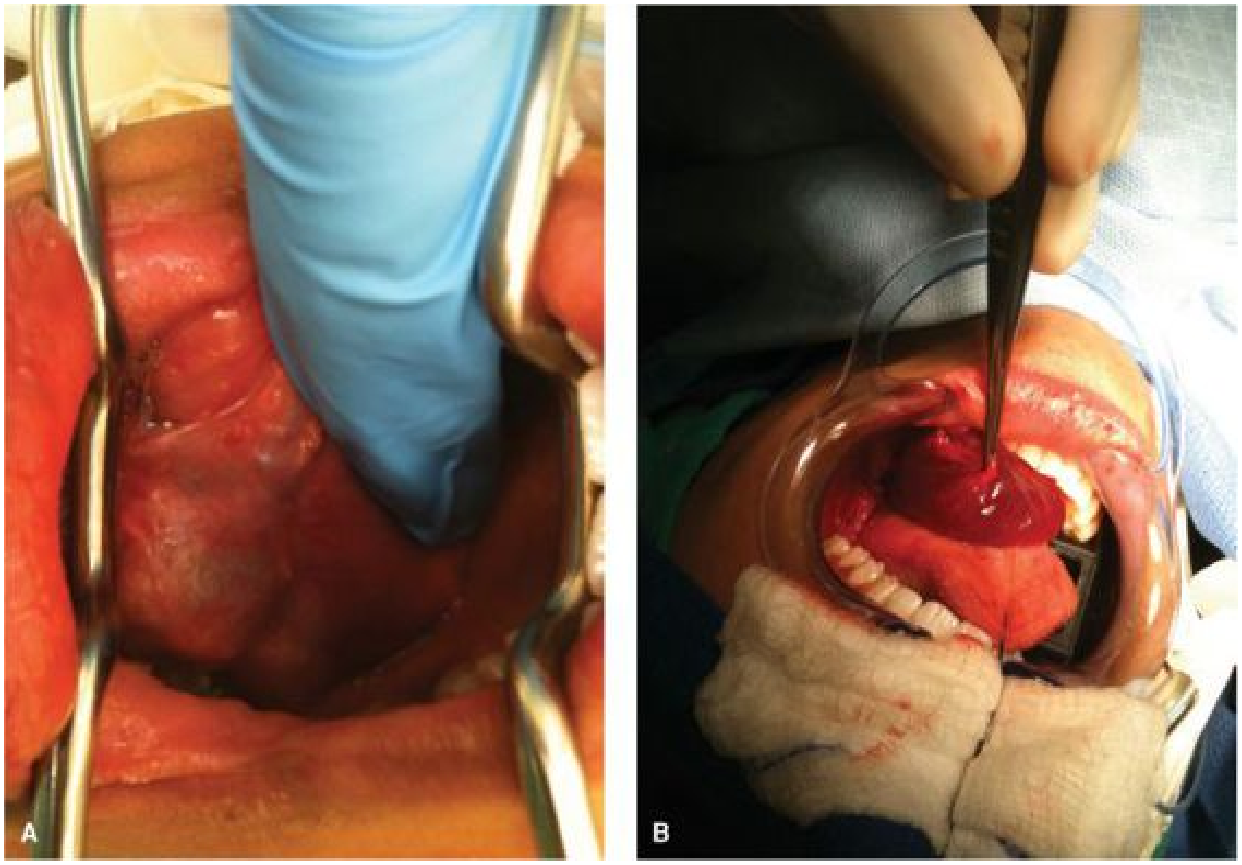

FIGURE 34-23 Lymphatic malformation on the right floor of mouth in a 10-year-old child (**A**). Tongue is pushed to the right to expose left lateral tongue and floor of mouth. Note bluish discoloration. Intraoperative view (**B**) of well circumscribed macrocystic LM. (*Used with permission from Prashant Malhotra, MD*.)

- **Syndromic associated anomalies**—Congenital anomalies of the head and neck can be associated with numerous genetic abnormalities and syndromes (**Figures 34-1** and **34-24**). (**Table 34-5**) lists some of those, which are more commonly encountered. Head and neck, other findings, and the causes are listed.

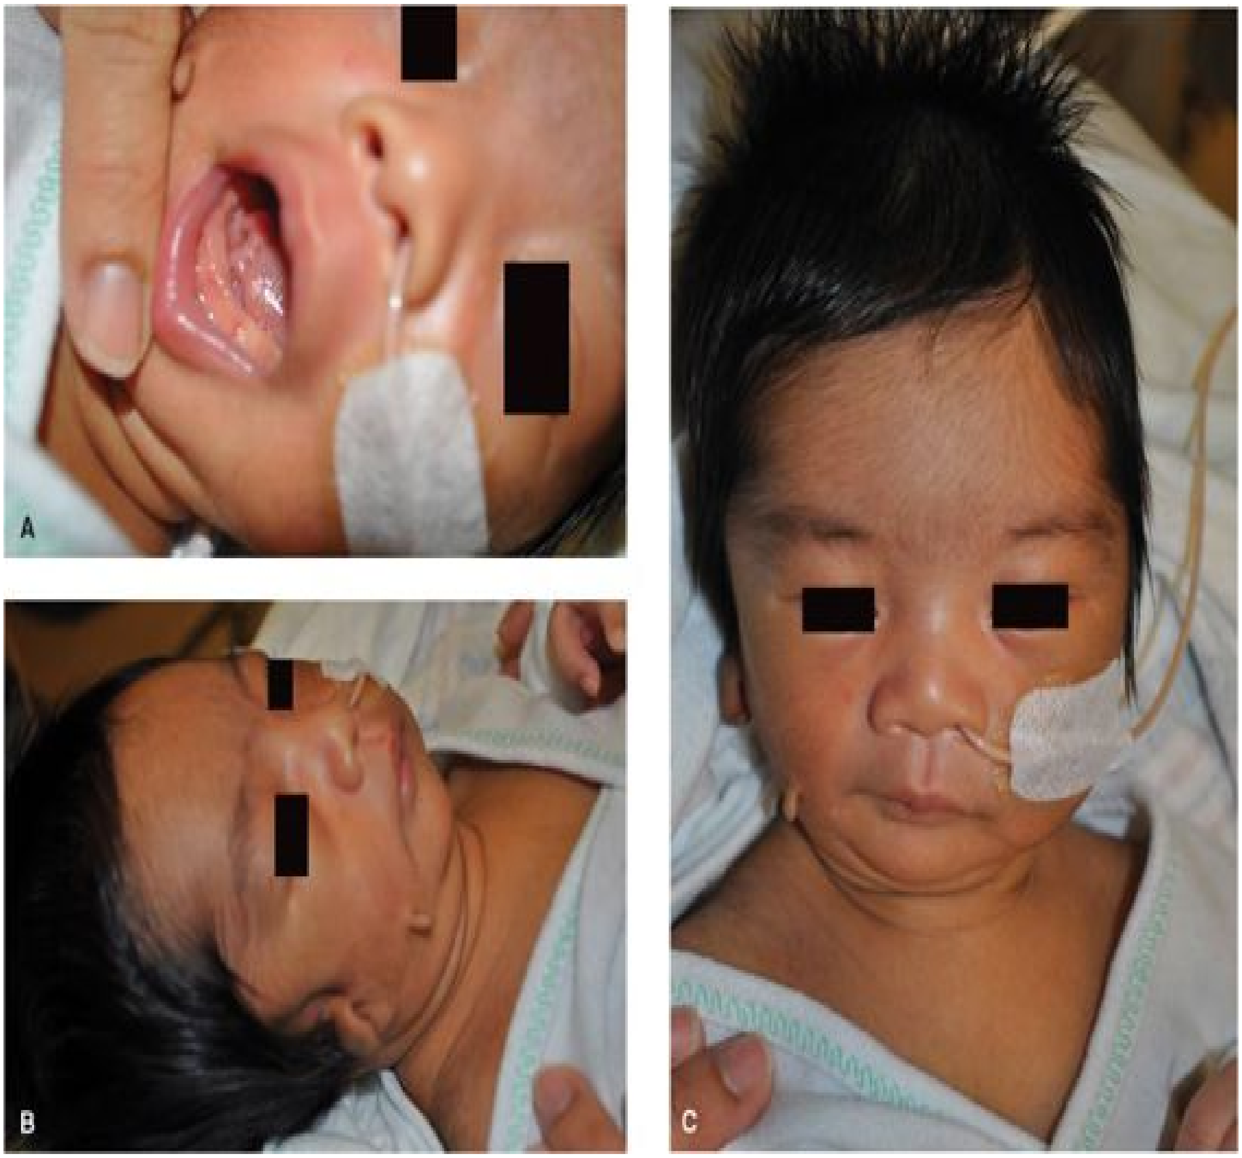

FIGURE 34-24 Hypoplastic right hemi-tongue in an infant with oculoauricularvertebral spectrum (OAVS or Goldenhar syndrome) on superior (**A**), lateral/oblique (**B**) and frontal (**C**) views. Note microtia (underdeveloped pinna), aural atresia, accessory skin tag, along with mastoid tip, malar, maxillary and mandibular hypoplasia (hemifacial microsomia) in views B and C. (*Used with permission from Prashant Malhotra, MD.*)

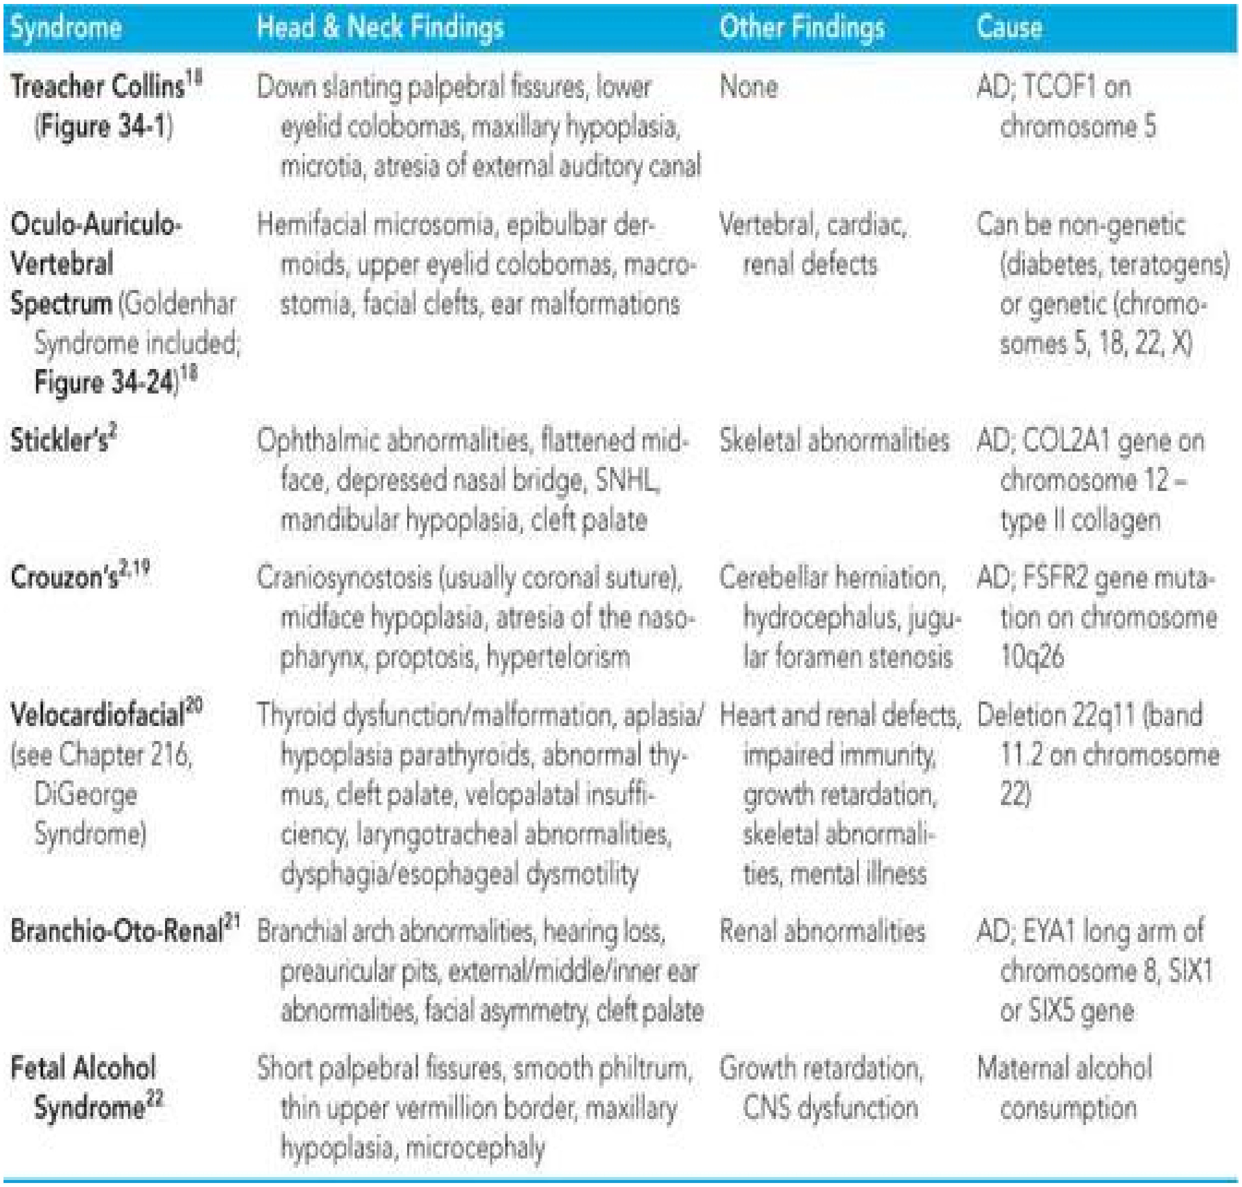
TABLE 34-5 Syndromes Associated with Head and Neck Findings



Syndrome	Head & Neck Findings	Other Findings	Cause
Treacher Collins[18] (**Figure 34-1**)	Down slanting palpebral fissures, lower eyelid colobomas, maxillary hypoplasia, microtia, atresia of external auditory canal	None	AD; TCOF1 on chromosome 5
Oculo-Auriculo-Vertebral Spectrum (Goldenhar Syndrome included; **Figure 34-24**)[18]	Hemifacial microsomia, epibulbar dermoids, upper eyelid colobomas, macrostomia, facial clefts, ear malformations	Vertebral, cardiac, renal defects	Can be non-genetic (diabetes, teratogens) or genetic (chromosomes 5, 18, 22, X)
Stickler's[2]	Ophthalmic abnormalities, flattened midface, depressed nasal bridge, SNHL, mandibular hypoplasia, cleft palate	Skeletal abnormalities	AD; COL2A1 gene on chromosome 12 – type II collagen
Crouzon's[2,19]	Craniosynostosis (usually coronal suture), midface hypoplasia, atresia of the nasopharynx, proptosis, hypertelorism	Cerebellar herniation, hydrocephalus, jugular foramen stenosis	AD; FSFR2 gene mutation on chromosome 10q26
Velocardiofacial[20] (see Chapter 216, DiGeorge Syndrome)	Thyroid dysfunction/malformation, aplasia/hypoplasia parathyroids, abnormal thymus, cleft palate, velopalatal insufficiency, laryngotracheal abnormalities, dysphagia/esophageal dysmotility	Heart and renal defects, impaired immunity, growth retardation, skeletal abnormalities, mental illness	Deletion 22q11 (band 11.2 on chromosome 22)
Branchio-Oto-Renal[21]	Branchial arch abnormalities, hearing loss, preauricular pits, external/middle/inner ear abnormalities, facial asymmetry, cleft palate	Renal abnormalities	AD; EYA1 long arm of chromosome 8, SIX1 or SIX5 gene
Fetal Alcohol Syndrome[22]	Short palpebral fissures, smooth philtrum, thin upper vermillion border, maxillary hypoplasia, microcephaly	Growth retardation, CNS dysfunction	Maternal alcohol consumption

35 GEOGRAPHIC TONGUE

Ernest Valdez, DDS
Richard P. Usatine, MD
Wanda C. Gonsalves, MD

PATIENT STORIES

A 4-year-old girl is brought to the pediatrician’s office because the mother is concerned about her child’s tongue having a “strange appearance.” She denies pain or discomfort and is unsure how long the lesions have been present. The lesions seem to change areas of distribution on the tongue. The examination reveals large, well-delineated, shiny and smooth, erythematous spots on the surface of the tongue (**Figure 35-1**). The diagnosis is geographic tongue (benign migratory glossitis). The physician explains that it is benign and that no treatment is needed unless symptoms develop.

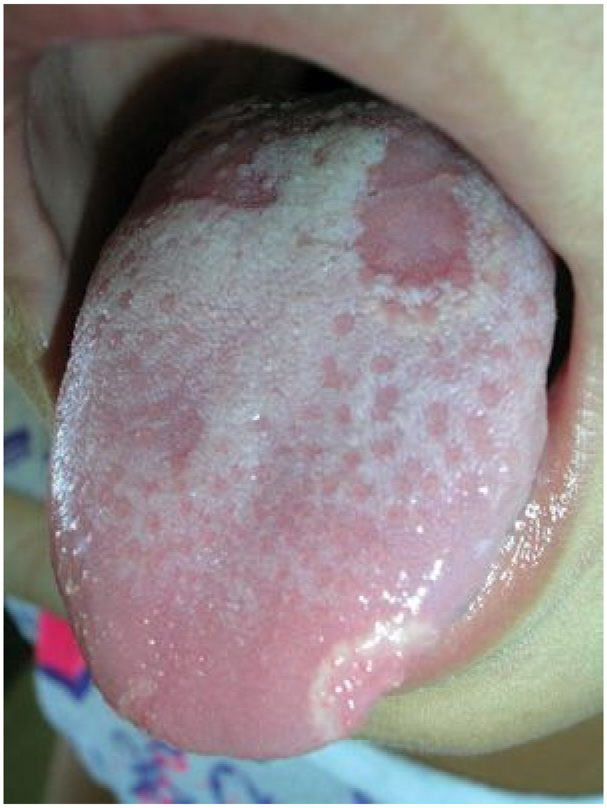

FIGURE 35-1 Geographic tongue (benign migratory glossitis) in a 4-year-old girl. Note the pink continent among the white ocean. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Geographic tongue is a recurrent, benign, usually asymptomatic, inflammatory disorder of the mucosa of the dorsum and lateral borders of the tongue. Geographic tongue is characterized by circinate, irregularly shaped erythematous patches bordered by a white keratotic band. The central erythematous patch represents loss of filiform papillae of tongue epithelium. Geographic tongue can, although rarely, present as symptomatic.

SYNONYMS

Benign migratory glossitis or geographic stomatitis.

EPIDEMIOLOGY

- Geographic tongue has an estimated prevalence of 1 to 3 percent of the population.[1]
- It may occur in either children or adults and exhibits a female predilection.
- Geographic tongue in the US has a greater prevalence among white and black persons than among Mexican Americans.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Geographic tongue is a common oral inflammatory condition of unknown etiology.
- Some studies have shown an increased frequency in patients with allergies, pustular psoriasis, stress, type 1 diabetes, fissured tongue, and hormonal disturbances.[3]
- Histopathologic appearance resembles psoriasis.[4]

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis is made by visual inspection and history of the lesion. The lesions are suggestive of a geographic map (hence geographic tongue) with pink continents surrounded by whiter oceans (**Figure 35-1**).

- Geographic tongue consists of large, well-delineated, shiny, and smooth, erythematous patches surrounded by a white halo (**Figure 35-2**).

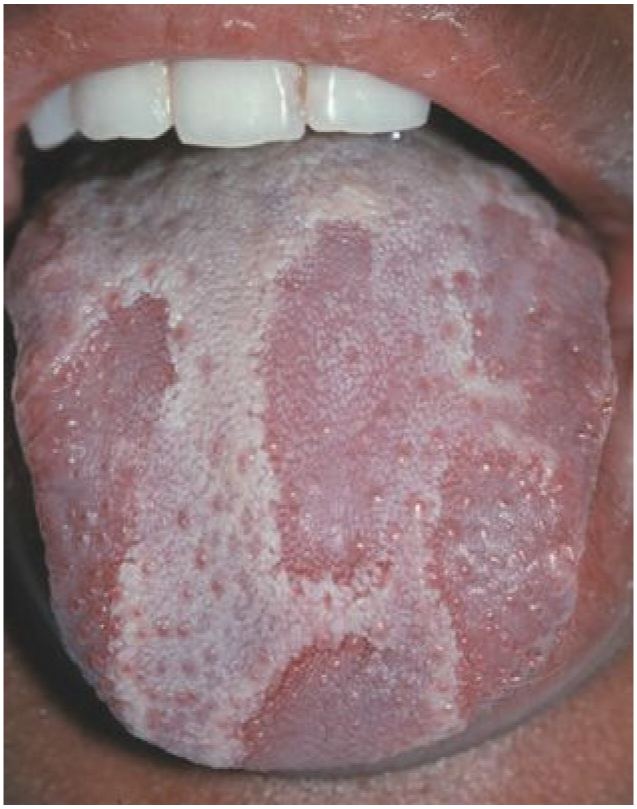

FIGURE 35-2 Geographic tongue (benign migratory glossitis). Note the pink continents among the white oceans. (*Reprinted with permission from Gonsalves WC, Chi AC, Neville BW. Common oral lesions: part II. Am Fam Phys 2007;75(4):501-508. Copyright © 2007 American Academy of Family Physicians. All rights reserved*.)

- Tongue lesions exhibit central erythema because of atrophy of the filiform papillae and are usually surrounded by slightly elevated, curving, white-to-yellow elevated borders (**Figures 35-1** and **35-2**).
- The condition typically waxes and wanes over time so the lesions appear to be migrating (hence migratory glossitis).
- Lesions may last days, months, or years. The lesions do not scar.

- Most patients are asymptomatic, but some patients may complain of pain or burning, especially when eating spicy foods.
- Suspect systemic intraoral manifestations of psoriasis or reactive arthritis if the patient has psoriatic skin lesions or has conjunctivitis, urethritis, arthritis, and skin involvement suggestive of reactive arthritis.

TYPICAL DISTRIBUTION

- The lesions are typically found on the anterior 2/3 of the dorsal tongue mucosa.
- Geographic tongue usually affects the tongue, although other oral sites may be involved such as the buccal mucosa, the labial mucosa, and, less frequently, the soft palate.[3]

DIFFERENTIAL DIAGNOSIS

- Lichen planus—Reticular forms are characterized by interlacing white lines commonly found on the buccal mucosa, or erosive forms, characterized by atrophic erythematous areas with central ulceration and surrounding radiating striae (see Chapter 138, Lichen Planus).
- Psoriasis—Intraoral lesions have been described as red or white plaques associated with the activity of cutaneous lesions (see Chapter 136, Psoriasis).
- Reactive arthritis—A condition characterized by the triad of “urethritis, arthritis, and conjunctivitis,” may have rare intraoral lesions described as painless ulcerative papules on the buccal mucosa and palate.
- Fissured tongue—An inherited condition in which the tongue has fissures that are asymptomatic. Although it has been called a *scrotal tongue* in the past, the term *fissured tongue* is preferred by patients (**Figure 35-3**).

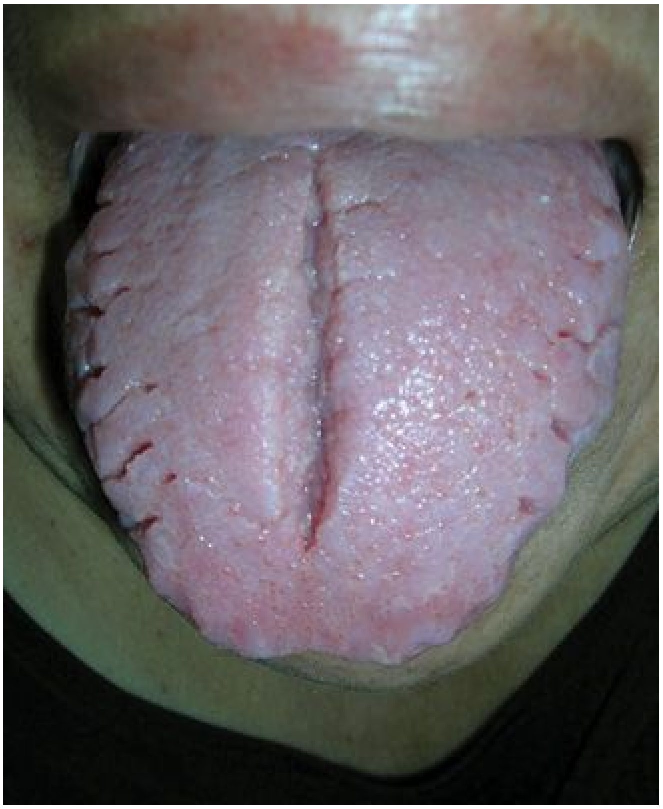

FIGURE 35-3 Fissured tongue present since birth. Although this has also been called a *scrotal tongue*, the preferred terminology is now fissured tongue, for obvious reasons. (*Used with permission from Richard P. Usatine, MD*.)

MANAGEMENT

Most individuals are asymptomatic and do not require treatment (**Figure 35-4**).

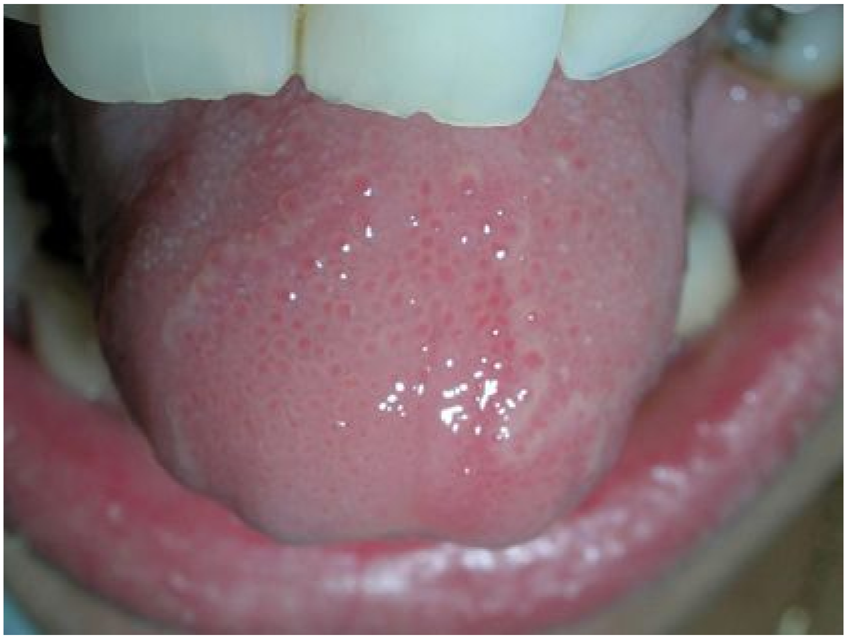

FIGURE 35-4 A mild asymptomatic case of geographic tongue. Note the atrophic filiform papillae and the subtle white halo. (*Used with permission from Richard P. Usatine, MD.*)

- For symptomatic cases, several treatments have been proposed for adults but not proven effective with good clinical trials:[6,7]
    - Topical steroids such as triamcinolone dental paste (Oralone or Kenalog in Orabase). SOR Ⓒ
    - Supplements such as zinc, vitamin B_{12}, niacin, and riboflavin. SOR Ⓒ
    - Antihistamine mouth rinses (e.g., diphenhydramine elixir 12.5 mg per 5 mL diluted in a 1:4 ratio with water). SOR Ⓒ
    - Topical anesthetic rinses.[6,7] SOR Ⓒ
- Because of safety concerns, these therapies are not recommended for young children.

Geographic tongue can rarely present as persistent and painful (**Figure 35-5**). In one case report, 0.1 percent tacrolimus ointment was applied twice daily for 2 weeks with significant improvement of symptoms.[8] SOR Ⓒ

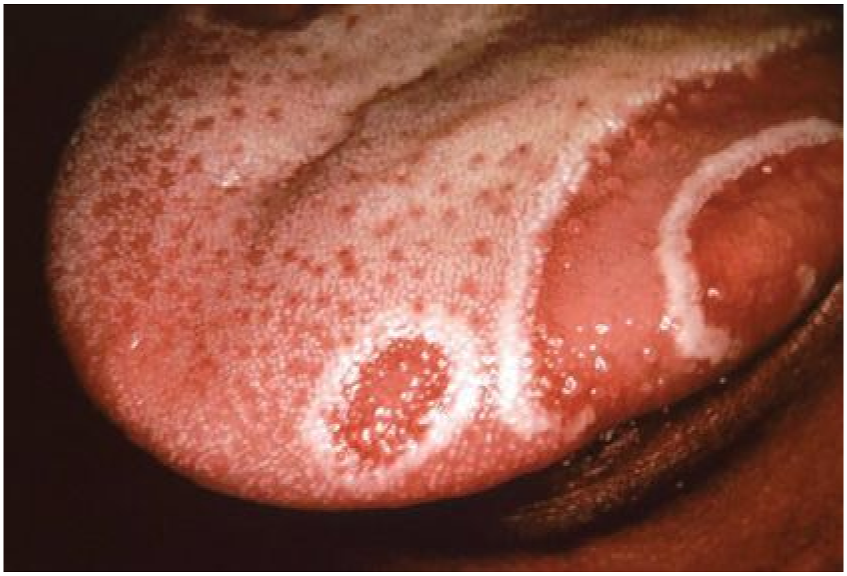

FIGURE 35-5 Geographic tongue with more severe symptomatology, including pain and a burning sensation when eating spicy foods. The contrast between the normal tongue tissue and the pink atrophic papillae is striking. (*Used with permission from Ellen Eisenberg, DMD*.)

No treatment has been proven to be uniformly effective.[9]

FOLLOW-UP

Instruct the parent to contact you if the symptoms continue past 10 days and to go to the emergency department immediately if:

- The tongue swells significantly.
- The patient has trouble breathing.
- The patient has trouble talking or chewing/swallowing.

PATIENT EDUCATION

Patients and parents should be reassured of the condition’s benign nature. Tell patients with geographic tongue to avoid irritating spicy foods and liquids.

36 EARLY CHILDHOOD CARIES

Adriana Segura DDS, MS
Wanda C. Gonsalves, MD

PATIENT STORY

A mother brings her 18-month-old son to the physician's clinic for his well-child examination. He is almost weaned from his bottle, but still drinks from a bottle to go to sleep. During the day, he uses a sippy cup to drink everything—from milk to soda. His mother has started giving him apple juice in the bottle instead of milk because he tends to get constipated. On performing an oral examination, the physician notices that several of his teeth have "white spots" (**Figure 36-1**). The physician discusses dental hygiene and treats him with topical fluoride gel.

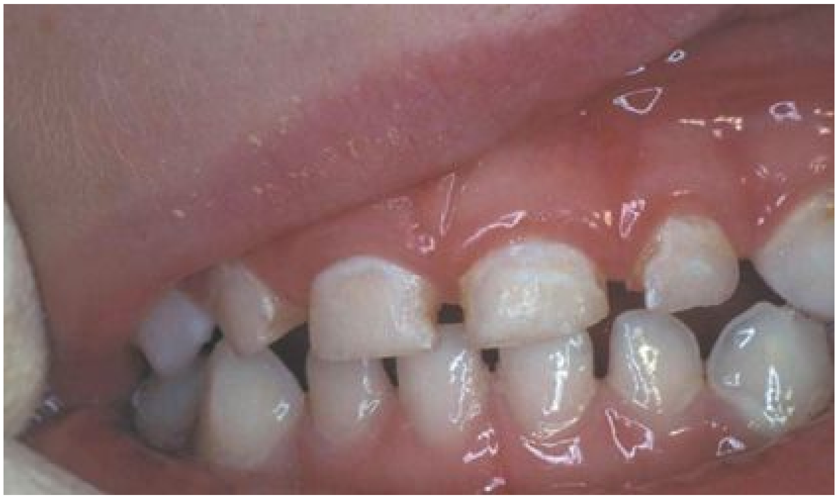

FIGURE 36-1 Demineralization at gingiva margins characterized by whitish discolorations. (*Used with permission from Gerald Ferretti, DMD.*)

INTRODUCTION

Dental caries continues to be the most prevalent chronic disease problem facing infants and children. The American Academy of Pediatric Dentistry, American Academy of Pediatrics, and American Dental Association recommend that a child's first visit to a dentist should occur 6 months after the eruption of the first tooth or at 1 year of age. Providing a dental home by age 1 year allows the health provider to complete a risk assessment, provide an introduction to dentistry, and provide anticipatory guidance. It is important to be able to recognize disease and to provide prevention strategies early on to the parents/caregivers.

SYNONYMS

Nursing bottle caries or baby bottles caries.

EPIDEMIOLOGY

- Early childhood caries (ECC; tooth decay) is the single most common chronic childhood disease. It is 5 times more common than asthma and 7 times more common than hay fever among children 5 to 7 years of age.[1]
- Tooth decay affects more than 25 percent of US children between 2 and 5 years of age and about half of those 12 to 15 years of age.
- Disparities in oral health exist—In 2002, 32 percent of Mexican American and 27 percent of non-Hispanic black children 2 to 11 years of age had untreated decay in their primary teeth, compared to 18 percent of non-Hispanic white children.[2, 3]
- ECC is defined as "the presence of one or more decayed (noncavitated or cavitated lesions), missing (as a consequence of caries), or filled tooth surfaces in any primary tooth in a child 71 months of age or younger (**Figures 36-2** to **36-4**)."[4]

- Consequences of ECC include poor self-esteem, diminished physical development, decreased ability to learn, higher risk of new caries, and added cost.[4]

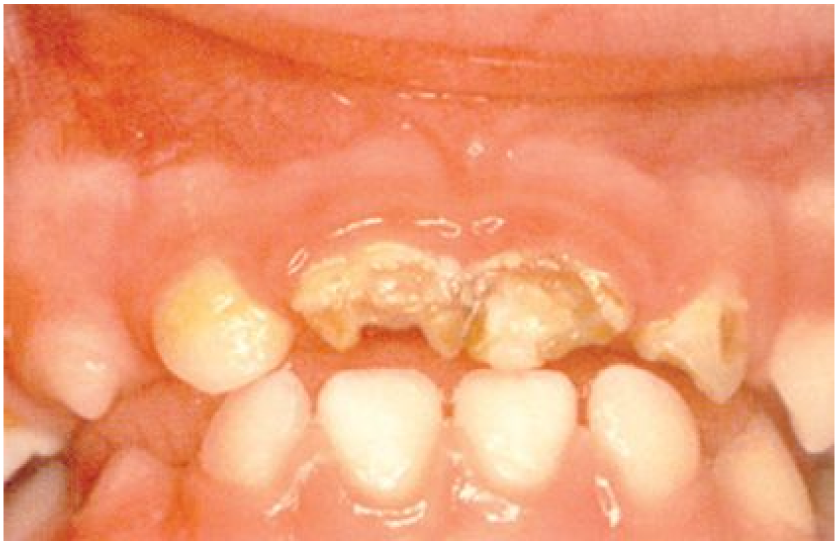

FIGURE 36-2 Central maxillary incisors with severe tooth decay, and bilateral maxillary lateral incisors with demineralized area near gingival line (yellow-brownish discolorations). The upper incisors are often the first teeth involved in nursing bottle caries. (*Used with permission from Gerald Ferretti, DMD*.)

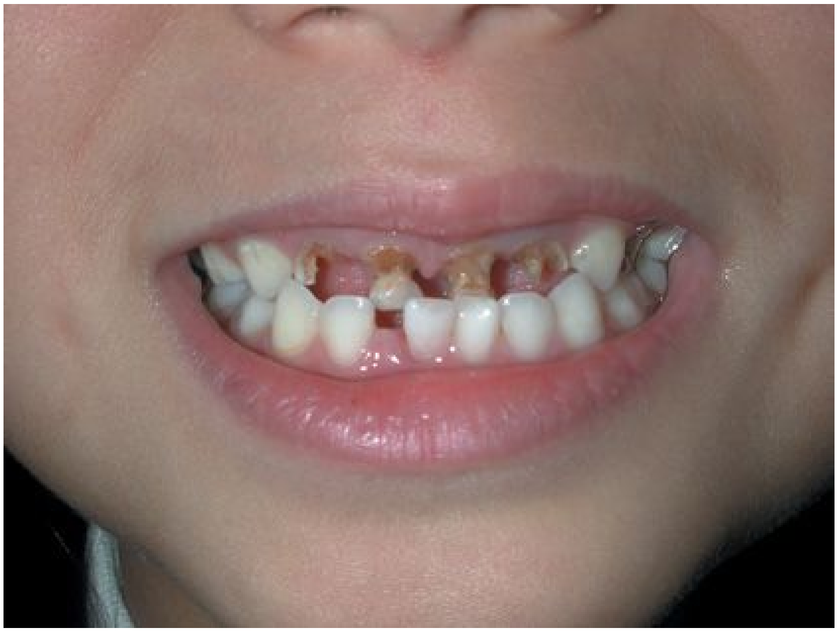

FIGURE 36-3 Severe ECC in a 4-year-old with severe decay of all four maxillary incisors. (*Used with permission from Richard P. Usatine, MD*.)

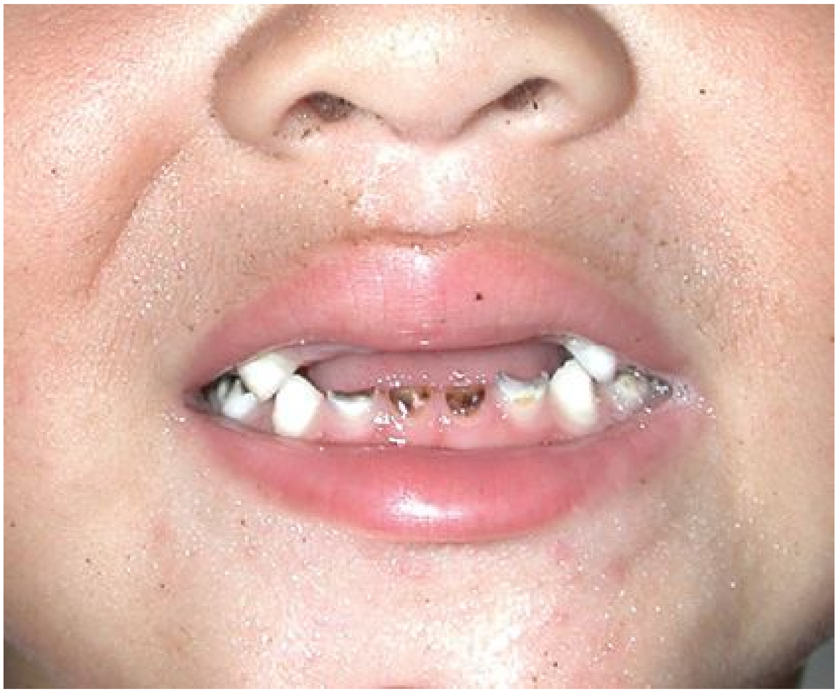

FIGURE 36-4 Severe ECC in a 3-year-old with multiple areas of cavitary lesions involving the mandibular incisors and missing maxillary incisors secondary to decay. (*Used with permission from Richard P. Usatine, MD*.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Dental caries is a multifactorial, infectious, communicable disease caused by the demineralization of tooth enamel (**Figure 36-1**) in the presence of a sugar substrate and acid-forming cariogenic bacteria, *Streptococcus mutans* (also known as *mutans streptococci*), which is considered to be the primary strain causing decay that are found in the soft gelatinous biofilm.
- Caries can develop at any time after tooth eruption. Early teeth are principally susceptible to caries caused by the transmission of *S. mutans* from the mouth of the caregiver or sibling(s) to the mouth of the infant or toddler. This type of tooth decay is called baby bottle tooth decay, nursing bottle caries, or ECC.

RISK FACTORS

Risk factors for caries development include:

- Frequent consumption of liquids.
- Repetitive use of a “sippy cup” containing sugars (juice, milk, formula, or soda).
- Consumption of sticky foods.
- Human breast milk is uniquely superior in providing the best possible nutrition to infants and, by itself, has been shown to be noncariogenic.[3]
- Nighttime bottle feeding and caregiver with caries.
- Drinking unfluoridated community water or bottled water, which usually lacks fluoride.
- Low socioeconomic status.
- Taking medications that contain sugar or cause dryness.

Lack of good oral hygiene practices.

Subnormal saliva and function.

DIAGNOSIS

CLINICAL FEATURES

- Demineralized areas develop on the tooth surfaces, between teeth, and on pits and fissures. These areas are painless and appear clinically as opaque or brown spots (**Figure 36-1**). White-spot lesions are the first indication the demineralization has started.
- Infection that is allowed to progress forms a cavity that can spread to and through the dentin (the component of the tooth located below the enamel)

and to the pulp (composed of nerves and blood vessels; an infection of the pulp is called pulpitis) causing pain, necrosis, and, perhaps, an abscess.

TYPICAL DISTRIBUTION

Demineralized (white or brown spots) and carious lesions generally occur at the margins of the gingiva upper incisors, and later first and second molars in pits and grooves of occlusal surfaces. Lower incisors are rarely affected.

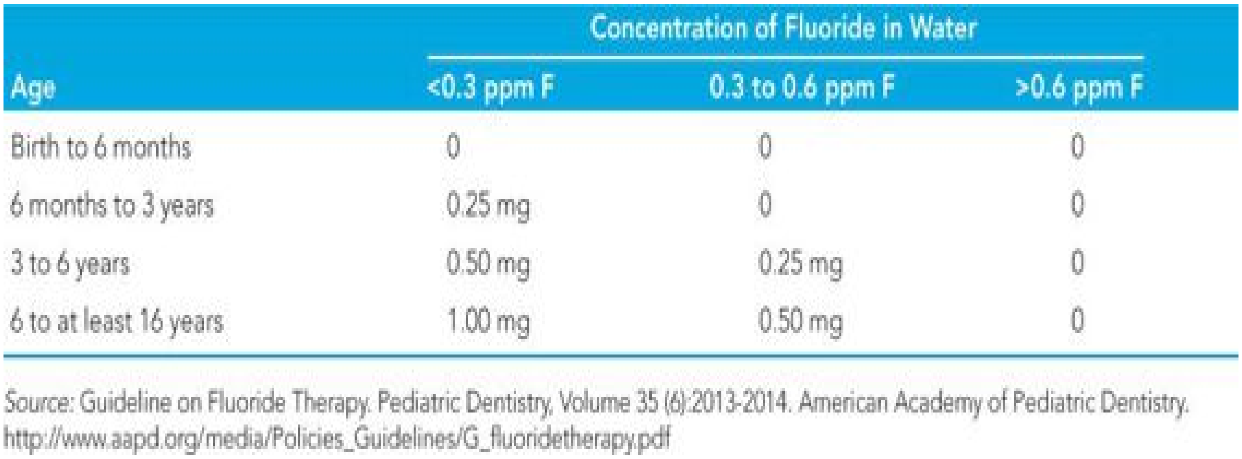
LABORATORY AND IMAGING

Demineralized lesions may not be seen on radiographs, but advanced carious lesions between and on the occlusal surfaces are detected by x-ray.

MANAGEMENT

- Counsel patients about the importance of good oral hygiene practices and perform a caries risk assessment during well-child examination visits.[5, 6] SOR Ⓑ
- Refer to the dental health professional for the application of pit and fissure sealants.[5, 6] SOR Ⓑ
- Before prescribing supplemental fluoride, the primary care provider must determine the fluoride concentration in the child’s primary source of drinking water. If fluoridated water is not available in the community, natural sources of fluoride are well water exposed to fluorite minerals and certain fruits and vegetables grown in soil irrigated with fluoridated water.[7] SOR Ⓑ
- Fluoride supplementation is not recommended for use by persons who live in communities whose water is optimally fluoridated (0.7 to 1.2 parts per million [ppm] or >0.6 mg/L). See **Table 36-1** for fluoride supplementation.[7] SOR Ⓐ

TABLE 36-1 Supplemental Fluoride Dosage Schedule



Age	Concentration of Fluoride in Water		
	<0.3 ppm F	0.3 to 0.6 ppm F	>0.6 ppm F
Birth to 6 months	0	0	0
6 months to 3 years	0.25 mg	0	0
3 to 6 years	0.50 mg	0.25 mg	0
6 to at least 16 years	1.00 mg	0.50 mg	0

Source: Guideline on Fluoride Therapy. Pediatric Dentistry, Volume 35 (6):2013-2014. American Academy of Pediatric Dentistry. http://www.aapd.org/media/Policies_Guidelines/G_fluoridetherapy.pdf

- Advise the caregiver to take the child to a dentist by age 1 year.[6] SOR Ⓒ
- Application of fluoride varnishes twice per year in moderate to high-risk children have been shown to prevent caries in demineralized enamel.[8] SOR Ⓐ

FOLLOW-UP

Ensure that any child whose teeth have “white spots” or visible caries is taken to a dentist for evaluation and treatment so the teeth can be saved from decay or repaired.

PATIENT EDUCATION[6]

- Give the child’s caregiver anticipatory guidance that is appropriate to the child’s age and dental development. Before the teeth erupt, the caregiver should use a washcloth or cotton gauze to clean a baby’s mouth and to transition the child to tooth brushing. SOR Ⓒ
- A “smear” of fluoridated toothpaste (approximately 0.1 mf fluoride) should be considered for children younger than 2 years of age who are at moderate risk or high risk for caries (**Figure 36-5**).[6] SOR Ⓑ

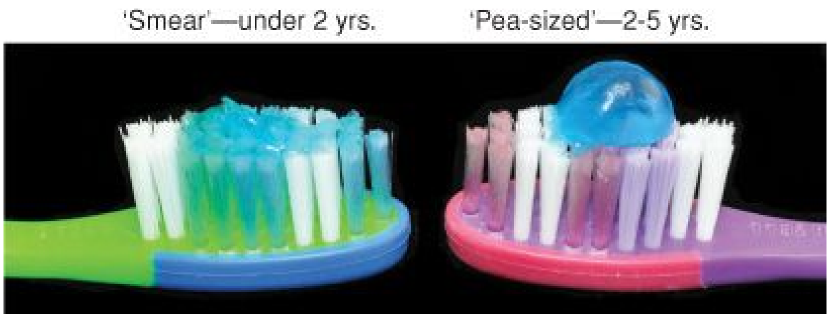


FIGURE 36-5 Comparison of a “smear” (*left*) with a “pea-sized” (*right*) amount of toothpaste. (*Used with permission from Richard P. Usatine, MD.*)

- A “pea size” amount of toothpaste (approximately 0.2 mg fluoride) is appropriate for children 2 through 5 years of age.[6] SOR B
- The caregiver should brush the child’s teeth until the child is capable of doing an adequate job (usually around age 7 years).
- Educate caregivers about the benefits of fluoride and fluorosis, and the possible side effects of using too much fluoride (see **Table 36-1**).
- Advise caregivers to teach the child to drink from a “sippy cup” as soon as possible and to avoid giving the child milk, juice, or soda in either a bottle or sippy cup when putting the child to bed.

Breastfeeding by itself is noncariogenic but when supplemented with other carbohydrates can place the child at risk for caries.[9,10]

The American Academy of Pediatric Dentistry (AAPD) promotes breastfeeding for infants but recommends cessation of ad libitum breastfeeding as the first primary tooth begins to erupt and other dietary carbohydrates are introduced.[9] SOR C

37 DENTAL COMPLICATIONS: HARD TISSUE (TEETH)

Homa Amini, DDS, MPH, MS
Ashok Kumar, DDS, MS
James R. Boynton, DDS, MS

PATIENT STORIES

A 9-year-old boy presents to his pediatrician after suffering trauma to his face 45 minutes ago while jumping on a trampoline (**Figure 37-1**). The mother presents with a tooth folded in a wet napkin. There are no signs or symptoms of trauma to other craniofacial structures nor signs of neurological trauma. Upon examination, a fully rooted permanent tooth is noted to have been lost from its socket and the adjacent tooth is fractured. He is diagnosed with avulsion of the maxillary right central incisor. After a call to the child's dentist, the pediatrician reimplanted the tooth as directed (**Figure 37-2**). The boy was then sent directly to the dentist for evaluation and stabilization.

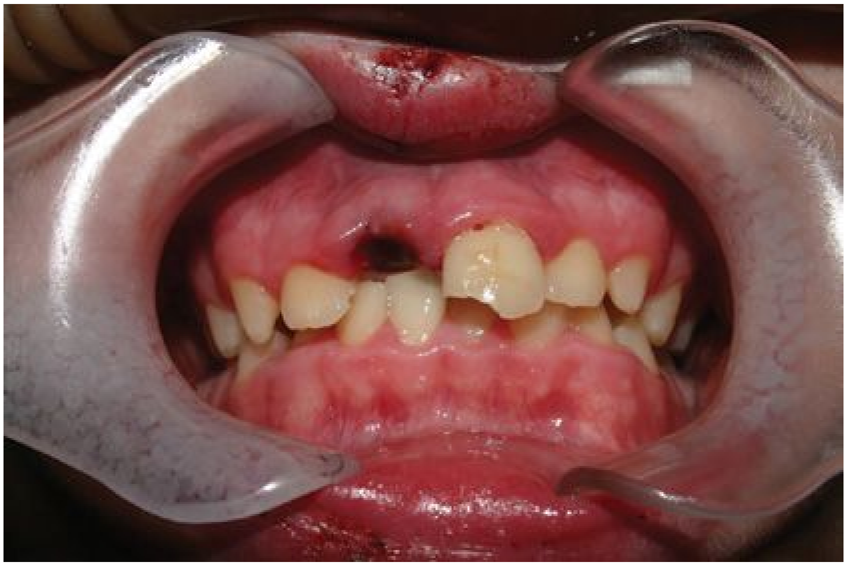

FIGURE 37-1 Maxillary right central incisor is completely avulsed out of its socket and maxillary left central incisor is fractured involving enamel and dentin. (*Used with permission from the Division of Pediatric Dentistry and Community Oral Health, The Ohio State University*.)

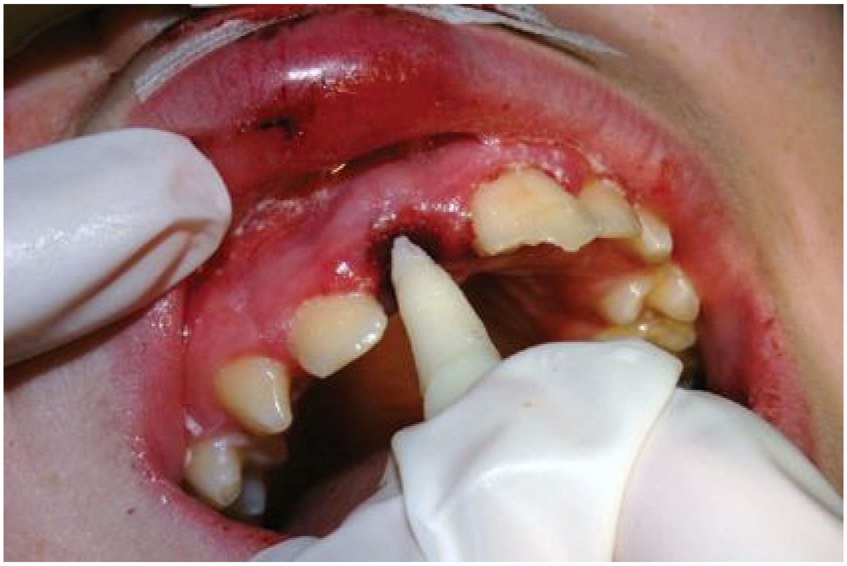

FIGURE 37-2 Avulsed permanent teeth should be reimplanted as soon as possible. Handle the tooth by the crown and avoid touching the root. (*Used with permission from the Division of Pediatric Dentistry and Community Oral Health, The Ohio State University*.)

INTRODUCTION

Dental trauma may involve a tooth fracture or the traumatic displacement of a whole tooth. Intraoral and extraoral soft tissue (involving the gingiva, oral mucosa, and the tongue) may be injured as well.

EPIDEMIOLOGY

- Dental trauma is most common among children with a slight male predilection; the most commonly traumatized teeth are the maxillary central incisors.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Most incidents of trauma are caused by accidents in or around the home or at school.
- The impact of the injury may cause damage to the hard tissue of the tooth, the pulpal tissue within the tooth, the periodontal ligament which holds the tooth in the arch, the alveolar bone, intraoral soft tissue, the maxilla/mandible, or other craniofacial structures.
- Dental trauma, or delayed treatment of a traumatized tooth, may cause necrosis of the pulp tissue within the tooth necessitating root canal therapy or inflammation of the periodontal ligament, which can result in resorption of the root.
- After ruling out neurological and damage to other craniofacial structures, referral to a dentist is necessary for a thorough clinical and radiographic intraoral examination.

RISK FACTORS

- Malocclusion of maxillary/mandibular teeth.
- Lower socioeconomic status.
- Risk-taking children.
- Children being bullied or under emotionally stressful conditions.
- Children with obesity or ADHD.[2]

DIAGNOSIS

CLINICAL FEATURES

- Tooth fractures:
    - Enamel fracture—Fracture confined to the outer enamel surface without exposing the underlying dentin. Normally asymptomatic, although fracture site may be rough to the touch.
    - Enamel/dentin fracture—Fracture involving the outer enamel and inner, more yellow-colored dentin. Normally moderate to severely sensitive to heat or cold (**Figure 37-3**).

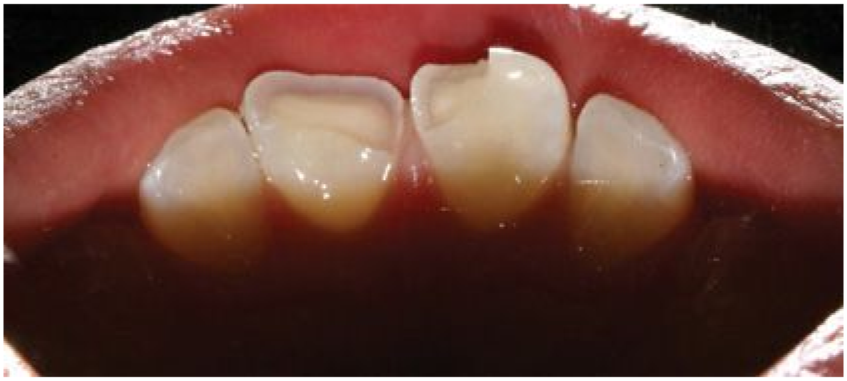

FIGURE 37-3 Tooth fracture involving the outer enamel and inner, more yellow-colored dentin. (*Used with permission from the Division of Pediatric Dentistry and Community Oral Health, The Ohio State University*.)

-
    - Enamel/dentin/pulp fracture—Fracture involving the enamel and dentin, which exposes the underlying vascular pulp tissue. Symptoms may range from no symptoms to sensitivity to heat and cold (**Figure 37-4**).

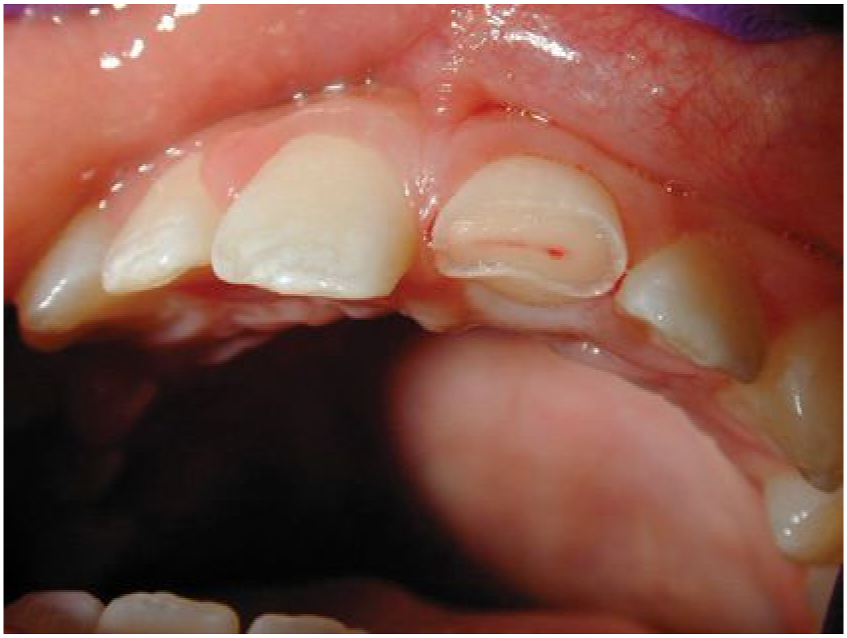

FIGURE 37-4 Tooth fracture resulting in pulpal exposure. (*Used with permission from the Division of Pediatric Dentistry and Community Oral Health, The Ohio State University*.)

- Tooth displacement injuries:
    - Concussion/subluxation—Injuries to a tooth resulting in tooth mobility and/or sensitivity without displacement from the socket. Teeth may be sensitive to touch or abnormally loose, but the tooth remains in its prior position.
    - Luxation—Displacement of a tooth from its position in its socket. Teeth may be luxated laterally from the socket, intruded into the socket, or extruded partially out of the socket. These injuries are often associated with damage to the supporting alveolar bone (**Figures 37-5** and **37-6**).

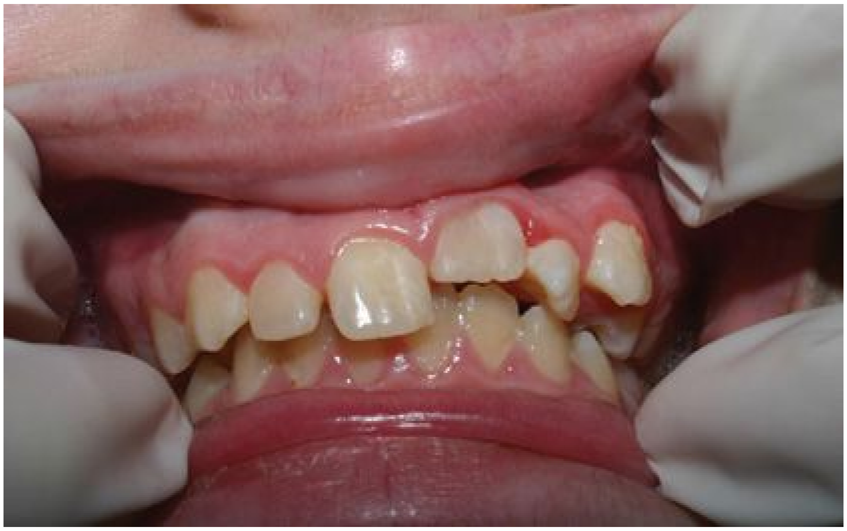

FIGURE 37-5 Traumatic dental injury resulting in intrusion of the tooth into the socket. (*Used with permission from the Division of Pediatric Dentistry and Community Oral Health, The Ohio State University*.)

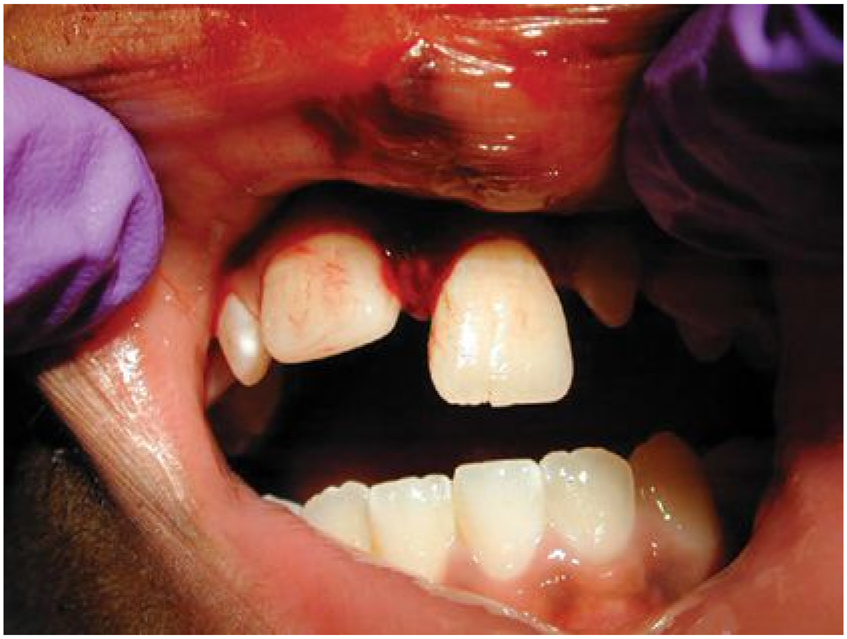

FIGURE 37-6 Traumatic dental injury resulting in partial extrusion of the tooth out of its socket. (*Used with permission from the Division of Pediatric Dentistry and Community Oral Health, The Ohio State University*.)

- Avulsion—Complete loss of tooth from socket. Tooth will be lost and a blood clot will form in the socket (**Figure 37-1**).

- Intraoral soft tissue trauma:
    - Laceration, abrasion, contusion of gingival, labial or lingual tissue, visible upon clinical examination (**Figure 37-7**).

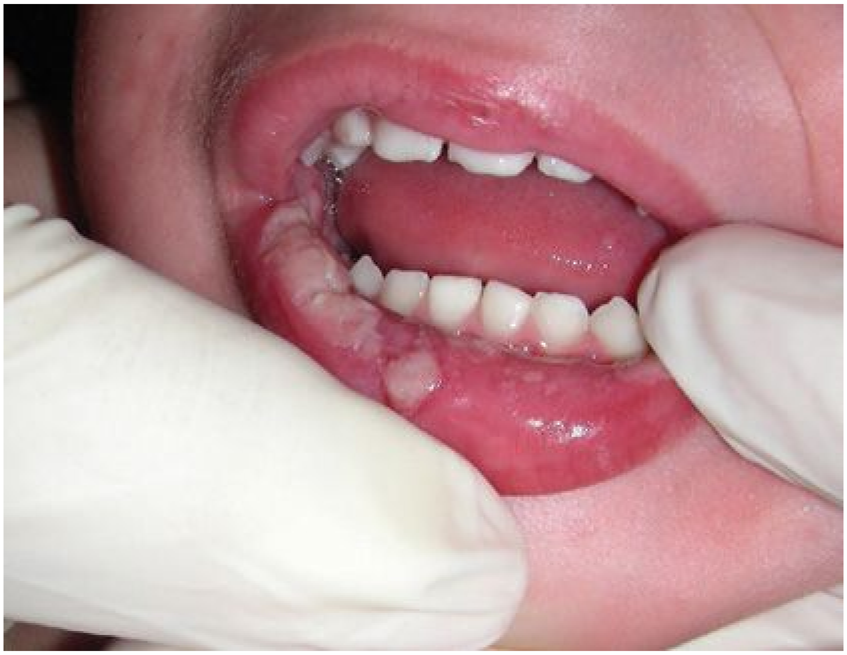

FIGURE 37-7 Soft tissue trauma of the lower lip associated with lip chewing following the use of local anesthesia in a 4-year-old child. (*Used with permission from the Division of Pediatric Dentistry and Community Oral Health, The Ohio State University*.)

IMAGING

To evaluate the extent of dental trauma, intraoral dental radiographs are exposed and evaluated by a dentist. A panoramic radiograph may be useful to evaluate suspected fracture of the mandible. Other head and neck radiographs, CT scans, and other imaging tests are not routinely ordered unless specifically indicated.

DIFFERENTIAL DIAGNOSIS

- Rule out child abuse, as approximately half of child abuse cases involve injuries to the head and neck.[3]
- Dental trauma may occur in conjunction with trauma to other head and neck structures; a thorough evaluation is critical to determine neurological trauma or trauma to other areas of the craniofacial complex.

MANAGEMENT

- Tooth fractures should be urgently referred to a dentist for clinical and radiographic evaluation and treatment. Treatment options for primary and permanent teeth are the same and may involve restoration of the fractured tooth surface and pulp therapy (**Figure 37-8**). Some fractured teeth are unable to be restored and must be extracted.

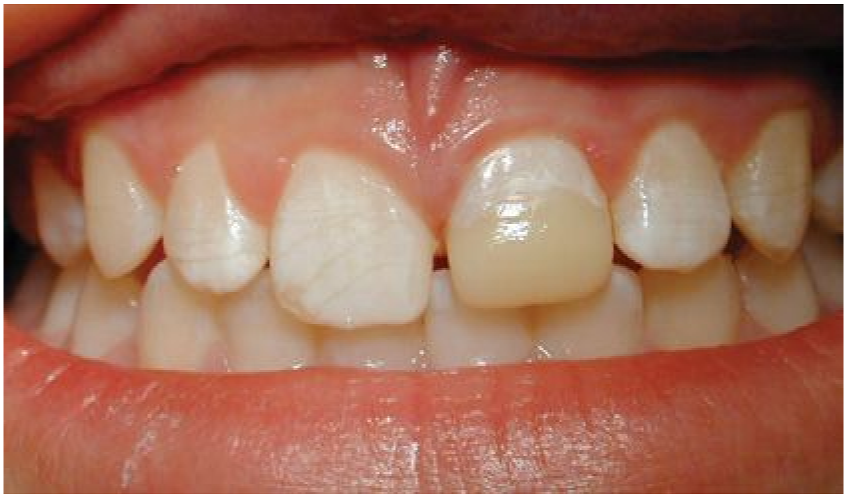

FIGURE 37-8 The left maxillary central incisor is restored with dental materials to its original form after a crown fracture. (*Used with permission from the Division of Pediatric Dentistry and Community Oral Health, The Ohio State University*.)

- Tooth displacement injuries should be urgently/immediately referred to a dentist for clinical and radiographic evaluation and treatment. Treatment for primary teeth may range from observation to extraction of the traumatized tooth. Treatment for permanent teeth may involve observation, repositioning, or extraction of the traumatized tooth.

- Avulsion injuries:
    - Primary tooth—Do not attempt to replace in socket. Refer to dentist for further evaluation.
    - Permanent tooth—Handle the tooth by the crown. Avoid touching the root. If the root has debris on it, rinse gently for a few seconds and then reimplant the tooth in its socket as quickly as possible. Have the patient bite on a washcloth to hold the tooth in place and refer to a dentist for urgent evaluation and stabilization of the tooth (**Figures 37-2** and **37-9**).

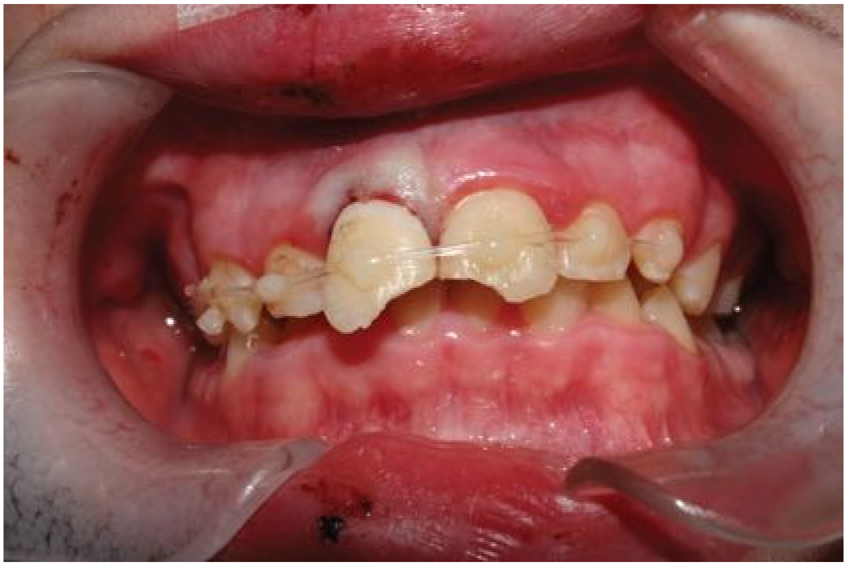

FIGURE 37-9 The avulsed teeth are stabilized by a splint after reimplantation. (*Used with permission from the Division of Pediatric Dentistry and Community Oral Health, The Ohio State University*.)

-
    - If not able to reimplant, tooth should be placed in a storage medium such as milk, Hank’s Balanced Salt Solution, or normal saline for transport, and the child should be immediately seen by a dentist for urgent evaluation and reimplantation.[4]
- Soft tissue injuries—Clean the wound with saline irrigation. Sutures may be indicated. Intraoral radiographs may be indicated to rule out foreign body impaction. Refer to dentist for evaluation and treatment.

MEDICATIONS

- Ibuprofen or acetaminophen as needed for pain.
- Chlorhexidine Gluconate Oral Rinse, 0.12 percent, rinse twice daily for 1 week.

PREVENTION AND SCREENING

- Wear a mouthguard when playing sports.
- Childproof the home (cover table corners and install safety gates near stairs).

PROGNOSIS

- Prognosis is dependent on the nature of the injury. Minor tooth fractures have a good prognosis after restoration of the fracture whereas extensive fractures do not. Minor displacement injuries have a good prognosis, whereas intrusion and avulsion of a tooth have the most guarded prognosis of dental injuries. Intraoral soft-tissue injuries typically have a good prognosis.

FOLLOW-UP

The patient’s dentist will follow-up with the patient on a routine schedule with clinical and radiographic examinations to evaluate the response of the pulp and periodontal ligament following the traumatic event.

PATIENT EDUCATION

Provide anticipatory guidance for prevention of traumatic dental injuries. Promote use of mouth guards for sport activities and advise parents to childproof their home.

38 DENTAL COMPLICATIONS—SOFT TISSUE (GINGIVA AND MUCOSA)

Sarat Thikkurissy, DDS, MS
Elizabeth Sutton Gosnell, DMD, MS
Dimitris N. Tatakis, DDS, PhD

ANKYLOGLOSSIA

PATIENT STORY

A 2-year-old male child presents with a chief complaint per mother of “not being able to stick out his tongue.” (**Figure 38-1**). On examination, the child could not protrude the tip of the tongue over the mandibular anterior teeth and could not effectively lick his upper lip. Neither gingival recession nor speech pathology was noted. A diagnosis of ankyloglossia was made. Frenectomy was suggested and delayed until child’s age made feasible necessary behavioral management in the dental chair.

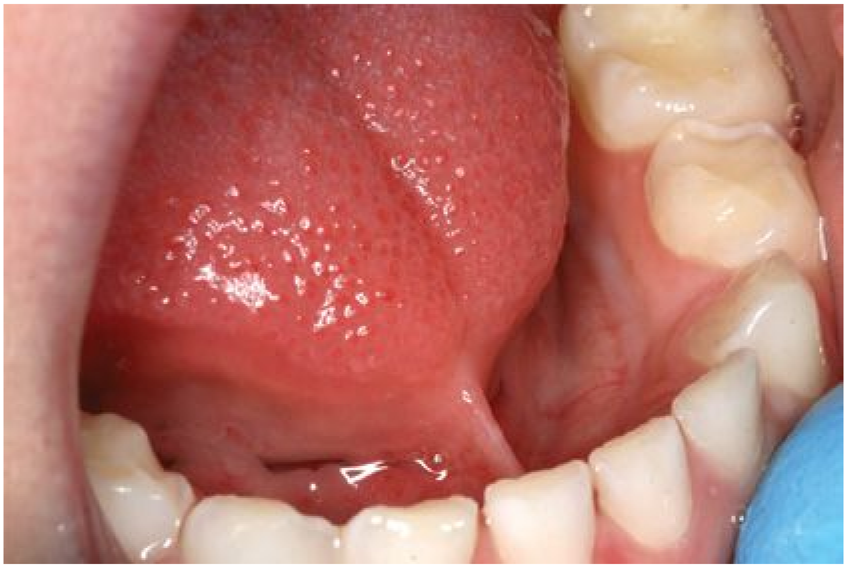

FIGURE 38-1 Ankyloglossia characterized by a short and thick frenum. (*Used with permission from Dimitris N. Tatakis DDS, PhD.*)

INTRODUCTION

Ankyloglossia refers to a congenital abnormality, where a short and/or thick lingual frenum may restrict tongue movement (**Figure 38-2**).[1] Severity may vary significantly.

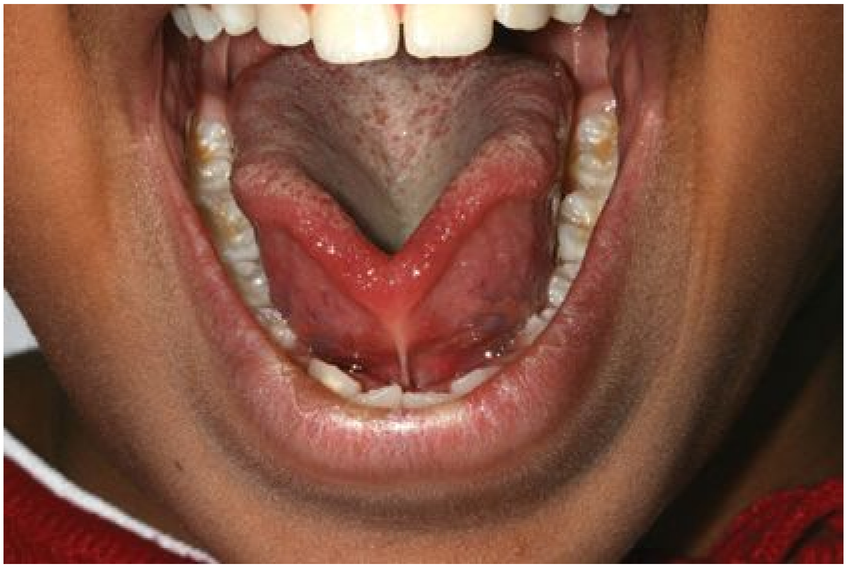

FIGURE 38-2 Ankyloglossia in a child restricting movement of the tongue. (*Used with permission from Dimitris N. Tatakis DDS, PhD.*)

SYNONYM

Tongue-Tie.

EPIDEMIOLOGY

- Reported prevalence varies from 0.1 to 10.7 percent, dependent on age population surveyed.[1]
- It has been reported as being more prevalent in males, although this is a controversial and inconclusive finding.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- This is a developmental, congenital condition.
- There have been reports associating ankyloglossia with specific syndromes such as X-linked cleft palate.[3]
- However, most incidences of ankyloglossia occur in individuals without any other congenital disease.
- A positive family history of ankyloglossia was noted in a wide range (10% to 53%) of families surveyed in a 2002 study,[4] while it has been strongly associated with maternal cocaine use.[5]

RISK FACTORS

- Family history.
- Maternal cocaine use (3.2 times the increased risk).[5]

DIAGNOSIS

CLINICAL FEATURES

- Variably short and thick lingual frenum with concomitant limitation of tongue mobility (range of motion) and/or functionality.
- Clinical diagnosis is typically made during early feeding disturbances in children, in which severe ankyloglossia prevents/impedes completion of a sufficient oral seal during nursing.
- Initial diagnosis in neonates and young infants might be made by lactation consultants.
- A randomized controlled trial demonstrated in 2005 that 95 percent of infants receiving surgical correction had improved feeding, compared to <10 percent in the control group.[6]

DIFFERENTIAL DIAGNOSIS

- Feeding and speech difficulties may be associated with other intrinsic behaviors and causative factors.
- Therefore, a comprehensive review is required to determine the possible contribution of ankyloglossia and the need for management.

MANAGEMENT

- Management approaches, which are surgical, are often based on the severity of the ankyloglossia and its impact (i.e., effects on feeding, speech, peer acceptance, social life and self image). SOR B
- A comprehensive evaluation of the severity of the problem and the impact of the problem on the child's pathology is important prior to any surgical correction.
- It should be noted that the literature reflects possible recurrence of ankyloglossia due to excessive scar tissue formation.[7]
- Surgical Options
    - Frenotomy—Surgical release of frenal constriction.
    - Frenectomy—Complete excision of entire frenum.
    - Frenuloplasty—Surgical rearrangement of frenal attachments and extension.

PATIENT EDUCATION

Parents should be advised to seek consultations from a pediatric dentist (or dentist familiar with ankyloglossia in young children), lactation consultant (if nursing is a specific issue), and speech pathologist (if speech is affected) to have a comprehensive evaluation of the child's limitations, to ensure that ankyloglossia is a contributing factor to child's pathology, prior to referring the child for surgical correction.

GINGIVITIS

PATIENT STORY

A 13-year-old female presents to your office because of persistent “bleeding” from her gums. The bleeding occurs most often during brushing of her teeth. She has no other history of bleeding or other contributory medical history. Her gingiva appear edematous and friable (**Figure 38-3**).

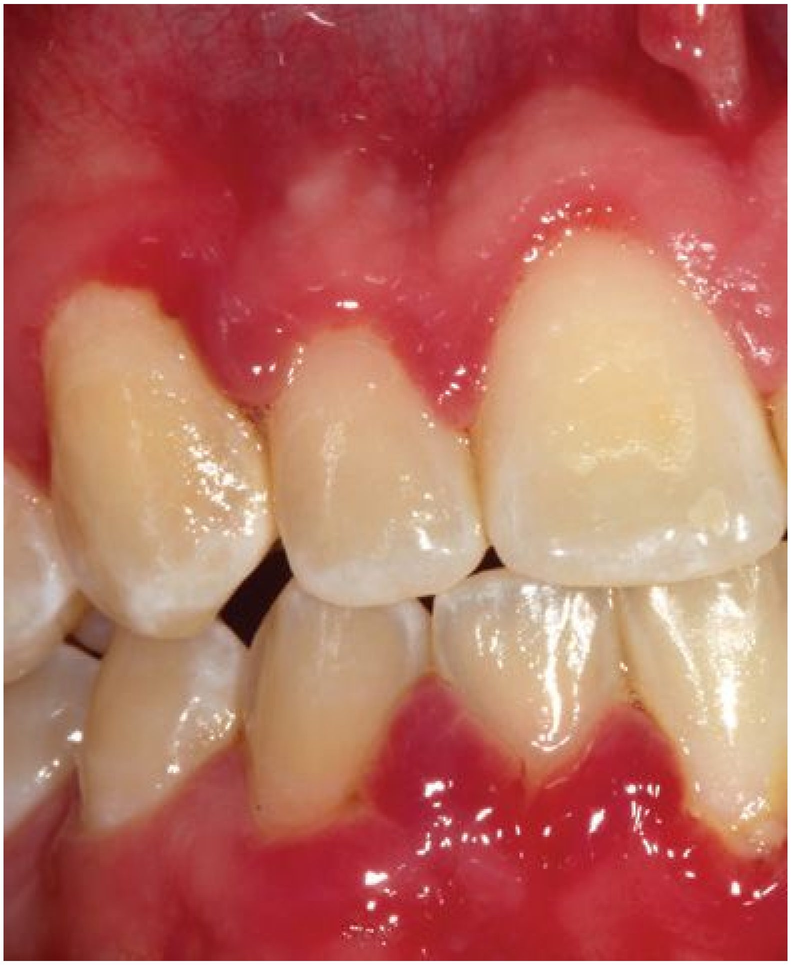

FIGURE 38-3 Gingivitis in an adolescent characterized by erythematous and edematous gingiva. (*Used with permission from Dimitris N. Tatakis DDS, PhD*.)

INTRODUCTION

Gingivitis refers to a reversible and (classically) bacterial-plaque mediated gingival inflammation. There are other sub-genres of gingivitis that may have additional etiologic factors (such as pregnancy gingivitis). Gingivitis does not include the broad spectrum of periodontal diseases in children (those associated with loss of soft and hard (alveolar bone) tissue support around the teeth).

SYNONYM

Gum disease or gingival disease.

EPIDEMIOLOGY

- Epidemiologic studies suggest a nearly universal prevalence of gingivitis in children and adolescents, beginning in the primary dentition and peaking during puberty.[8,9]
- The lingual surfaces of primary and permanent molars are most often affected by gingivitis.[8]
- The American Academy of Periodontology International Workshop on Classification of Periodontal diseases and conditions lists dental plaque-induced gingival disease as a distinct category of disease that affect “young individuals.” There are specific conditions (namely puberty and diabetes) that can modify the gingival response to bacterial plaque.[11]

ETIOLOGY AND PATHOPHYSIOLOGY

- Gingivitis is a plaque-induced, bacterial mediated condition. Commonly isolated pathogens associated with gingivitis include *Actinomyces* sp. and

Capnocytophaga sp.[10]

- However, irrespective of specific bacterial colonization, the progression of gingivitis is typically associated with poor oral hygiene and plaque-accumulation.
- Fluctuations in gonadotrophic hormone levels associated with puberty may modify the gingival inflammatory response, increasing susceptibility to gingivitis.
- Unfavorable insulin levels in diabetic patients may also have this effect.[12,13]
- The presence of local factors that favor plaque accumulation (e.g., tooth crowding or orthodontic appliances) or prevent proper oral hygiene (e.g., erupting teeth) may predispose areas to gingivitis development.

RISK FACTORS

- Bacterial plaque accumulation.
- Poor oral hygiene.
- Poor control of diabetes.
- Circumpubertal hormone changes.
- Mouthbreathing.

DIAGNOSIS

CLINICAL FEATURES

- Typically painless, erythematous and edematous marginal (and papillary) gingiva with shiny surface appearance.

- Increased severity of inflammation is associated with greater prevalence of bleeding upon provocation (e.g., during toothbrushing).

DIFFERENTIAL DIAGNOSIS

- Pyogenic granuloma—Typically localized gingival enlargement that may be painful; often associated with pregnancy.
- Gingival abscess—Painful, localized gingival swelling; typically sudden onset and classically associated with a foreign body of some type.
- Acute necrotizing ulcerative gingivitis—Gingivitis characterized by pain, bleeding, and necrotic (punched out) interdental (papillary) and/or marginal gingiva; typically sudden onset; associated with smoking and stress-inducing conditions.
- Vitamin C deficiency associated gingivitis—Typically accompanied by systemic manifestations (petechiae, ecchymoses, or impaired wound healing); rare in populations with adequate food supply.
- Leukemia—Inflamed gingiva (shiny, red, and edematous) with bleeding a common feature; systemic symptoms may include fever, malaise, easy bruising or bleeding, and bone or joint pain.

MANAGEMENT

- Daily, attentive and effective oral hygiene habits are paramount.
- Younger children (those 10 and younger) will often require some form of direct parental involvement in performing oral hygiene procedures.
- Use of oral hygiene adjuncts, such as mouthrinses, may help.[14] SOR A

PREVENTION & PATIENT EDUCATION

- The American Academy of Pediatric Dentistry/American Academy of Pediatrics' position is that all children should visit a dentist by the age of one or eruption of first tooth.
- During this visit, anticipatory guidance will help caregivers understand how to assess whether oral hygiene is adequate.

MUCOCELE

PATIENT STORY

An 11-year-old boy presents with a chief complaint of a "bump" on his lip that has been there for about 1 month. The lesion has fluctuated in size, and is painless, unless he bites on it, which sometimes happens when he is playing. A mucocele was the working clinical diagnosis (**Figure 38-4**). The lesion was excised and the child healed uneventfully.

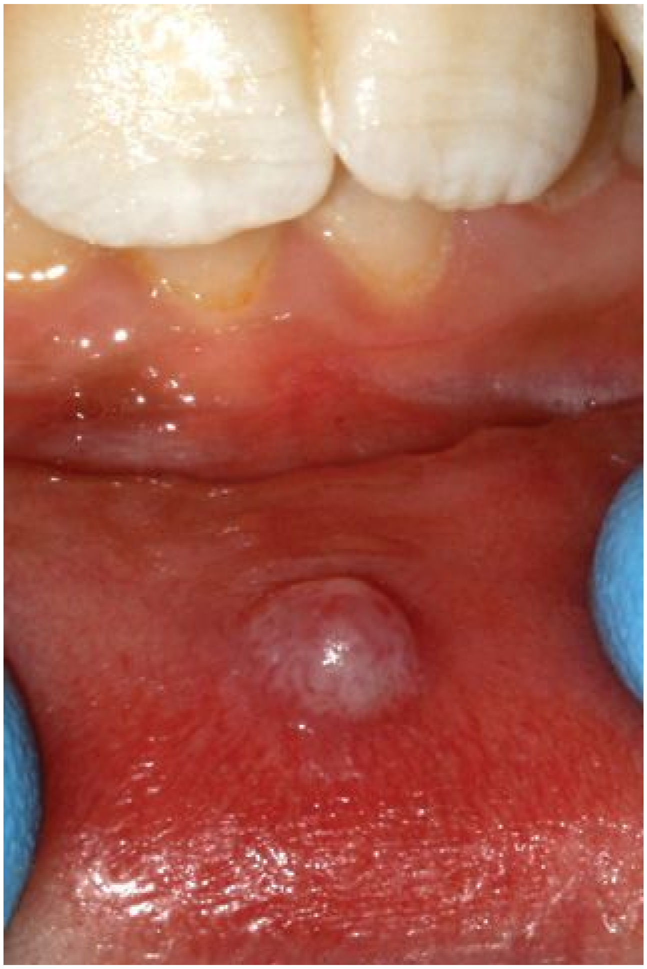

FIGURE 38-4 Mucocele apparent on the lower lip of this boy. (*Used with permission from Dimitris N. Tatakis DDS, PhD.*)

INTRODUCTION

Traumatic injury or pathologic alteration of minor salivary glands in the lip may result in mucous accumulation (pseudocyst). This may result in a swelling on the lip that alters in size due to mucous accumulation and extravasation.

SYNONYM

Mucous retention cyst/phenomena; Ranula (when on floor of mouth); Mucocele of Glands of Blandin-Nuhn (ventral tongue surface).

EPIDEMIOLOGY

- Most often occurs in the second decade of life,[15] with no gender predilection.
- Studies have reported average progression time to be about 6 months.
- A large retrospective analysis determined the overall prevalence to be 16 percent of lesions found in over 4,000 children during a 30-year period.[18]

ETIOLOGY AND PATHOPHYSIOLOGY

- Traumatic injury of minor salivary gland ducts in the lip, leading to mucous extravasation into adjacent tissues.[16]
- Size fluctuations are directly related to mucin accumulation within the lesion. Lip lesions are often related to the bite (occlusion) (**Figure 38-5**).

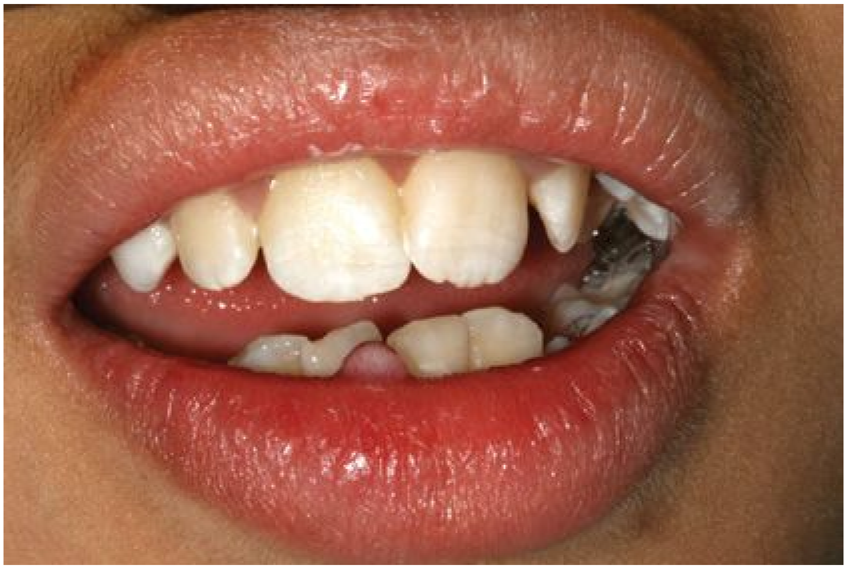

FIGURE 38-5 Mucocele on the lower lip of this child. (*Used with permission from Dimitris N. Tatakis DDS, PhD.*)

RISK FACTORS

- Self-injurious behaviors, such as lip biting.
- Previous history of mucocele.
- Lichen Planus (associated with multiple mucoceles).
- Graft versus host disease.

DIAGNOSIS

CLINICAL FEATURES

- Typically painless, soft/fluctuant papule, translucent, or pink to bluish color, smooth surface; may acquire nodular appearance if persisting for longer periods.
- While it is common to have a working clinical diagnosis, final diagnosis can only be made following histological examination, which reveals mucin and minor salivary gland components.

DIFFERENTIAL DIAGNOSIS

- Lymphangioma.
- Hemangioma.
- Traumatic hematoma.
- Irritation (traumatic) fibroma.

- Verucca Vulgaris wart—Often present on other sites of body as well.

MANAGEMENT

- Typically, surgical excision.
- Aspiration is not an effective treatment.
- Incomplete lesion removal or further trauma to the minor salivary glands may result in recurrence.
- Recent literature has suggested that conventional surgical excision is a definitive treatment of mucoceles.[17] SOR Ⓑ
- Reported recurrence rates vary between 4 to 8 percent.[17,18]

PREVENTION

- As these lesions are often traumatically induced, prevention is challenging.
- Children with large overjet (protruding maxillary teeth) may be more prone to lip biting as well as those patients with self-injurious biting behaviors.

PATIENT EDUCATION

Encourage patients to avoid any self-injurious behaviors.

PARENT RESOURCES

- **www.ncbi.nlm.nih.gov/pubmedhealth/PMH0002605**.

GINGIVAL FIBROMA

PATIENT STORY

A 7-year-old female presents with a parental chief complaint of “pink bump on her gums” (**Figure 38-6**). The child has adequate oral hygiene, a regular dentist and no clinical evidence of dental caries. An excisional biopsy was performed and a diagnosis of gingival fibroma was made.

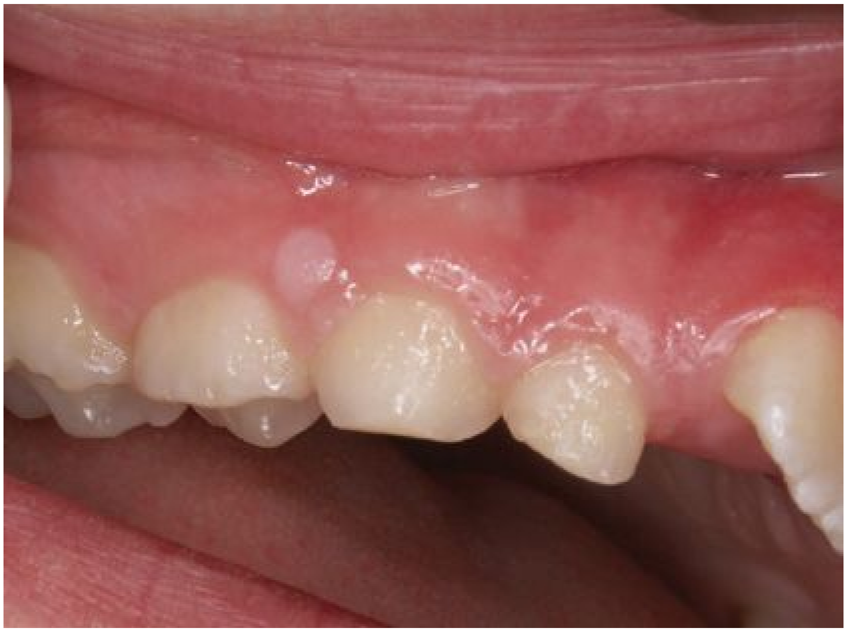

FIGURE 38-6 Fibroma seen on the upper gingiva of a child. (*Used with permission from Dimitris N. Tatakis DDS, PhD*.)

INTRODUCTION

Gingival fibroma may be classified as a localized reactive gingival lesion, characterized by connective tissue hyperplasia, resulting of chronic irritation. It is a benign lesion, but due to potential severity of differential diagnoses, histopathological examination is warranted.[19]

SYNONYM

Traumatic fibroma or irritation fibroma.

EPIDEMIOLOGY

- In a population-based study of over 25,000 biopsies, approximately 7 percent were localized reactive gingival lesions.[20]
- Fibromas, potentially occurring on any mucosal surface, are among the most common oral lesions.

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology of gingival fibroma is considered to be chronic irritation or persistent trauma.
- In children, there is the possibility that improper oral hygiene or oral habits may contribute to chronic irritation.

RISK FACTORS

- Chronic irritation/trauma.
- Tuberous Scelerosis—Demosplastic fibroma variant.

DIAGNOSIS

CLINICAL FEATURES

- Typically normal or pale pink color, smooth surface, firm to rubbery consistency, and sessile base.
- Definitive diagnosis is made based on histologic examination and history.

DIFFERENTIAL DIAGNOSIS

- Pyogenic Granuloma (may be associated with pregnancy).
- Peripheral Giant Cell Granuloma.
- Peripheral Ossifying Fibroma (may present with characteristic radiographic appearance of mixed radiopaque and radiolucent lesion).

MANAGEMENT

- Excisional biopsy, along with removal of source of irritation, is a conservative and highly effective method of management. SOR Ⓑ
- Failure to eliminate/control local irritant may lead to recurrence.

PREVENTION

- Elimination/correction of identified local irritants or sources of chronic trauma.

PATIENT EDUCATION

- Cessation of any self-injurious behaviors or habits.

PATIENT RESOURCES

39 HERPES SIMPLEX VIRUS GINGIVOSTOMATITIS

Camille Sabella, MD

PATIENT STORY

A 12-month-old previously healthy boy is seen in the office with a 3-day history of fever and ulcerative lesions on his lips and mouth. Over the past day the lesions had spread to his face and around his eye (**Figure 39-1**). His mother has noted that the lesions have evolved from flat to raised lesions to fluid-filled ulcers. The boy has been irritable, and over the past day, has refused to eat and drink. He appears dehydrated and is admitted to the hospital for intravenous fluid hydration.

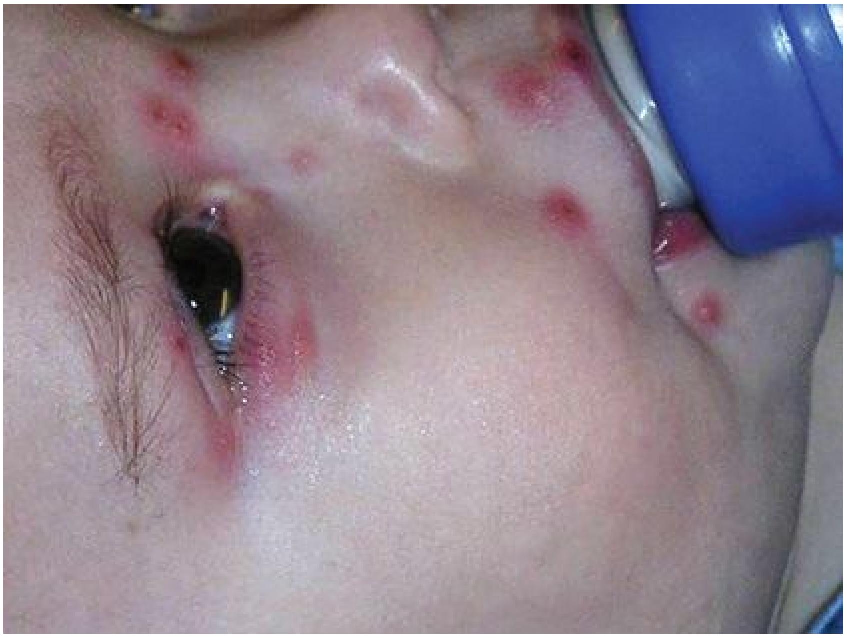

FIGURE 39-1 Vesicular lesions of primary HSV infection in a 12-month-old infant. (*Used with permission from Johanna Goldfarb, MD.*)

INTRODUCTION

Primary herpes simplex virus (HSV) infection occurs commonly in infants and children. While most infections are asymptomatic, the most common clinical manifestation of primary HSV infection is gingivostomatitis. This infection in otherwise healthy infants and children is self-limited, but can occasionally lead to dehydration and hospitalization. Immunocompromised individuals who are infected with HSV may have more severe and systemic manifestations.

SYNONYMS

Oro-labial HSV infection; cold sores; fever blisters; herpetic stomatitis.

EPIDEMIOLOGY

- Most perioral HSV infections are asymptomatic; thus, manifestations of HSV infections are apparent in a small proportion of patients who become infected.[1]
- Primary infection with HSV-1 usually occurs in infants and children.[2]
- Acquisition occurs after mucocutaneous contact between a susceptible host and a contact who is shedding the virus.
- Transmission occurs commonly from an asymptomatic individual who is shedding the virus after primary infection or after reactivation of the virus.
- Incubation period is 3 to 4 days.

ETIOLOGY AND PATHOPHYSIOLOGY

- Most infections are caused by HSV-1.
- Primary infection occurs when the virus penetrates through abraded skin or mucosal surfaces.
- HSV enters cutaneous neurons and then migrates to the sensory ganglia, where the virus replicates and then returns to the inoculation site via peripheral sensory ganglia.[3]
- Skin and mucous membrane changes are more severe following primary infection than following reactivation of the virus.
- Establishment of lifelong latency is a hallmark feature of all herpes viruses; latency is established in the trigeminal ganglia.
- Periodic reactivation of the virus occurs, resulting in spread of the virus down the neuroaxis, causing shedding of the virus and possible recurrent skin lesions.

RISK FACTORS

- Possible triggers of reactivation of HSV include stress, exposure to ultraviolet light, intercurrent infections, manipulation of nerve roots, dental manipulation, hormonal changes, and immunosuppression.

DIAGNOSIS

CLINICAL FEATURES

.. Primary infections

- Fever, irritability, and tender submandibular lymphadenopathy are common in symptomatic patients.
- Vesiculo-ulcerative lesions can occur on the palate, gingiva, tongue, lip, and face (**Figures 39-2** and **39-3**).[4]

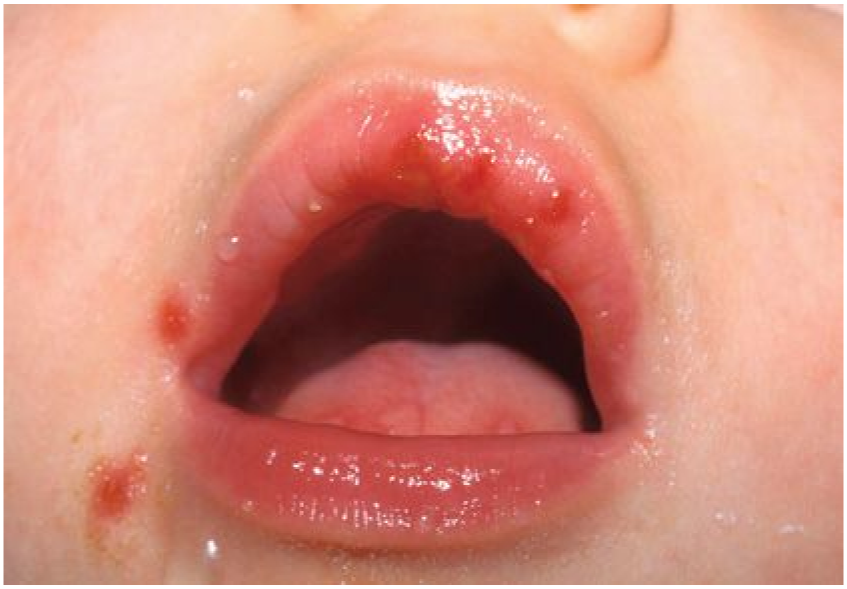

FIGURE 39-2 HSV stomatitis in an infant. Note the cluster of vesicles on the upper lip. (*Used with permission from Johanna Goldfarb, MD*.)

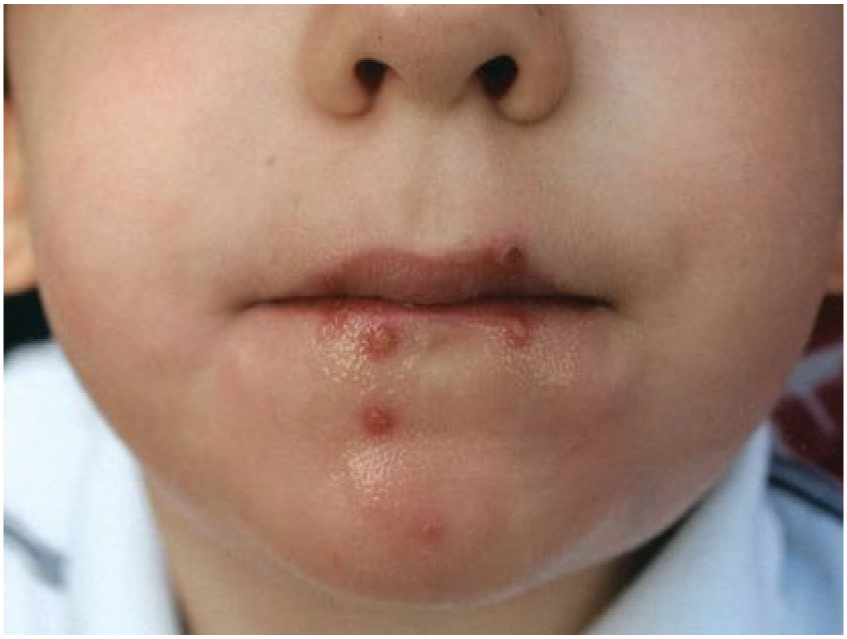

FIGURE 39-3 HSV stomatitis in a school-aged child. (*Used with permission from Camille Sabella, MD*.)

- Lesions are associated with pain and intraoral edema (**Figure 39-4**).

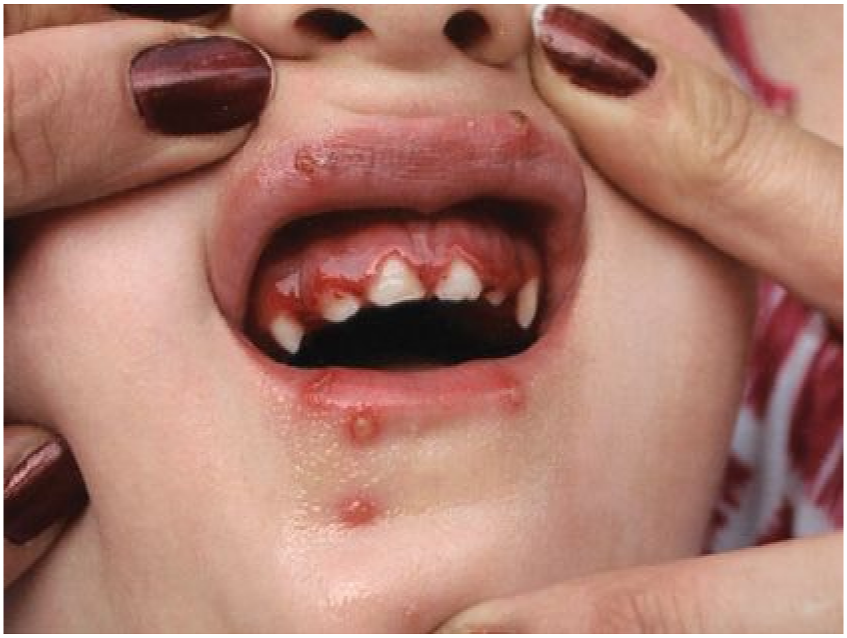

FIGURE 39-4 HSV stomatitis in the same child. Note the marked gingival edema, characteristic of a primary HSV infection. (*Used with permission from Camille Sabella, MD*.)

- Involvement of the peri-orbital area can occur via autoinoculation or as a manifestation of the primary infection (**Figure 39-5**).

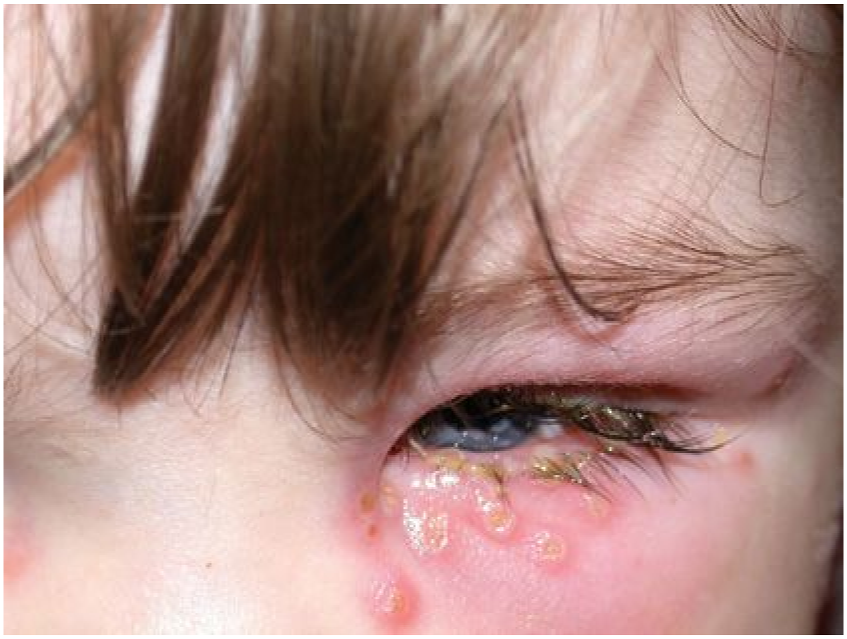

FIGURE 39-5 Periorbital vesiculo-bullous HSV lesions in a toddler. (*Used with permission from Paul Rychwalski*, *MD*.)

- Lesions evolve from vesicles to shallow ulcers on an erythematous base.
- Lesions may last 2 to 3 weeks.
- Inability to take oral liquids and solids is common.
- Most common cause of hospitalization is dehydration.
- Immunocompromised patients may have more severe involvement of the mouth and face, and may evolve into disseminated disease (**Figure 39-6**).

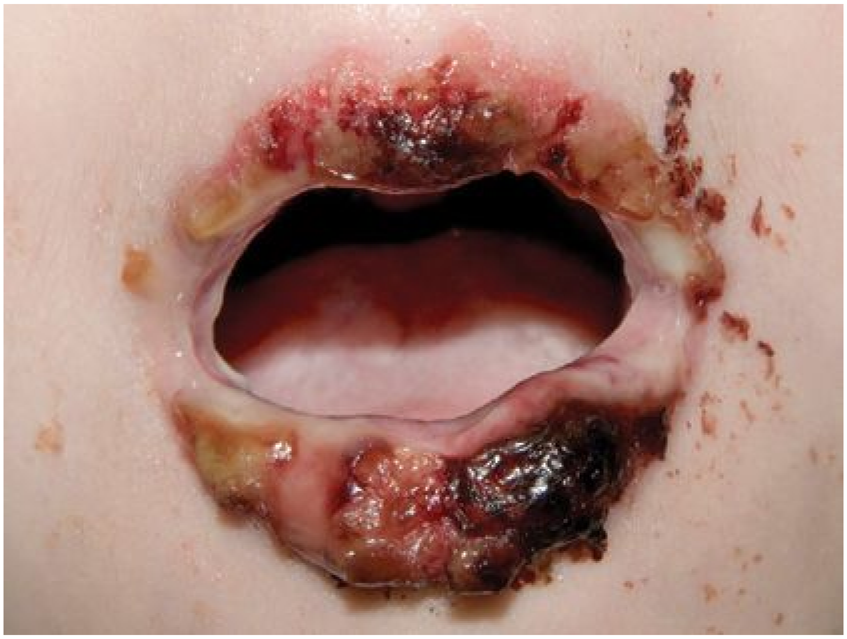

FIGURE 39-6 HSV stomatitis in a child who has acute leukemia. Note the widespread involvement of the infection. (*Used with permission from Camille Sabella, MD*.)

.. Reactivation

- Most reactivation of HSV from the trigeminal ganglia results in asymptomatic infection/shedding.
- Signs and symptoms in those who are symptomatic are mild: prodromal burning, pain, tingling may precede the eruption by 1 to 2 days.[5]
- On average, three to five lesions are present.
- Lesions begin as vesicles, evolve into pustules or ulcers in 1 to 2 days, and heal completely within 7 to 10 days.

DISTRIBUTION

- In primary infections, lesions may occur on the palate, gingival, tongue, lips, and facial areas.
- Outer edge of the vermillion border is the most common site of reactivation.

LABORATORY TESTING

- Often a clinical diagnosis based on classic signs and symptoms.
- When a virologic diagnosis is required, samples of the skin should be obtained by aspirating contents of intact skin lesions or by swabbing the base of the denuded skin lesions.
- Culture of HSV from skin lesions is the most sensitive and specific method of diagnosing an active HSV infection.[6]
- Yield of recovery of HSV by culture very high when taken from a vesicular lesions and much lower from a crusted lesion.[6]
- The average time to positive culture for HSV utilizing cytopathic effect is 2 to 5 days. However, immunofluorescent staining of tissue cell cultures can rapidly confirm the presence of HSV and distinguish between HSV-1 and HSV-2.
- Direct immunofluorescent staining of infected cells (obtained by unroofing a lesion and removing cells from the base of the lesion) is 80 to 90 percent sensitive and very specific. This can provide a rapid diagnosis.[7,8]
- A Tzank test less sensitive and specific than culture and direct immunofluorescent staining.

DIFFERENTIAL DIAGNOSIS

- Aphthous stomatitis is frequently confused with HSV; this most commonly occurs inside the mouth rather than on the lips and external to the mouth.
- Erythema multiforme/Stevens Johnson syndrome usually manifests with more systemic manifestations, such as rash and eye involvement, as well as more severe oral involvement with necrosis and sloughing of the mucosa (**Figure 39-7**). HSV is a recognized cause of erythema multiforme/Stevens Johnson syndrome.

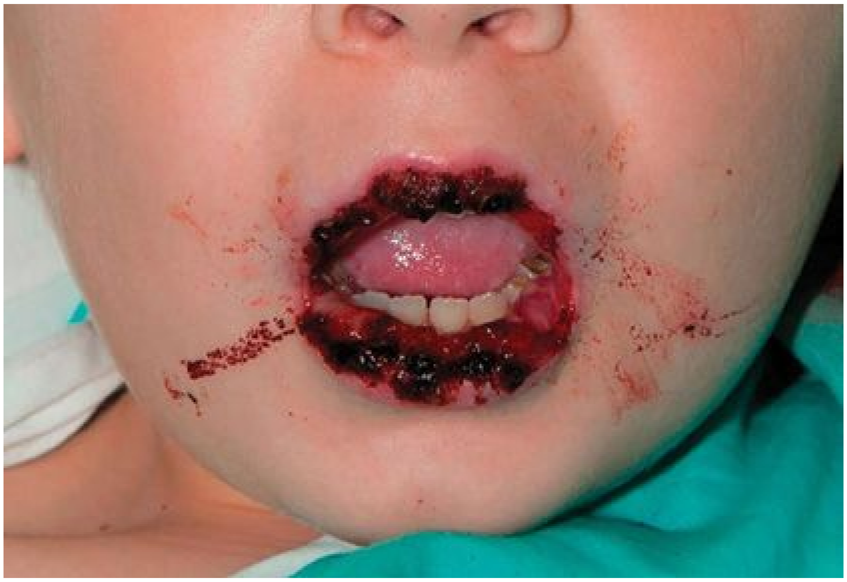

FIGURE 39-7 Stevens-Johnson syndrome, characterized by necrosis and sloughing of the mucosa. (*Used with permission from Camille Sabella, MD*.)

MANAGEMENT

MEDICATIONS

- For primary infections, oral acyclovir shortens duration of oral lesions, and results in earlier disappearance of fever, extraoral lesions, and drinking and eating difficulties.[9] SOR Ⓐ
- Some experts treat hospitalized children who have primary HSV infection with intravenous acyclovir. SOR Ⓒ
- For HSV reactivation, topical acyclovir is not effective; oral acyclovir is marginally effective in immunocompetent hosts.[10,11] SOR Ⓑ
- Prophylactic administration of oral acyclovir reduces the number of recurrences in adults with frequent recurrent orolabial HSV infection.[12–14] Pediatric studies are lacking.

REFERRAL

Healthy children who have frequent recurrences of HSV gingivostomatitis may be referred to a pediatric infectious diseases specialist to discuss possible suppressive therapy.

PROGNOSIS

- The infection is self-limited in immunocompetent hosts.
- Immunocompromised hosts have higher risk of disseminated disease.

PATIENT EDUCATION

Parents should be counseled that oral HSV infections in otherwise healthy children are benign and self-limited, are often asymptomatic, and require symptomatic care.

40 APHTHOUS ULCER

Richard P. Usatine, MD

PATIENT STORY

A 5-year-old girl is in her pediatrician's office for her school physical and immunizations when her mother asks about her child's complaint of mouth pain. The girl is otherwise healthy and on physical examination a small round ulcer is seen on the nonkeratinized mucosa above the upper teeth (**Figure 40-1**). The necrotic center with slightly raised borders and surrounding erythema were easily recognized features of an aphthous ulcer. The pediatrician reassured the mother that this will go away spontaneously without medication or treatment. She suggested to avoid giving the child acidic or spicy foods in the coming days and to be careful to not traumatize the ulcer further with vigorous toothbrushing.

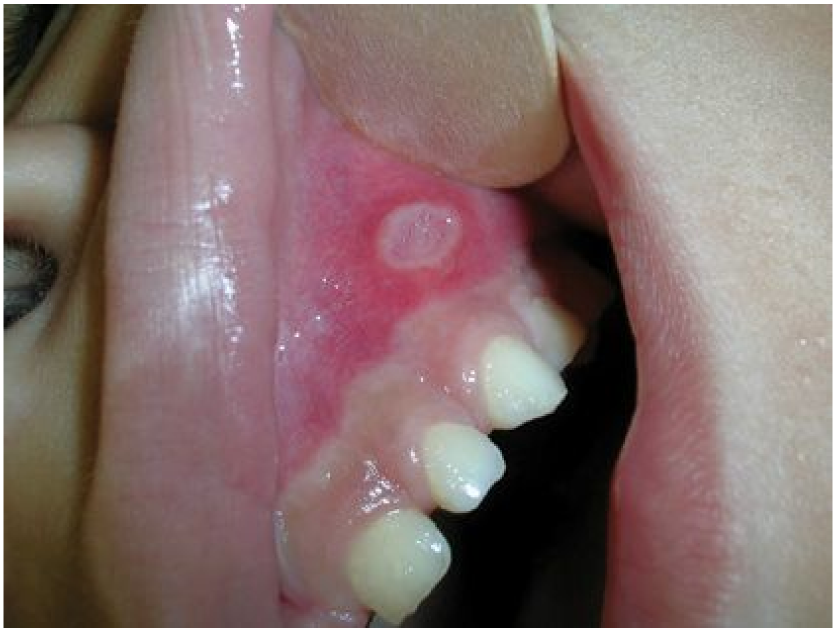

FIGURE 40-1 Aphthous ulcer located on unkeratinized (movable) mucosa in a 5-year-old girl. It is slightly raised, round, with a white-yellow necrotic center and surrounding erythema. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Aphthous ulcers are painful ulcerations in the mouth, which can be single, multiple, occasional, or recurrent. These ulcers can be small or large but are uniformly painful and may interfere with eating, speaking, and swallowing. Oral trauma, stress, and systemic diseases can contribute to the occurrence of these ulcers but no precise etiology is apparent. Recurrent aphthous stomatitis (RAS) is a frustrating condition that merits aggressive treatment aimed at pain relief and prevention.

SYNONYMS

Canker sores, aphthous stomatitis, aphthae, recurrent aphthous ulcer (RAU), or recurrent aphthous stomatitis (RAS).

EPIDEMIOLOGY

- Twenty percent of the general population are reported to have aphthous ulcers.[1]
- One and 1/2 percent of children and adolescents have been reported to have RAUs.[2]
- RAS is more common in females, in people younger than age 40 years, in whites, in nonsmokers, and in people of high socioeconomic status.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- The precise etiology and pathogenesis of this condition remains unknown, although a variety of host and environmental factors have been implicated.
- A positive family history is seen in about 1/3 of RAS patients. A genetic predisposition is suggested by an increased frequency of HLA types A2, A11, B12, and DR2.[2]
- In one study, Th1 (T-helper subtype 1) activation was more intense in the patients with RAUs. Many conditions that increase the incidence of RAUs, such as psychologic stress, NSAIDs, Crohn disease, and celiac disease, also shift the immune response toward the Th1 subtype. Conditions and medications that inhibit the Th1 immune response pathway, such as pregnancy, thalidomide, glucocorticoids, and tetracycline, decrease the incidence of RAUs.[3]
- Another study found a significantly higher-than-normal serum level of tumor necrosis factor (TNF)-α in 20 to 39 percent of patients in the ulcerative stage of RAUs.[3] Medications that have anti–TNF-a effects, such as pentoxifylline, levamisole, and thalidomide, have also been found to be useful in the treatment of RAUs.[2–4]
- Although studies show that there are active immune mechanisms associated with RAUs, there is still much to learn regarding their etiology and pathogenesis.

RISK FACTORS

- Oral trauma.
- Stress and anxiety.
- Systemic diseases (celiac disease, Crohn disease, Behçet syndrome, HIV, or reactive arthritis).

- Medications (NSAIDs, β-blockers, or angiotensin-converting enzyme inhibitors [ACEIs]).
- Vitamin deficiencies (zinc, iron, B_{12}, or folate).
- Food and chemical sensitivities.

DIAGNOSIS

CLINICAL FEATURES

History:

- Symptoms may begin with a burning sensation and the pain is exacerbated by moving the area affected by the ulcer.
- Eating often hurts, especially foods and drinks with a high acidic content.
- Ask about recurrences and onset in relation to the use of medications.
- Ask about GI symptoms, genital ulcers, HIV risk factors, and joint pain.

Physical:

- Three clinical variations are described based on the size of the ulcers:
  1. Minor (3 to 10 mm) (**Figure 40-1**)—most common.
  2. Major (>10 mm) (**Figure 40-2**).

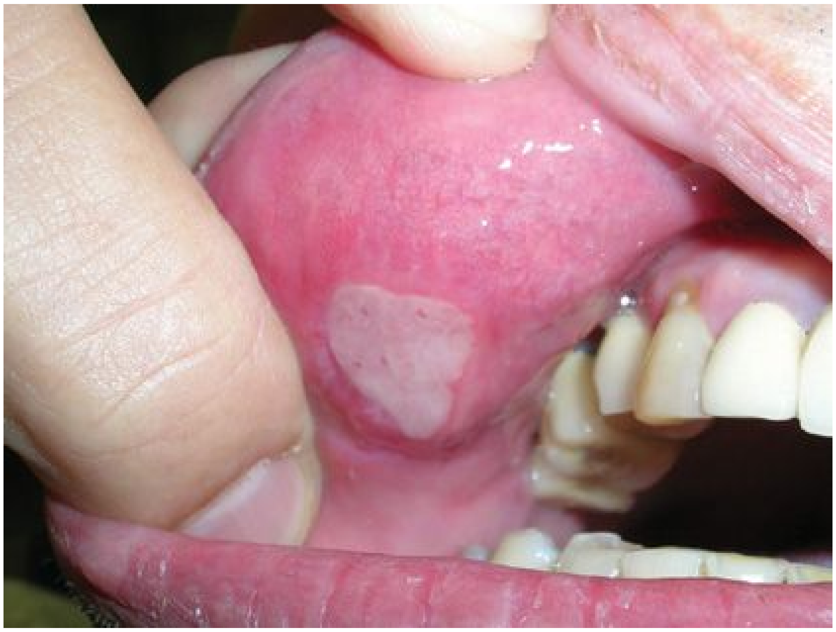

FIGURE 40-2 Major aphthous ulcer on the buccal mucosa of a man who has been suffering with recurrent aphthous stomatitis for the past year. (*Used with permission from Richard P. Usatine, MD.*)

3. Herpetiform (<3 mm and multiple ulcers)—least common.

- The most common minor form appears as rounded, well-demarcated, single, or multiple ulcers less than 1 cm in diameter that usually heal in 10 to 14 days without scarring.
- Herpetiform aphthae usually do not present until the second or third decade of life.[1]
- The ulcers are solitary or multiple covered by a gray or tan pseudomembrane and surrounded by an erythematous halo (**Figure 40-1**).

TYPICAL DISTRIBUTION

Aphthous ulcers usually involves nonkeratinizing mucosa (e.g., labial mucosa, buccal mucosa, or ventral tongue) (**Figure 40-3**). Aphthous ulcers spare the attached gingiva and the hard palate (nonmovable mucosa). Aphthous ulcers can even appear adjacent to the tonsillar mucosa (**Figure 40-4**).

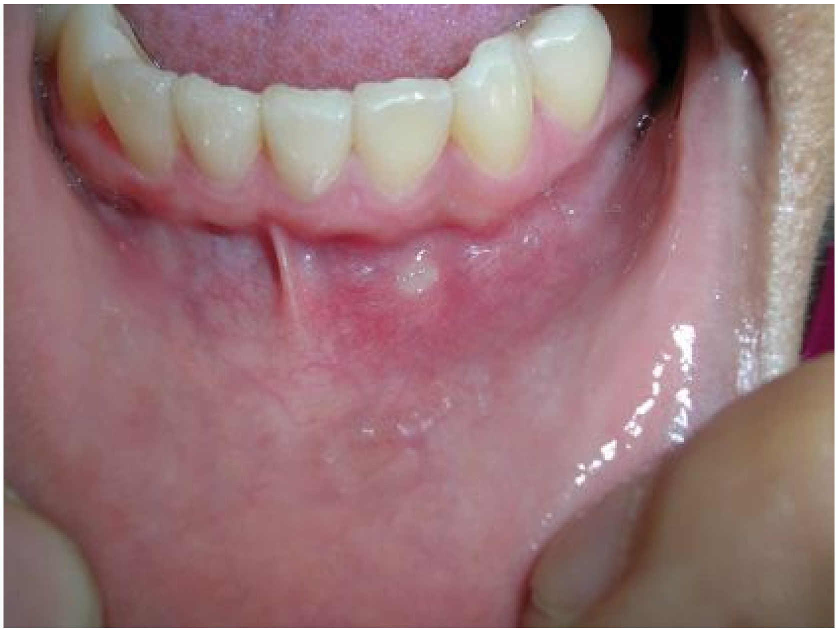

FIGURE 40-3 One small aphthous ulcer on the lower labial movable mucosa of a child. (*Used with permission from Richard P. Usatine, MD*.)

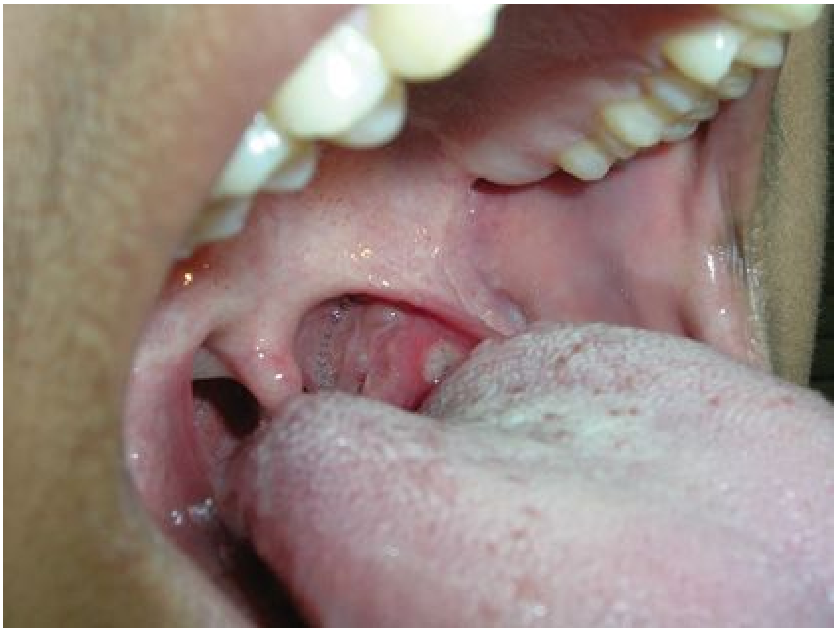

FIGURE 40-4 Aphthous ulcer near the tonsillar mucosa in a young boy with a sore throat. (*Used with permission from Richard P. Usatine, MD*.)

CLASSIFICATION

Simple aphthosis—Aphthae are few at a time, not associated with systemic diseases, and occurs only 2 to 4 times per year.

Complex aphthosis—Aphthae are associated with systemic diseases, there are many lesions at one time, which can include genital aphthous ulcers, or there is a continuous disease activity with new ulcers developing as older lesions heal or the ulcers recur more often than 4 times per year. Behçet disease is one example of a complex aphthosis.

LABORATORY TESTS

The diagnosis of a single episode of aphthous ulcers is usually based on history and physical examination. If there is RAS, consider complete blood count (CBC), ferritin, B_{12}, folate, erythrocyte sedimentation rate (ESR), viral culture, biopsy, and/or HIV testing, if indicated. If there is evidence of malabsorption, consider testing for celiac disease (see Chapter 60, Celiac Disease).

DIFFERENTIAL DIAGNOSIS

- Primary oral herpes simplex virus (primary gingivostomatitis)—Begins as vesicular lesions, which quickly ulcerate on all mucosal lesions in the mouth. It is accompanied by systemic manifestations such as fever, malaise, anorexia, and sore throat. The ulcers are located on movable and nonmovable oral mucosa (includes attached gingiva and hard palate). Lesions may also appear on keratinized surfaces such as the lip (see Chapter 39, HSV Gingivostomatitis and Chapter 114, Herpes Simplex).
- Hand, foot, and mouth disease presents as mucocutaneous lesions involving the hand, foot, and mouth caused by enterovirus. Any area of oral mucosa may be involved. Lesions resolve within 1 week (see Chapter 113, Hand Foot, and Mouth Disease).
- Herpangina causes multiple ulcers in the mouth, especially on the soft palate and the anterior fauces (**Figure 29-9**). It is caused by coxsackievirus

A16 in most cases. The distribution of the ulcers is different than in aphthous ulcers.

- Thrush—White plaque, when removed, appears red. Scrape the white plaque with a tongue depressor and add KOH to the slide and the preparation will be positive for pseudohyphae and/or budding yeast (see Chapter 121, Candidiasis).
- Erythema multiforme (EM)—Mucocutaneous lesion preceeded by infection of herpes simplex virus (HSV), *Mycoplasma pneumoniae*, or exposure to certain drugs or medications. Oral lesions begin as patches and evolve into large shallow erosions and ulcerations with irregular borders. Common sites include the lip, tongue, buccal mucosa, floor of the mouth, and soft palate. The presence of targetoid skin lesions should help differentiate EM from RAS (see Chapter 151, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).
- Behçet disease was originally characterized by three conditions: 1) recurrent oral aphthous ulcers (**Figure 40-5**), 2) genital ulcers, and 3) uveitis. The aphthous ulcers appear no different from those found in people without Behçet disease. The recurrent genital ulcers are painful and heal with scarring. Diagnosis is now based on agreed clinical criteria that require recurrent oral ulcers and two of the following: recurrent genital ulcers, ocular inflammation, defined skin lesions, and pathergy.[5] Behçet disease is a type of complex aphthosis. If Behçet disease is suspected, refer the patient to an ophthalmologist to look for signs of uveitis or retinal vasculitis. Behçet disease is a multi-system vasculitis and referral to a rheumatologist may also be helpful (see Chapter 75, Mucosal Ulcerative Disorders).

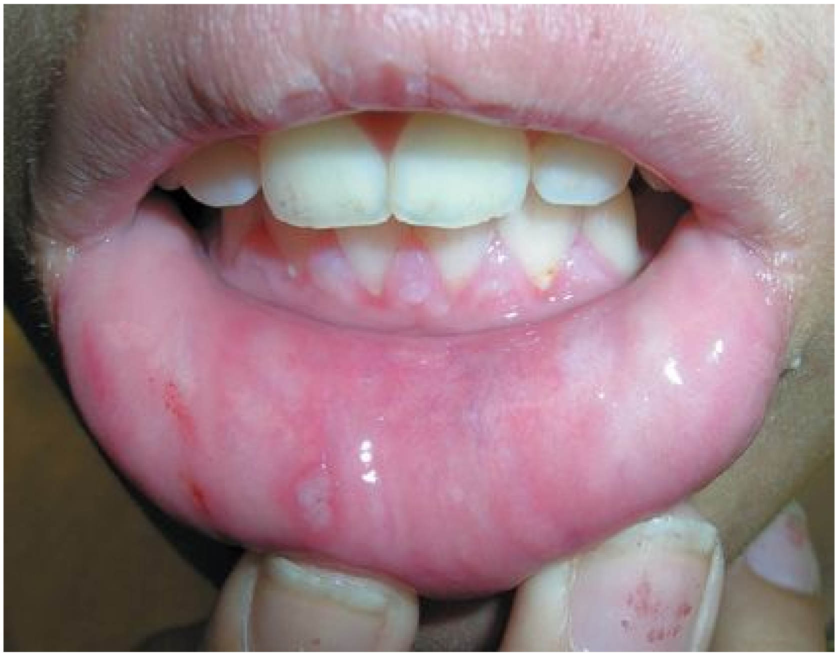

FIGURE 40-5 Behçet disease characterized by recurrent oral and genital ulcers in a 17-year-old girl. (*Used with permission from Richard P. Usatine, MD*.)

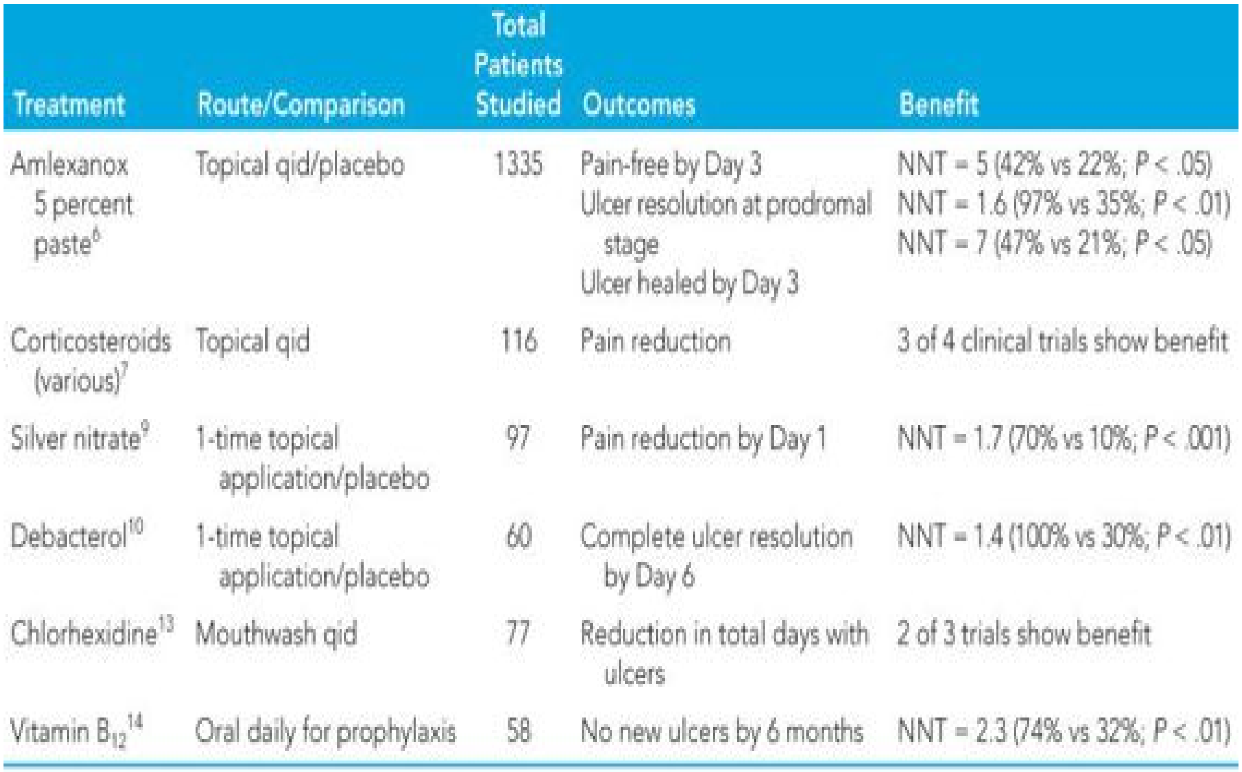
- PFAPA syndrome (periodic fever, aphthae, pharyngitis, and adenitis) is also a complex aphthosis condition with systemic symptoms and multiple areas of involvement (see Chapter 176, Periodic Fever Syndromes).

MANAGEMENT

Identify and treat any vitamin deficiency, systemic disease, or recurrent oral trauma. Stress management is reasonable for all persons. See **Table 40-1** for an evidence-based summary of treatments.

TABLE 40-1 Evidence-based Summary of Treatments



Treatment	Route/Comparison	Total Patients Studied	Outcomes	Benefit
Amlexanox 5 percent paste[6]	Topical qid/placebo	1335	Pain-free by Day 3 Ulcer resolution at prodromal stage Ulcer healed by Day 3	NNT = 5 (42% vs 22%; $P < .05$) NNT = 1.6 (97% vs 35%; $P < .01$) NNT = 7 (47% vs 21%; $P < .05$)
Corticosteroids (various)[7]	Topical qid	116	Pain reduction	3 of 4 clinical trials show benefit
Silver nitrate[9]	1-time topical application/placebo	97	Pain reduction by Day 1	NNT = 1.7 (70% vs 10%; $P < .001$)
Debacterol[10]	1-time topical application/placebo	60	Complete ulcer resolution by Day 6	NNT = 1.4 (100% vs 30%; $P < .01$)
Chlorhexidine[13]	Mouthwash qid	77	Reduction in total days with ulcers	2 of 3 trials show benefit
Vitamin B_{12}[14]	Oral daily for prophylaxis	58	No new ulcers by 6 months	NNT = 2.3 (74% vs 32%; $P < .01$)

Adapted from: Bailey J, McCarthy C, Smith RF. Clinical inquiry. What is the most effective way to treat recurrent canker sores? *J Fam Pract.* 2011;60:621-632. With permission from Frontline Medical Communications.

NONPHARMACOLOGIC

Most isolated aphthae require no treatment or only periodic topical therapy.

MEDICATIONS

- Amlexanox 5 percent paste (Aphthasol) reduces ulcer size, pain duration, and healing time.[6] It is nonprescription and the paste is applied directly to ulcers four times a day until ulcers heal.[6] SOR Ⓑ
- Topical corticosteroids, such as clobetasol gel or fluocinonide gel, can promote healing and lessen the severity of RAS.[7] Patients should be instructed to dab the area of ulcer dry, apply the gel, paste, or cream after rinsing, and avoid eating or drinking for at least 30 minutes. SOR Ⓑ
- Lidocaine 1 percent cream applied to aphthous ulcers was found to reduce pain intensity compared to the placebo cream.[8] SOR Ⓑ

- Silver nitrate cautery can lessen the pain of an aphthous ulcer with a single application. The application is painful and probably would only be acceptable to a teen wanting immediate relief of the pain. This must be performed by the physician in the office. The time to healing does not change.[9]
- Debacterol is another topical agent that reduces pain in one day and requires a prescription. It is also painful on application so its use is limited.[10]

COMPLEMENTARY AND ALTERNATIVE THERAPY

Vitamin C was shown to reduce the frequency of minor RAS and the severity of pain by 50 percent in a small group of teens. They were given 2000 mg/m^2 per day of ascorbate.[11]

REFERRAL

Consider referring children with periodic fever with aphthous stomatitis, pharyngitis, and adenitis (PFAPA) syndrome for tonsillectomy or adenotonsillectomy. A meta-analysis found little evidence to support surgery, but the authors concluded that surgery is an option when symptoms markedly interfere with the child’s quality of life and medical treatment has failed.[12] SOR C

PREVENTION

- Chlorhexidine mouth rinse was shown to reduce the total days with recurrent aphthous ulcers in two of three studies.[13] SOR B
- Oral vitamin B_{12} was studied in a RCT of adults. A sublingual dose of 1000 mcg of vitamin B_{12} was used by patients in the intervention group for 6 months. During the last month of treatment more participants in the

intervention group reached a status of “no aphthous ulcers” (74.1% vs. 32.0%; $P < 0.01$). The treatment worked regardless of the serum vitamin B_{12} level.[14] SOR B This could be used as a treatment in older and/or adult-size teens.

PATIENT EDUCATION

Foods that are spicy or acidic worsen pain and should be avoided during outbreaks. Recommend the use of a soft bristled toothbrush as trauma from a firm toothbrush could precipitate an aphthous ulcer.

41 CLUBBING AND CYANOSIS

Danyal Thaver, MBBS
Athar M. Qureshi, MD

PATIENT STORY

A 9-year-old boy from rural Asia was brought to the clinic by his parents for complaints of being tired and “blue.” Further history reveals that he has had frequent episodes of squatting after exertion which relieves some of the symptoms temporarily. On exam, he has clubbing of the fingers and toes with cyanosis of the lips and oral mucous membranes (**Figure 41-1**). A harsh systolic ejection murmur is best heard at the left mid and upper sternal border. An echocardiogram confirms the diagnosis of tetralogy of Fallot.

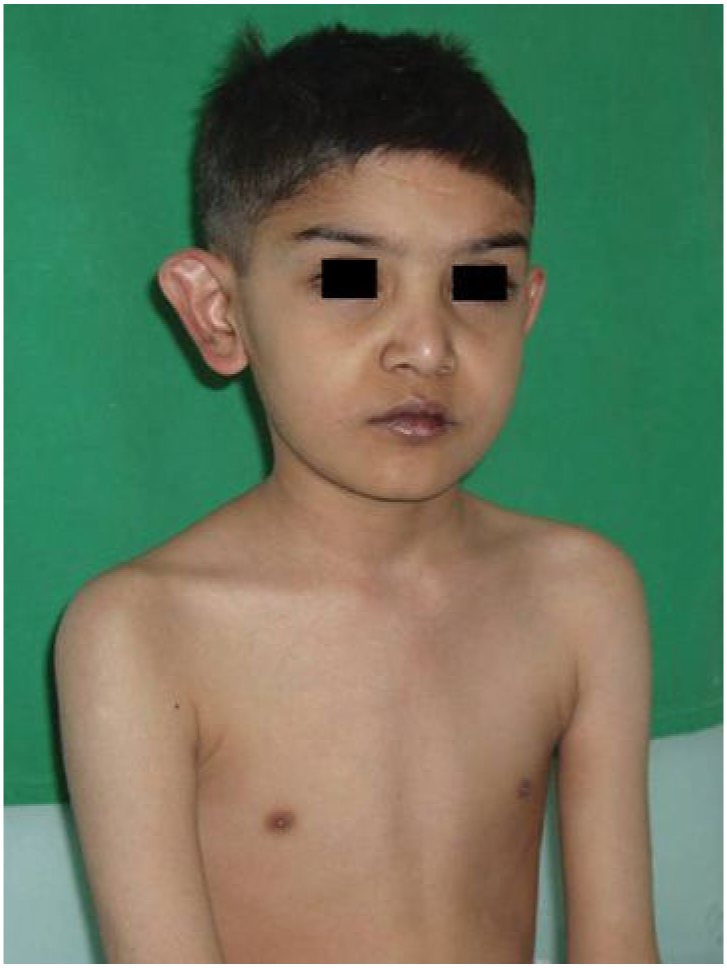

FIGURE 41-1 Central cyanosis of the lips in this 9-year-old boy with unrepaired Tetralogy of Fallot. (*Used with permission from Athar M. Qureshi, MD*.)

INTRODUCTION

Clubbing is the enlargement of the distal fingers or toes along with the formation of convex shaped fingernails or toenails.

Cyanosis is the bluish discoloration of the skin or mucous membranes due to increased quantity of deoxyhemoglobin in the blood. Unless otherwise specified, cyanosis in this chapter refers to central cyanosis.

SYNONYMS

Clubbing: Hypertrophic osteoarthropathy.
Cyanosis: Central cyanosis or hypoxemia.

EPIDEMIOLOGY

- Clubbing and cyanosis are disease manifestations seen worldwide and their incidence is difficult to discern.
- Chronic cyanosis as a result of unrepaired congenital heart disease is seen mainly in developing nations.

ETIOLOGY AND PATHOPHYSIOLOGY

- The exact etiology of clubbing is unknown. However, it has been hypothesized that it may result from megakaryocytes that have bypassed the pulmonary vascular bed and entered the systemic circulation or from platelet clumps that form and/or enter the systemic circulation. They then release platelet-derived growth factor causing clubbing.[1,2]
- A right to left cardiac shunt or significant lung disease easily allows platelets to bypass the lungs and hence cause clubbing. Conditions that result in platelet excess, that is, inflammatory bowel disease, may also result in clubbing.
- Cyanosis occurs due to reduced capillary blood oxygen saturation and becomes apparent when deoxyhemoglobin in the blood exceeds a value of 3 to 5 g/dL (corresponding arterial saturations of 70 to 85 percent).[3]

RISK FACTORS

► Clubbing

- Lung disease including chronic infections or malignancies.
- Cyanotic congenital heart disease (most common cause in children), endocarditis.
- Chronic gastrointestinal disorders, i.e., inflammatory bowel disease, liver cirrhosis.
- Hereditary.

► Cyanosis

- Cyanotic heart disease.
- Lung disorders.

DIAGNOSIS

CLINICAL FEATURES

► Clubbing

- Fluctuation and softening of the nail bed can be appreciated early. Enlargement of the distal segments of affected extremities that is usually painless develops (**Figures 41-2** and **Figure 41-3**).

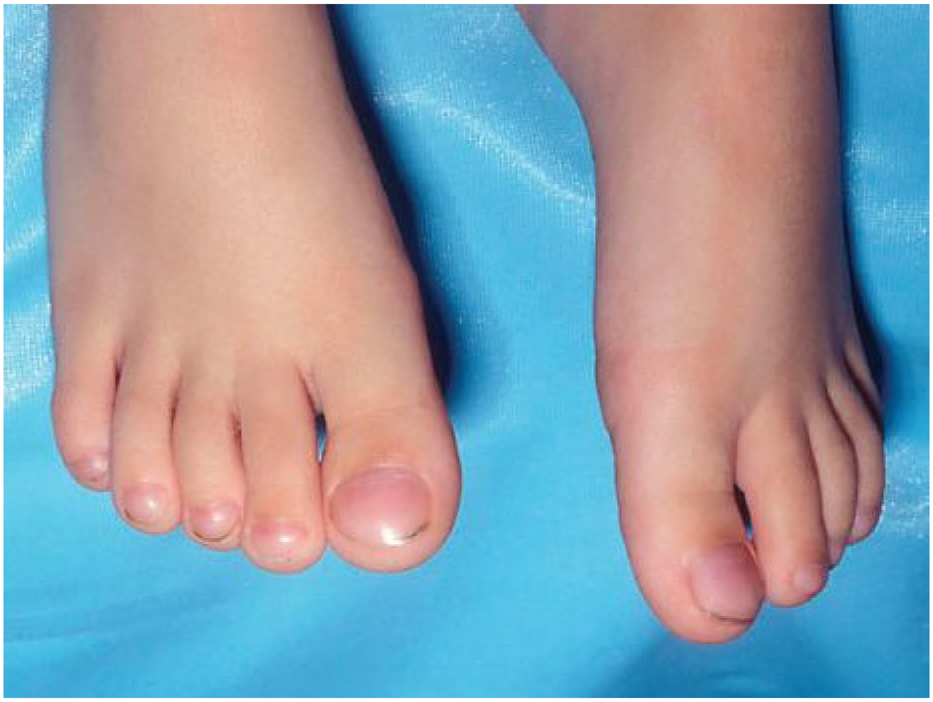

FIGURE 41-2 Clubbing of the toes in this 3.5 year old with severe immune deficiency and chronic lung disease—note the convex shaped toenails. (*Used with permission from Johanna Goldfarb, MD*.)

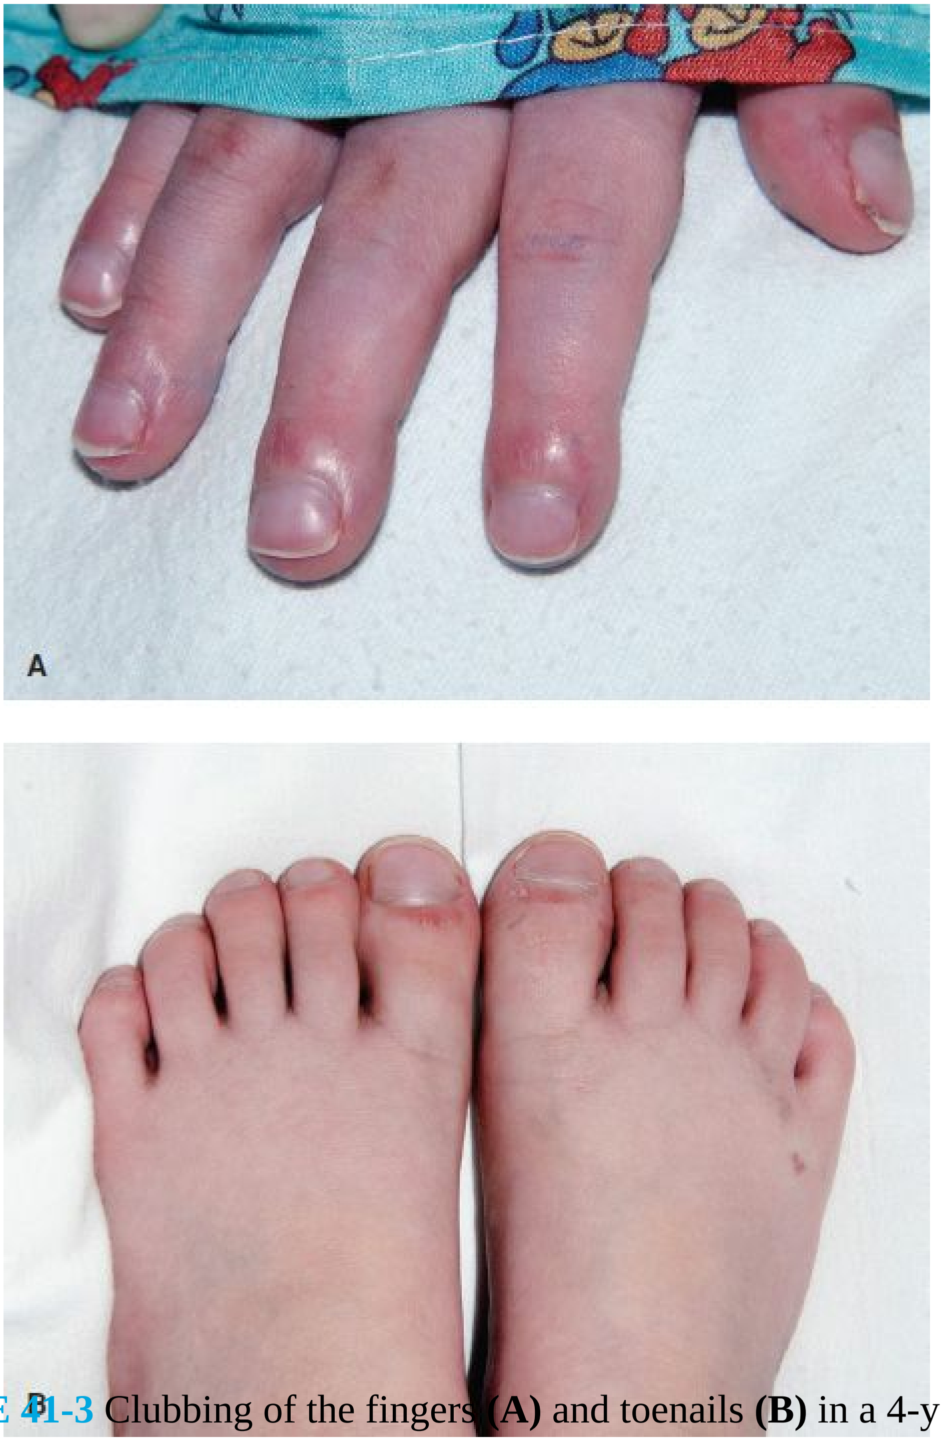

FIGURE 41-3 Clubbing of the fingers **(A)** and toenails **(B)** in a 4-year-old with cyanotic heart disease consisting of tricuspid atresia and a Glenn circulation. As opposed to the child in **Figure 41-2**, note the cyanotic nail beds. (*Used with permission from Athar M. Qureshi, MD*.)

- Reduction in the angle between the nail plate and the finger. When the nail beds of corresponding right and left digits are opposed, the diamond-shaped space is obliterated ("Schamroth sign") (**Figure 41-4**).

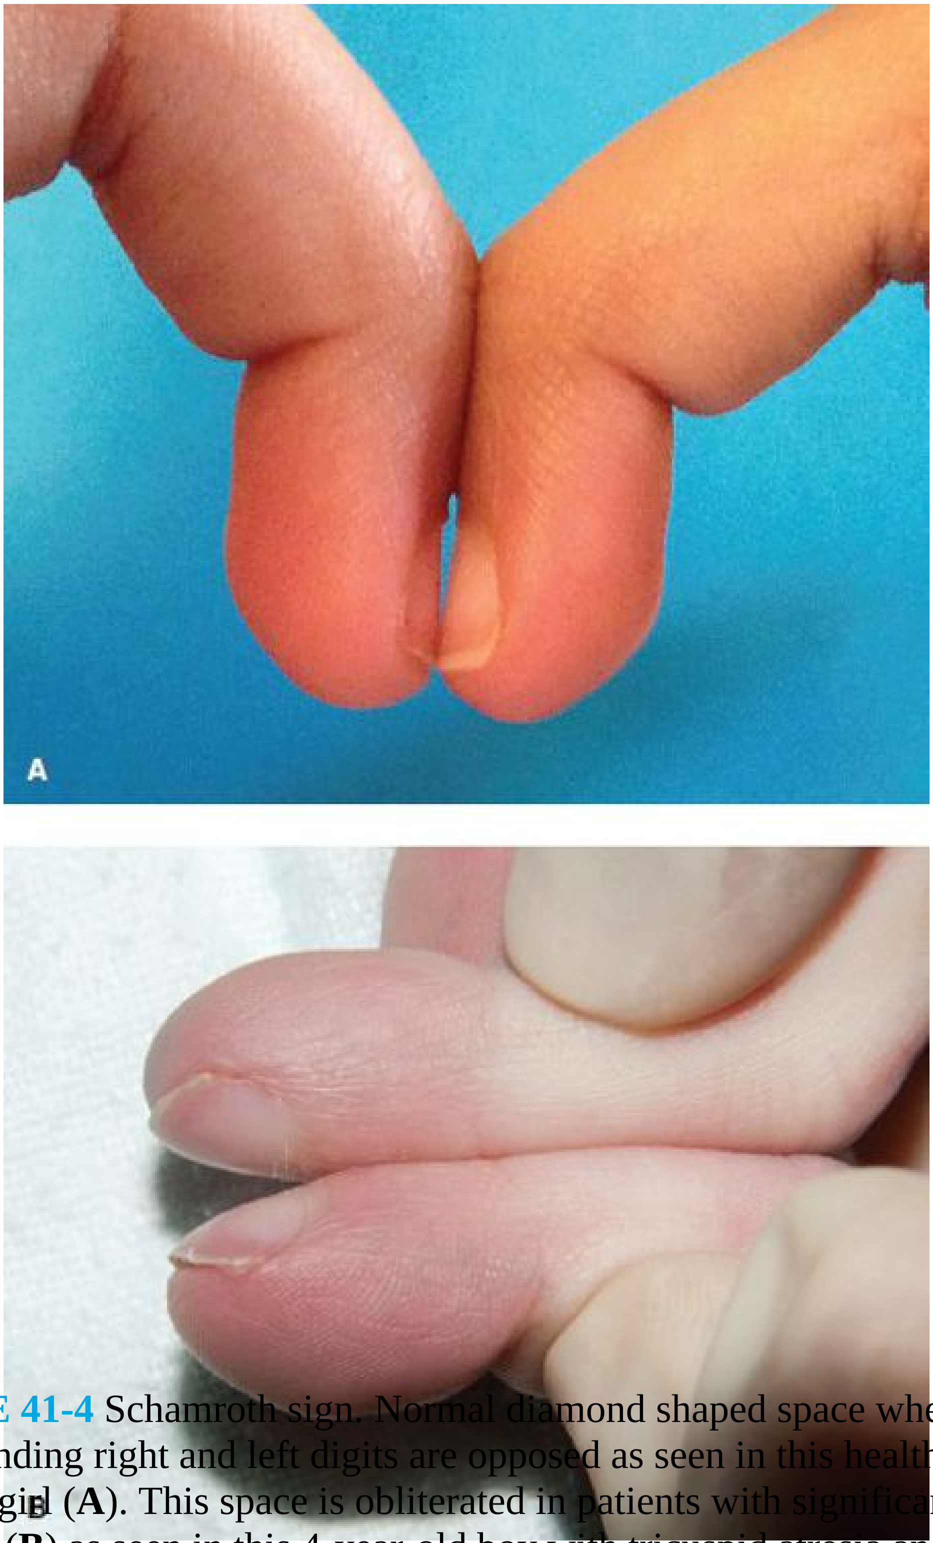

FIGURE 41-4 Schamroth sign. Normal diamond shaped space when corresponding right and left digits are opposed as seen in this healthy 6-year-old girl (**A**). This space is obliterated in patients with significant clubbing (**B**) as seen in this 4-year-old boy with tricuspid atresia and a Glenn circulation. (*Used with permission from Athar M. Qureshi, MD*.)

- In later stages, distal segments of the digits may develop a typical "drumstick" appearance (**Figure 41-5**).

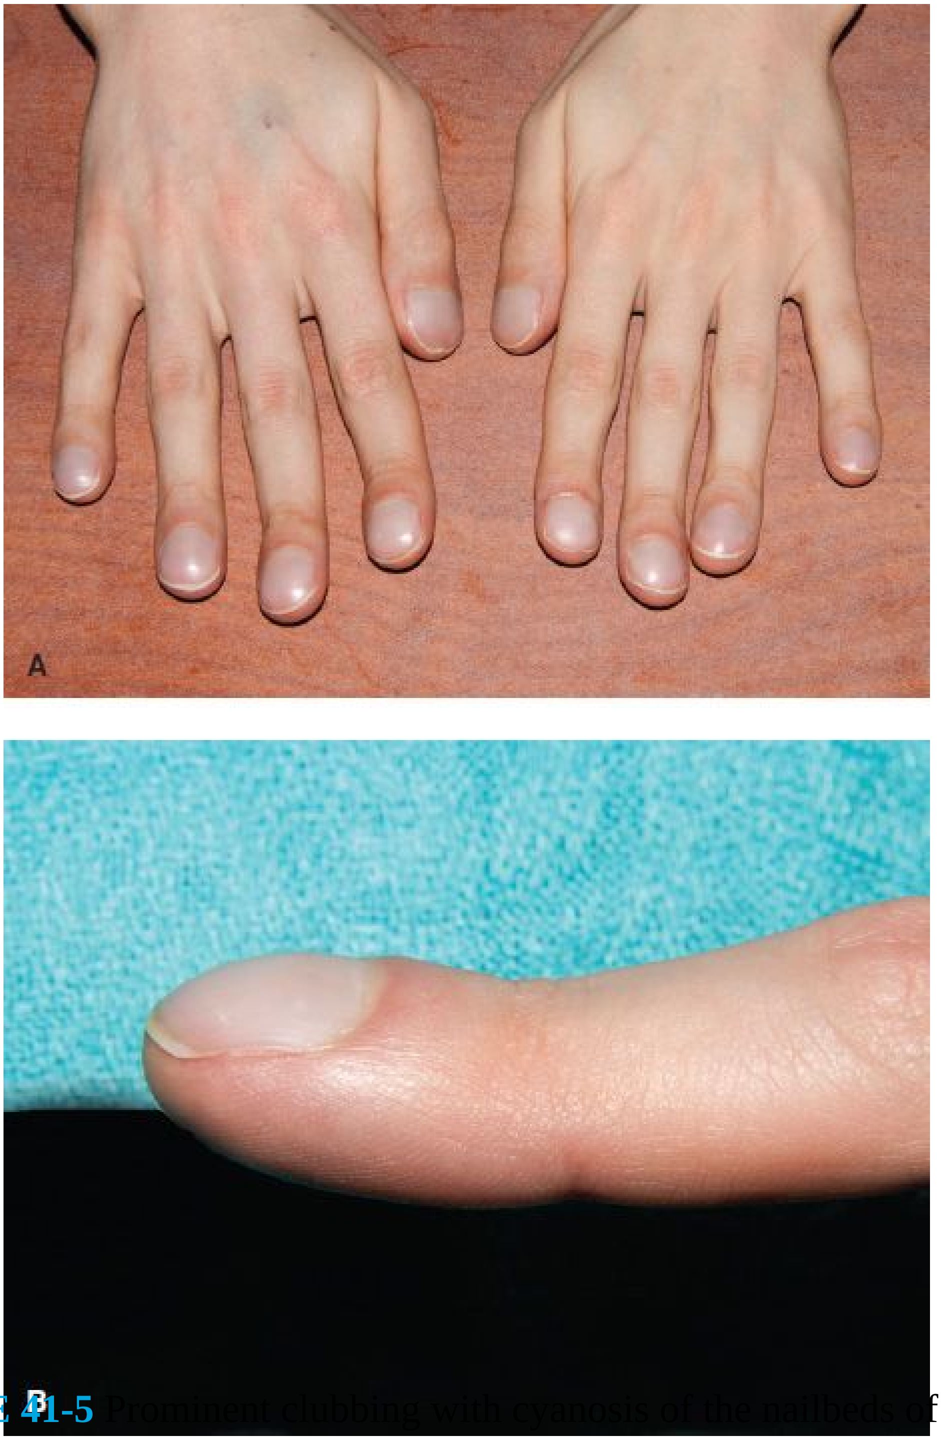

FIGURE 41-5 Prominent clubbing with cyanosis of the nailbeds of the hands is seen in this 25-year-old with uncorrected cyanotic congenital heart disease (**A**). Drumstick like appearance of an index finger can be seen in a side profile view (**B**). (*Used with permission from Athar M. Qureshi, MD*.)

► Cyanosis

- Patients have symptoms such as dyspnea or fatigue.
- Oxygen saturations are low.
- A thorough examination should be performed seeking an etiology based on common risk factors (see the previous section).

DISTRIBUTION

- Clubbing is present in distal segments of fingers and toes.
- In patients with central cyanosis, bluish discoloration is most evident in the nail beds, lips (**Figure 41-1**), and mucous membranes of the oral cavity or conjunctivae.

LABORATORY TESTING

- Systemic oxygen saturation should be measured. A congenital heart disease is strongly suggested if the oxygen saturation (and $_pO2$) does not significantly increase.
- Methemoglobin levels should be obtained if methemoglobinemia is suspected.

IMAGING

- The need for imaging depends on suspected etiology.
- A chest x-ray should be performed to detect any cardiac or lung disease. A chest CT or MRI may then be ordered if necessary.
- Echocardiography helps the diagnosis of unrepaired congenital cardiac defects.
- Abdominal imaging including ultrasound and endoscopy may be needed for gastrointestinal causes.

DIFFERENTIAL DIAGNOSIS

▶ Clubbing

- See risk factors.

▶ Cyanosis

- Hemoglobin abnormalities, for example, methemoglobinemia. In this condition, (congenital or acquired) cyanosis and low saturations are present with a normal $_{p}O2$.
- Peripheral cyanosis or “acrocyanosis” (sparing of mucous membranes) is due to sluggish blood flow and may occur with normal arterial blood saturation. This occurs in the extremities of babies due to vasospasm when they are cold and is usually transient. (see Chapter 4, Birth of a Child, Figure 4-1).
- Circumoral cyanosis occurs around the lips due to prominent veins. Prominent veins can also be seen on the forehead giving the impression of cyanosis. This is a benign finding.

MANAGEMENT

Definitive treatment of both clubbing and cyanosis is to treat the underlying cause.

NONPHARMACOLOGIC

- Supplemental oxygen if hypoxemia is the cause of cyanosis.
- Patients who develop Eisenmenger’s syndrome (as a result of irreversible pulmonary hypertension from an unrepaired congenital cardiac defect

causing a right to left shunt) or who have chronic cyanosis from other reasons are at increased risk of polycythemia.[4]

- Phlebotomies may be needed to treat hyperviscosity, although this may result in iron deficiency.

MEDICATIONS

Medications, as appropriate, are used to treat the underlying cause.

SURGERY

- A variety of surgical procedures may be indicated depending on the cause.
- Surgery (or cardiac interventional catheterization procedures) may be indicated to repair congenital heart defects (as long as irreversible pulmonary hypertension is not present).
- Surgery may be indicated for lung pathology (i.e., resection of lung tumors) and for treatment of inflammatory bowel disease. Liver transplant may be needed for end stage liver cirrhosis.

REFERRAL

Referrals to a cardiologist, pulmonologist, gastroenterologist and other specialists may be required depending on the etiology.

PREVENTION AND SCREENING

- Early diagnosis of cardiac, pulmonary, gastrointestinal, or other chronic diseases.
- Fetal ultrasounds may detect cardiac lesions in utero.

PROGNOSIS

Prognosis depends on the underlying condition and symptoms may be reversed by treating the cause early in the disease course.

FOLLOW-UP

These patients need frequent follow-up visits due to the chronic nature of their underlying illnesses.

PATIENT EDUCATION

Patients should be educated about the implications of chronic cyanosis and polycythemia, that is, potential cerebrovascular accidents or brain abscess formation in cardiac lesions with right to left shunts.

42 ACYANOTIC CONGENITAL HEART DISEASE

Asif Padiyath, MD
Peter Aziz, MD

The three most important and common types of acyanotic congenital heart disease are:

- Atrial septal defect.
- Ventricular septal defect.
- Patent ductus arteriosus.

All three conditions are covered sequentially in this chapter.

ATRIAL SEPTAL DEFECT

PATIENT STORY

A 4-year-old recent immigrant from Nicaragua presents to her pediatrician for a well-child examination. She does not have any significant past medical history. On examination, she was found to have a normodynamic precordium, widely split and fixed S2 and a grade 2/6 systolic ejection murmur in the pulmonary auscultation area. She is diagnosed with an atrial septal defect (ASD) (**Figure 42-1**).

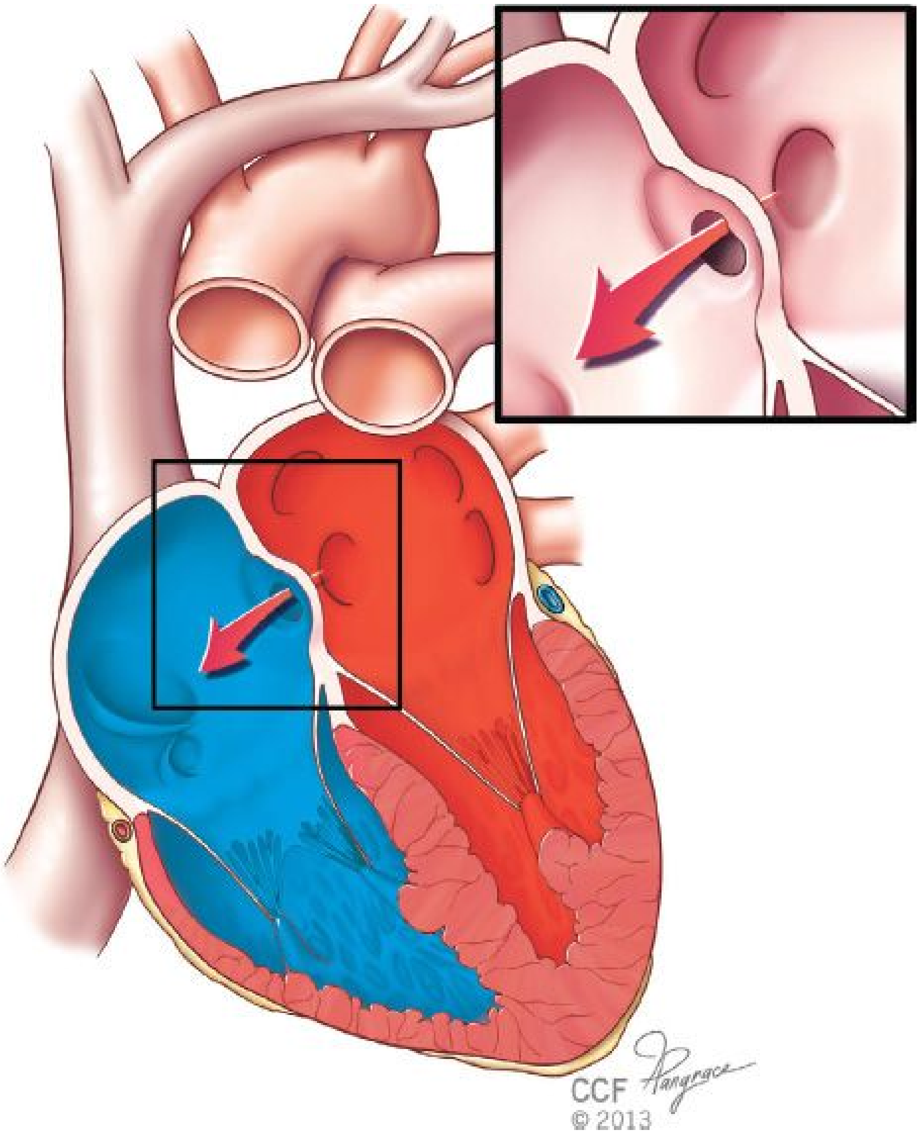

FIGURE 42-1 Atrial septal defect with flow from the left atrium to the right atrium as depicted by the red arrow. (*Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2012. All Rights Reserved*.)

INTRODUCTION

Any opening in the atrial septum is described as an ASD. Although many of these defects close spontaneously, early diagnosis and follow-up is essential in preventing sequelae from undiagnosed ASD’s.

EPIDEMIOLOGY

- Atrial septal defects (ASD) account for 10 percent of all congenital heart disease and as much as 20 to 40 percent of congenital heart disease presenting in adulthood.[1,2]

ETIOLOGY AND PATHOPHYSIOLOGY

- There are three major types of atrial septal defects.
  - Ostium secundum defect is the most common type of ASD. It results from incomplete adhesion between the flap valve associated with the foramen ovale and the septum secundum after birth. It also includes patent foramen ovale, which results from abnormal resorption of the septum primum during the formation of the foramen secundum.
  - Ostium primum defects are the second most common type of ASD. This is a form of atrioventricular septal defect and is commonly associated with mitral valve abnormalities. These defects are caused by incomplete fusion of septum primum with the endocardial cushion.
  - Sinus venosus defect is the least common of the three. The defect is located along the superior (SVC type) or inferior (IVC type) aspect of the atrial septum. Anomalous connection of the right-sided pulmonary veins is common and should be expected in the SVC type. Abnormal fusion between the embryologic sinus venosus and the atrium causes these defects.
    - A clinically significant moderate to large defect, if undiagnosed and untreated, can cause enlargement of right atrium and right ventricle.
    - Dilation of the right atrium can also lead to the development of atrial arrhythmias.
    - Older patients may develop pulmonary vascular disease leading to Eisenmenger syndrome, which is the most significant long-term complication of an ASD.

RISK FACTORS

- ASDs may occur on a familial basis.
- Holt-Oram syndrome and Ellis van Creveld syndrome are associated with ASDs.

DIAGNOSIS

CLINICAL PRESENTATION

- ASD can go undiagnosed for decades due to subtle physical examination findings and lack of symptoms.
- Defects which are even moderate-to-large typically do not cause symptoms in childhood as in the previous vignette described.
- Some patients however may manifest symptoms of easy fatigability, recurrent respiratory infections, or exertional dyspnea.

PHYSICAL EXAMINATION

- Patients can have a hyperdynamic right ventricular impulse due to increased diastolic filling and large stroke volume.
- A dilated pulmonary artery can cause a palpable pulsation and an ejection click.
- S_2 is often widely split and fixed because of persistence of left to right shunting during inspiration as well as expiration causing delayed closure of the pulmonary valve.
- A systolic ejection murmur heard in the pulmonary area is a result of increased right ventricular stroke volume across the pulmonary outflow tract.

- The blood flow across the ASD does not cause a murmur at the site of the shunt because no substantial pressure gradient exists between the atria.

ECG FINDINGS

- Patients with untreated clinically significant ASDs can have right axis deviation, RSR’ pattern suggestive of right bundle branch block of various degrees and right atrial enlargement (tall ‘p’ waves in the limb leads >2.5 mm).
- The “crochetage” pattern is described as the presence of a notch in the apex of R waves in the inferior leads which is characteristic of an ASD (**Figure 42-2**).

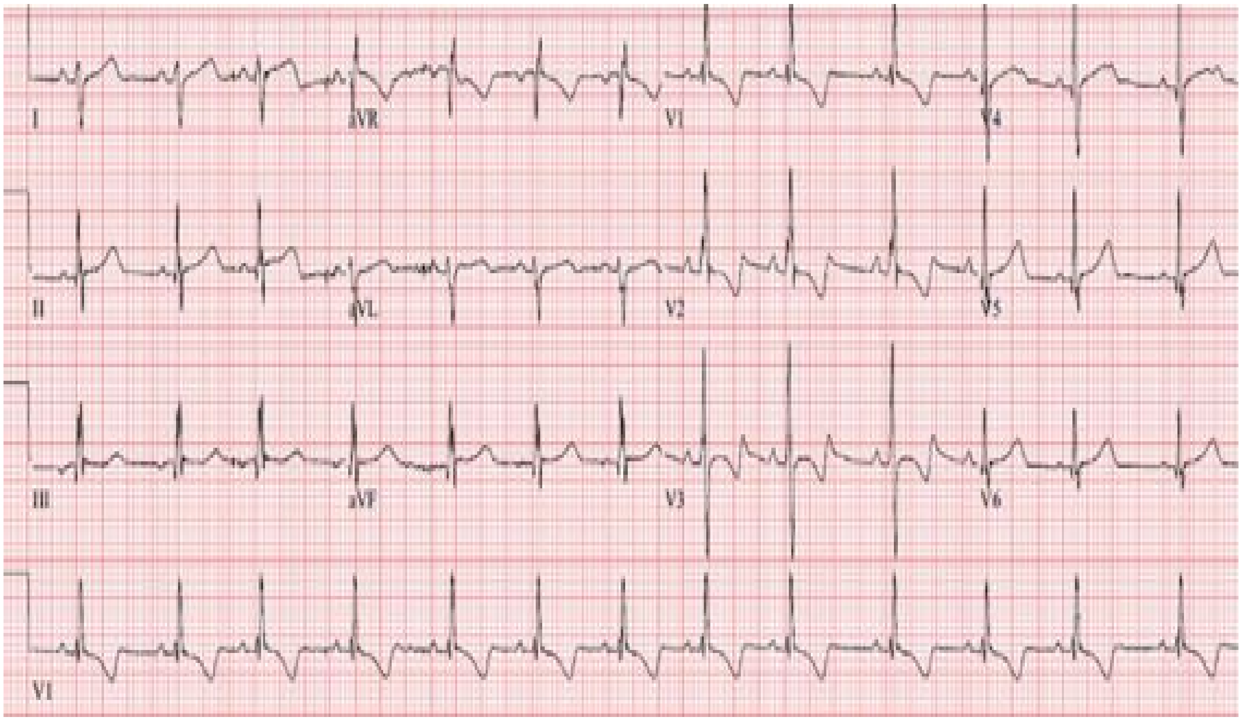

FIGURE 42-2 ECG in a patient with an ASD. Note the RSR’ pattern in V1 (incomplete RBBB) and the “crochetage pattern” in the inferior leads (II, III, aVF). (*Used with permission from Peter Aziz, MD.*)

IMAGING

- Definitive diagnosis is made with a transthoracic echocardiogram.
- Doppler and contrast echocardiography can provide additional confirmation by visualizing atrial shunting.

DIFFERENTIAL DIAGNOSIS

- Physical exam findings of systolic murmur over the pulmonary area with a widely split (but not fixed) S2 can be found in patients with pulmonary stenosis.

MANAGEMENT

- For practical purposes, any defect 8 mm or larger with evidence of left to right shunt should be closed when identified, even at a very young age, because such defects will likely never close spontaneously.[3–5] SOR A
- Smaller defects (<3 mm) in asymptomatic patients can be followed clinically as a majority of them spontaneously close.[6] SOR A
- Closure can be achieved surgically or with device closure via catheterization.
- The size of the lesion is the major determining factor regarding the type of closure, which can be used.

REFERRAL

- Children diagnosed with an ASD require referral to a pediatric cardiologist.

PROGNOSIS

- The prognosis for patients who are diagnosed with ASD and do not develop pulmonary vascular disease is generally good.

FOLLOW-UP

- Close follow-up of patients diagnosed with an ASD is essential in determining the need for an intervention or continued observation.

PATIENT RESOURCES

VENTRICULAR SEPTAL DEFECT

PATIENT STORY

A full-term, 2-month-old male infant with an unremarkable perinatal history presents for a well-child examination. He is gaining weight appropriately. On physical exam, he is found to have a grade IV/VI holosystolic murmur in the left lower parasternal area. He did not have a documented murmur during the examination performed in the newborn nursery. A ventricular septal defect (**Figure 42-3**) is suspected and he is referred to a pediatric cardiologist, who confirms the diagnosis by echocardiography.

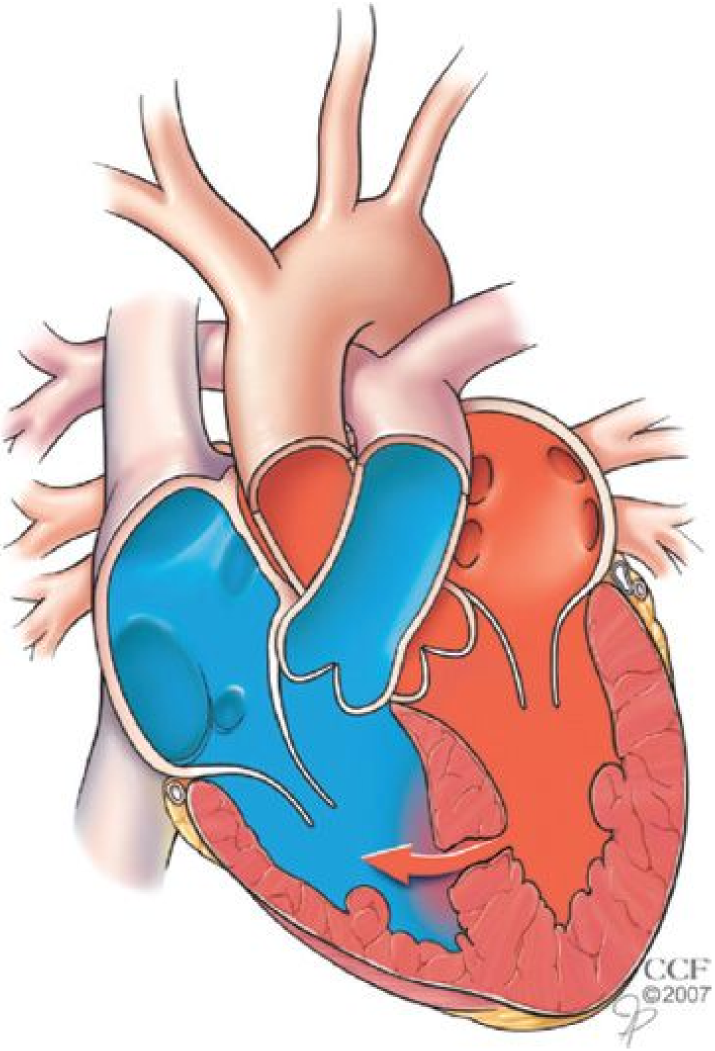

FIGURE 42-3 Ventricular septal defect with flow from the left ventricle to the right ventricle as depicted by the red arrow. (*Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2012. All Rights Reserved*.)

INTRODUCTION

The term ventricular septal defect (VSD) describes an opening in the ventricular septum.

EPIDEMIOLOGY

- A VSD is the most common lesion seen in congenital heart disease overall.
- In the recent years, a prevalence rate of 2.5 per 1000 live births has been determined.[7]

ETIOLOGY AND PATHOPHYSIOLOGY

- Ventricular septal defects result from a delay in closure of the interventricular septum beyond the first 7 weeks of intrauterine life.
- The ventricular septum has four parts: inlet septum, trabecular septum, infundibular septum/outlet septum, and membranous septum.
- Overall, VSDs can be classified into four broad categories.
  - Conoventricular defects—A defect in the small translucent structure located immediately superior to the division of the septal band and adjacent to the commissure between the anterior and septal leaflet of the tricuspid valve.
  - Muscular defect—This type may be located anywhere in the muscular part of the septum.
  - Conoseptal hypoplasia defect—This type of defect is located just under the pulmonary valve. The adjacent right coronary aortic valve cusp often prolapses into the VSD with or without aortic regurgitation.
  - Inlet defect—This type of defect often involves AV valves and has a strong association with Down syndrome.
- The size of the defect and the pulmonary vascular resistance usually determines the hemodynamics in these patients.

- As the drop occurs in the high fetal pulmonary arteriolar resistance in the immediate postnatal life, left to right shunting begins.
- With larger defects, pulmonary artery pressure remains high resulting in right ventricular failure.

RISK FACTORS

- VSD can be associated with a genetic syndrome or as a part of a constellation of heart defects.

DIAGNOSIS

CLINICAL PRESENTATION

- Most infants with small defects remain asymptomatic and the murmur will not be evident until the pulmonary artery pressures significantly decrease.
- Smaller defects can produce the classic murmur of VSD, which is a loud, holosystolic murmur in the left, lower parasternal area.
- Larger defects can manifest as congestive failure resulting in poor feeding, diaphoresis with feeds, tachypnea, and poor growth.
- Physical exam can show signs of cardiac failure, tachypnea, hyperdynamic precordium, and hepatomegaly.
- In larger defects since there no pressure gradient between the ventricles, the classic holosystolic murmur may not be present.

IMAGING AND OTHER INVESTIGATIONS

- Electrocardiography—Most of the children with small VSDs have normal ECGs. Those with larger defects can show biventricular hypertrophy. In endocardial cushion defects, superior axis deviation can be seen.

- Echocardiography—Two-dimensional imaging with color flow Doppler can accurately identify the defects and degree of shunting.

DIFFERENTIAL DIAGNOSIS

- Tricuspid regurgitation and mitral regurgitation can be distinguished by definitive echocardiographic studies.

MANAGEMENT

- Medical management.
  - Maximizing growth and feeding is critical
  - Diuretics, digoxin, and angiotensin-converting enzyme inhibitors may be used to treat congestive heart failure symptoms. SOR Ⓒ
- Surgical management.
  - Surgical management is largely guided by the size and location/type of the defect and should be individualized. In general, if surgery is needed, it is performed between 3 and 6 months of age to prevent long-standing pulmonary hypertension.
- Small defects in clinically asymptomatic patients older than 1 year of age should be followed up every 1 to 2 years. SOR Ⓒ
- Larger defects with unrestrictive flow should undergo surgical closure during early infancy. SOR Ⓒ
- Larger defects with restrictive flow can be followed medically given that many defects will decrease in size. SOR Ⓒ

REFERRAL

- All patients with VSDs need to be evaluated by a pediatric cardiologist.

PROGNOSIS

- Asymptomatic, small muscular VSDs have excellent prognosis and spontaneous closure is common.
- If no pulmonary vascular disease is present, large-sized defects also carry an excellent prognosis post-repair.

FOLLOW-UP

- Patients with VSDs, especially the ones with moderate to large-sized VSDs need close follow-up to monitor for adequate weight gain in order to nutritionally prepare them for a possible surgical intervention if deemed necessary.
- Older patients with unrepaired VSDs should be followed for any progression to cardiac failure

PATIENT EDUCATION

- Parents should be educated on the options for potential surgical vs medical management and watchful waiting of VSD’s.

PATENT DUCTUS ARTERIOSUS

PATIENT STORY

A 16-day-old boy, born prematurely at 24 weeks gestational age is in the neonatal intensive care unit and has just been started on primer feeds. He develops abdominal distention. An abdominal radiograph shows pneumatosis intestinalis suggestive of necrotizing enterocolitis. On physical examination, he has a blood pressure of 66/18 mm Hg, bounding pulses in the femoral arteries and a grade II/VI continuous murmur in the left 2nd intercostal space. Echocardiography confirms the diagnosis of a patent ductus arteriosus (PDA) (**Figure 42-4**).

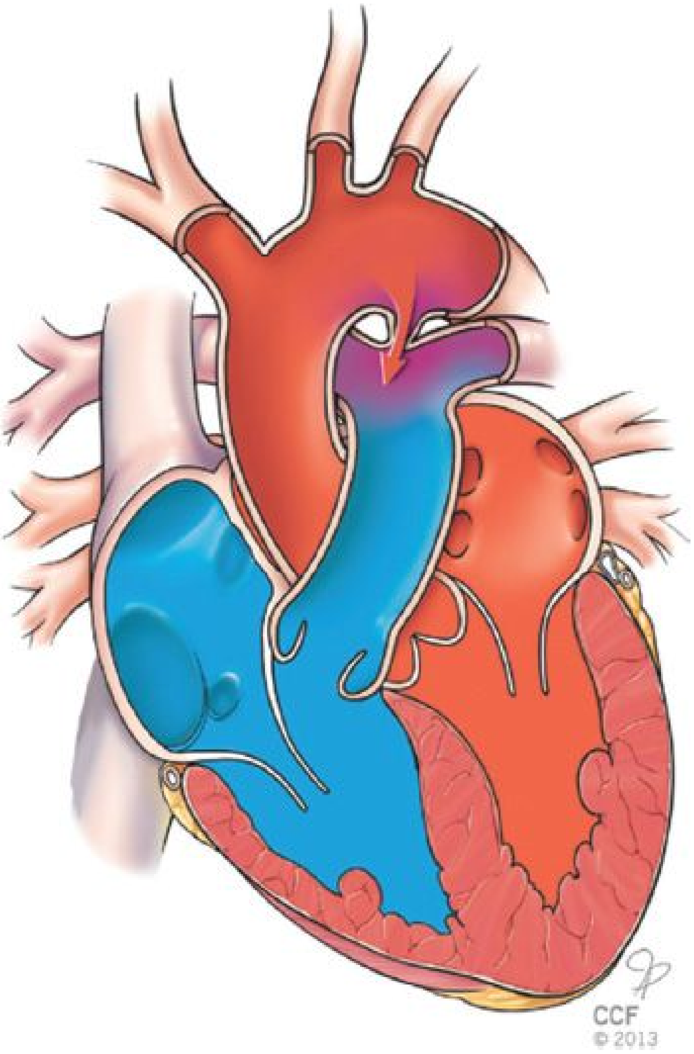

FIGURE 42-4 Patent ductus arteriosus with flow from the aorta to the pulmonary artery as depicted by the red arrow. (*Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2012. All Rights Reserved*.)

INTRODUCTION

Patent ductus arteriosus (PDA) represents a persistent communication between the aorta and the pulmonary artery that results from failure of normal physiologic closure of the fetal ductus arteriosus (**Figure 42-4**).

EPIDEMIOLOGY

- Reported prevalence of PDA in infants ranges from 0.138 to 0.8 per 1000 live births.[7,8]
- PDA persists longer among premature infants and prematurity also accounts for some of the PDAs seen long after infancy.

ETIOLOGY AND PATHOPHYSIOLOGY

- With the first respiratory gasps after birth, the ductus arteriosus closes through muscular constriction; later with thickening of the endothelium and occlusion via thrombosis.
- When the closure does not take place, there is a persistent runoff from the aorta to the pulmonary artery, with excessive blood flow to the lungs, left atrium, left ventricle, and to the ascending aorta.

RISK FACTORS

- Prematurity is the major risk factor.
- Antenatal rubella infection around the time of conception can cause PDA in the infant.
- Also children born at high altitude have a higher prevalence of PDAs compared those born at sea level.

DIAGNOSIS

CLINICAL FEATURES

- Symptoms and signs are proportionate to the amount of blood passing into the pulmonary circulation.
- With a small shunt in a full-term newborn, a crescendo systolic murmur in the second left intercostal space might be the only feature.
- In a newborn with a larger shunt, during the diastolic flow there could be runoff to the pulmonary circulation causing wide pulse pressures as illustrated in the vignette.
- Bounding peripheral pulses might be palpable for the same reason. The murmur can be softer due to less turbulent flow through the PDA.
- Older children typically have the “classic” cardiac exam of PDA consisting of a crescendo systolic murmur peaking in intensity at aortic closure and continuing into diastole as a high-frequency, decrescendo diastolic murmur in the second left intercostal space.

IMAGING

- Echocardiography—PDA are easily visualized with 2 D echocardiography.

DIFFERENTIAL DIAGNOSIS

- Continuous murmur of a PDA needs to be differentiated from:
  - Venous hum—More prominent with patient sitting rather that lying down with evanescent quality.
  - Coronary artery fistula to one of the cardiac chambers—Usually not the loudest at the second left intercostal space.
  - Ruptured sinus of Valsalva—New murmur, location might be similar to that of PDA.

MANAGEMENT

- PDA can be managed medically, surgically or by cardiac intervention.
- Medical management.
    - In premature patients (those weighing less 1000 g) indomethacin is recommended even in the absence of a clinically significant left to right shunt.[9] SOR Ⓐ
    - For those weighing greater than 1000 g, when signs relating to a significant shunt appear, indomethacin is recommended.[10] SOR Ⓐ
- Surgical Management
    - Surgically repair is performed by open thoracotomy or via Video Assisted Thoracic Surgery (VATS).
- Cardiac Intervention
    - Closure with cardiac catheterization employing coils (or special devices for larger defects) have comparable results with that of VATS treated patients.[11] SOR Ⓐ

REFERRAL

- In the neonatal age group, this patient group is usually managed by a neonatologist or a cardiac surgeon.
- Older children with a persistent ductus arteriosus, require referral to a pediatric cardiologist for management.

PREVENTION

- Prevention of maternal rubella by widespread immunization is one way of preventing PDA in the neonate.

- Use of prophylactic indomethacin in the absence of a ductus in those weighing less than 1000 g is controversial and is generally not recommended.[9,12] SOR B

PROGNOSIS

Patients with isolated PDA have excellent prognosis. Spontaneous closure occurs in >34 percent in extremely low-birth-weight neonates.[13]

FOLLOW-UP

Patients who have had permanent closure do not require a follow-up by Pediatric Cardiologist.

43 CYANOTIC CONGENITAL HEART DISEASE

Amara Majeed, MBBS
Athar M. Qureshi, MD

PATIENT STORY

A 20-day-old baby boy is brought into the emergency department by his parents who noticed that he was “blue.” On examination, he is alert and is cyanotic with an oxygen saturation of 83 percent. His cardiac exam reveals a mild right precordial heave with a harsh, long-grade 3/6 systolic ejection murmur at left upper sternal border. In the ED, he becomes more cyanotic (oxygen saturation of 60%), irritable and his murmur becomes softer. An echocardiogram was performed which identified cyanotic congenital heart disease (Tetralogy of Fallot) (**Figure 43-1**). He was treated medically and then underwent palliative surgery with a Blalock Taussig shunt. He was discharged in stable condition to be followed up on an outpatient basis until he could have further corrective surgery at a later date.

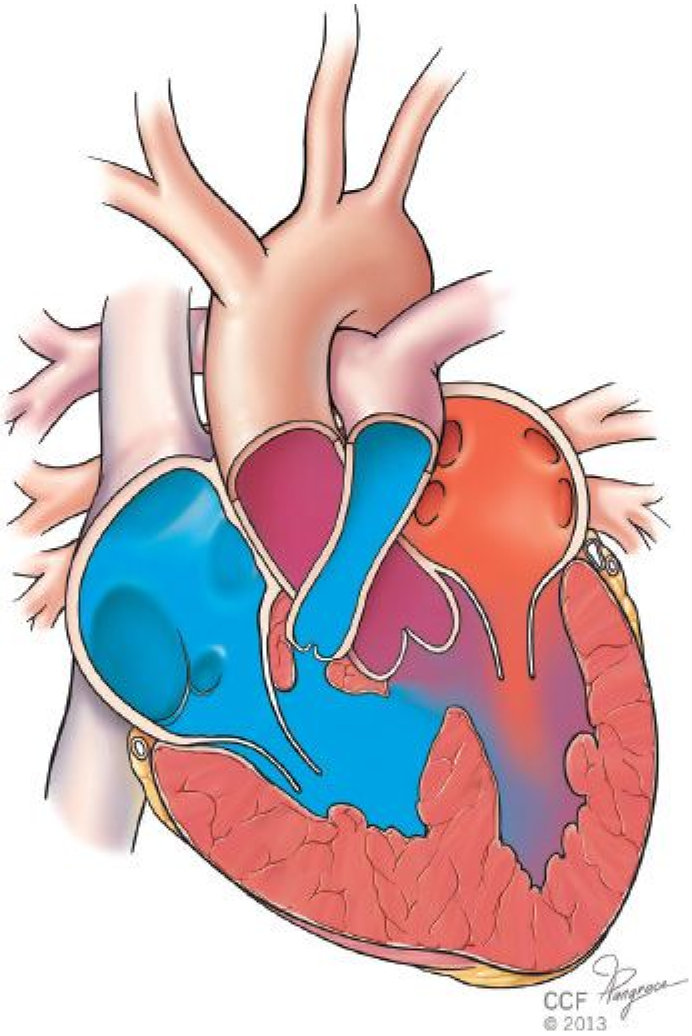

FIGURE 43-1 Tetralogy of Fallot. Note the four components, “anterior-malaligned” VSD, pulmonary stenosis, over-riding aorta and right ventricular hypertrophy. (*Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2012. All Rights Reserved*.)

INTRODUCTION

Cyanotic congenital heart disease is an anatomic malformation of the heart or great vessels which occurs during intrauterine development (resulting in a right to left shunt) and manifests as cyanosis in the neonatal period.

EPIDEMIOLOGY

- Congenital heart defects are the most common type of birth defect in the US, affecting nearly 1 percent of newborns, although this number is variable depending on methodology.[1]
- A significant portion of patients with potentially fatal forms of congenital heart disease have cyanotic defects.
- The most common forms of cyanotic congenital heart disease are:[2]
  - Tetralogy of Fallot (**Figure 43-1**), transposition of the great arteries (**Figure 43-2**), truncus arteriosus, tricuspid atresia, total anomalous pulmonary venous return, or pulmonary valve stenosis (severe or critical pulmonary valve stenosis).

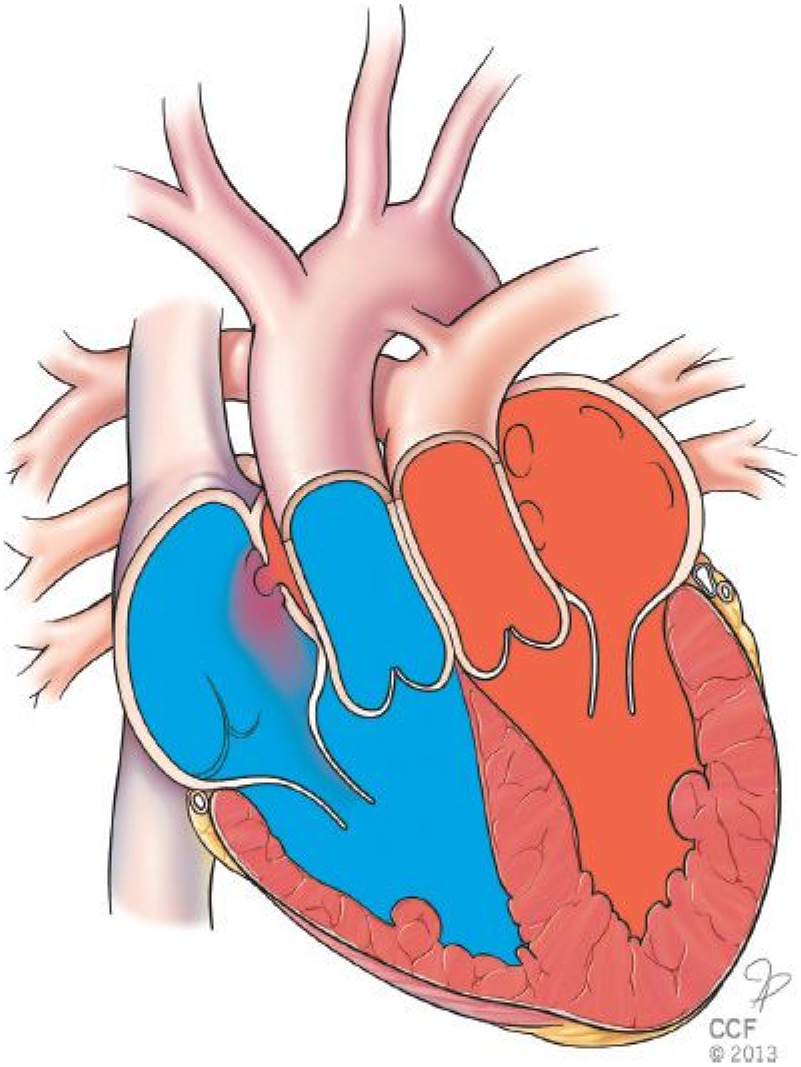

FIGURE 43-2 Transposition of the great arteries with the aorta arising from the right ventricle and the pulmonary artery arising from the left ventricle. Mixing (via an atrial septal defect, ventricular septal defect or patent ductus arteriosus) is essential for survival before corrective surgery. (*Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2012. All Rights Reserved*.)

- Other examples: Ebstein's anomaly, double outlet right ventricle, pulmonary atresia, or multiple single ventricle variants.

ETIOLOGY AND PATHOPHYSIOLOGY

- Most cases are due to an unknown etiology and are multifactorial.
- Systemic venous blood bypasses the pulmonary circulation, resulting in a right to left shunt, systemic arterial desaturation and clinical cyanosis.
- Depending on the predominant physiology, cyanosis may be variable and not the primary underlying problem.

RISK FACTORS

Hereditary or genetic risk factors

- Relatives with congenital heart disease.
- Genetic syndromes, which include congenital heart disease as a feature (i.e., DiGeorge syndrome).[1,3]

Maternal risk factors

- In vitro fertilization.
- Cardiac teratogen exposure (e.g., alcohol, lithium, isotretinoin, anticonvulsants, thalidomide, organic solvents).[4]
- Maternal illness (e.g., diabetes, phenylketonuria, rubella).[4]

Fetal risk factors

- Includes extra cardiac anomalies in the fetus, aneuploidy, hydrops, abnormal fetal situs, chromosomal abnormality, and monochorionic twins.

DIAGNOSIS

CLINICAL FEATURES

- Clinical features are highly variable depending on the particular lesion.
- Central cyanosis is present.
- Respiratory distress, hypercyanotic spells, poor feeding, or failure to thrive may be present depending on the specific lesion.
- Vital signs may show tachycardia, tachypnea, decreased oxygen saturation, and hypotension.
- A difference between preductal and postductal oxygen saturations may be present.
- Blood pressures in all four extremities may detect a coexistent coarctation of aorta.
- Cardiac exam may reveal abnormal heart sounds and a pathological murmur depending on the type of lesion.
- Signs of congestive heart failure may be present, that is, tachypnea, subcostal retractions, and hepatomegaly.

LABORATORY TESTING

- Hyperoxia test is done to distinguish cardiac from respiratory cause of cyanosis. The oxygen saturation and P_{O2} does not significantly increase with cyanotic congenital heart disease.
- Complete blood count, arterial blood gas, and a blood culture to rule out sepsis are generally indicated.

IMAGING

- Chest x-ray (**Figure 43-3**).

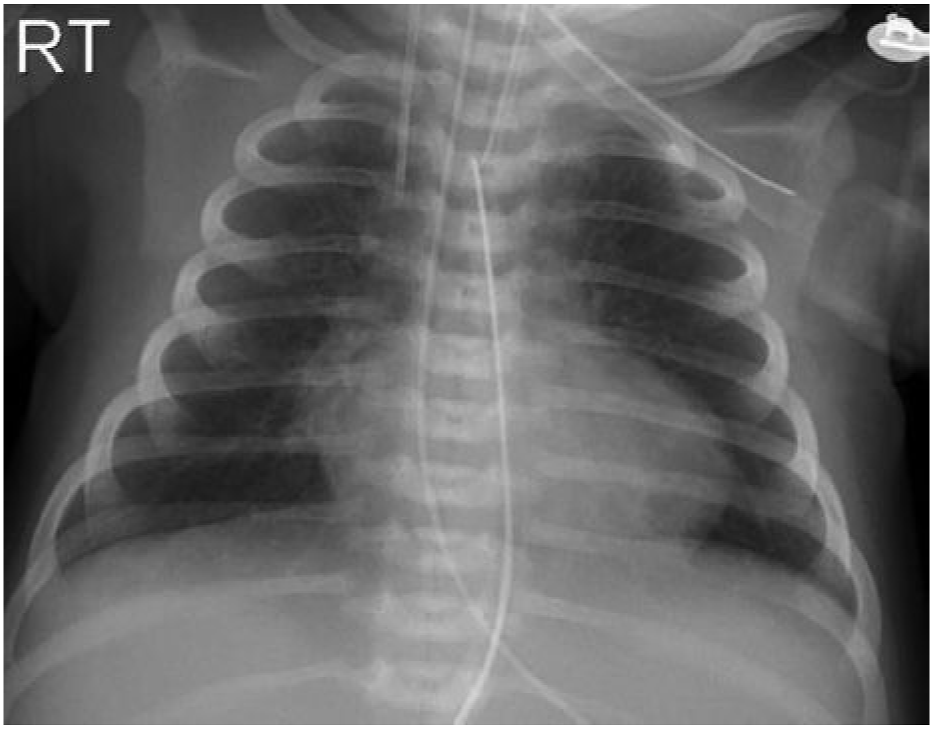

FIGURE 43-3 CXR (AP view) of an infant with tetralogy of Fallot. Note the upturned cardiac apex and concave pulmonary shadow representing a “boot-shaped heart.” Relatively dark lung fields from decreased pulmonary blood flow are also seen. (*Used with permission from Athar M. Qureshi, MD*.)

- Electrocardiogram.
- Echocardiogram.

DIFFERENTIAL DIAGNOSIS

- Pulmonary disorders including pulmonary hypertension can be excluded with the previous history and imaging studies.
- Poor peripheral perfusion due to sepsis, hypoglycemia, dehydration, and hypoadrenalism.
- Abnormal hemoglobin, for example, methemoglobinemia.

MANAGEMENT

NONPHARMACOLOGICAL

- Supportive care with cardiorespiratory support and vigilant monitoring to ensure adequate perfusion and oxygenation.
- Maintain neutral thermal environment.
- Provide supplemental oxygen or mechanical ventilation as required.
- Increased caloric intake.

MEDICATIONS

- Prostaglandin E1 infusion is indicated where there is a suspicion of having ductal dependent physiology.
- Correction of metabolic derangements and acid-base balance.
- Diuretics, digoxin, and angiotensin converting enzyme inhibitors may be used depending on the physiology present.
- Vasopressors to correct hypotension.

SURGERY

- Cardiac catheterization, which can be diagnostic or therapeutic.
- Balloon atrial septostomy can be done to create a connection between the left and right atria in patients with transposition of the great arteries or left sided obstructive lesions (**Figure 43-4**).

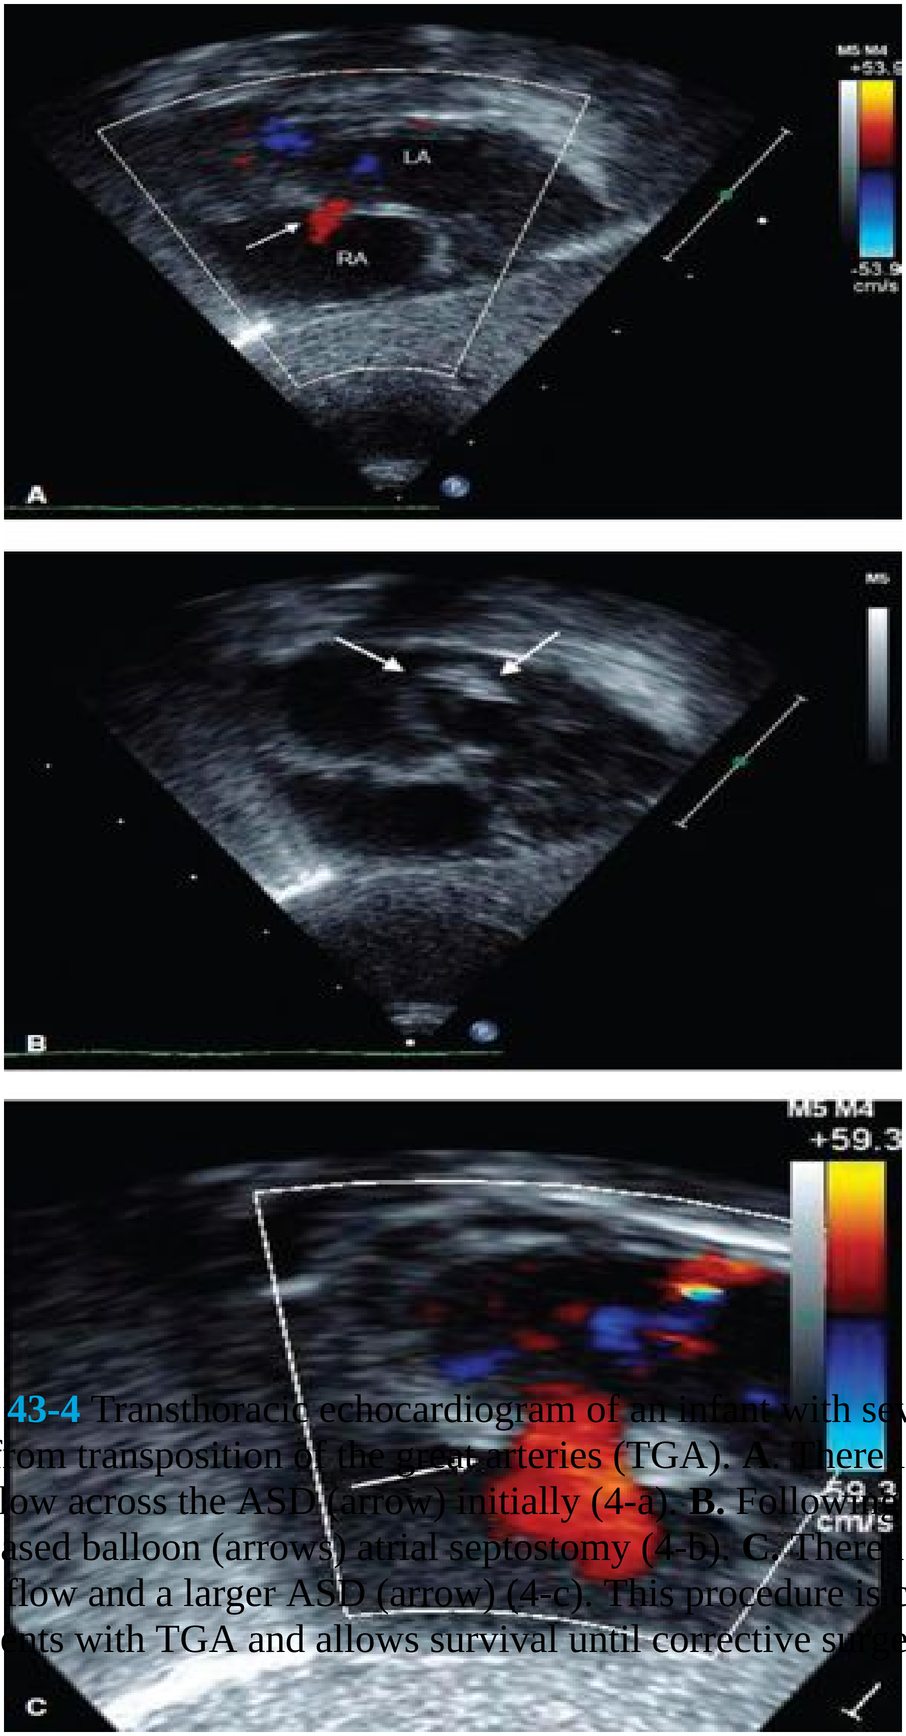

FIGURE 43-4 Transthoracic echocardiogram of an infant with severe cyanosis from transposition of the great arteries (TGA). **A.** There is minimal flow across the ASD (arrow) initially (4-a). **B.** Following a catheter-based balloon (arrows) atrial septostomy (4-b). **C.** There is much improved flow and a larger ASD (arrow) (4-c). This procedure is critical for many patients with TGA and allows survival until corrective surgery can be

performed. (RA = right atrium, LA = left atrium). (*Used with permission from Athar M. Qureshi, MD.*)

- Balloon valvuloplasty can be done in valvular pulmonary stenosis to increase blood flow across the valve (**Figure 43-5**).

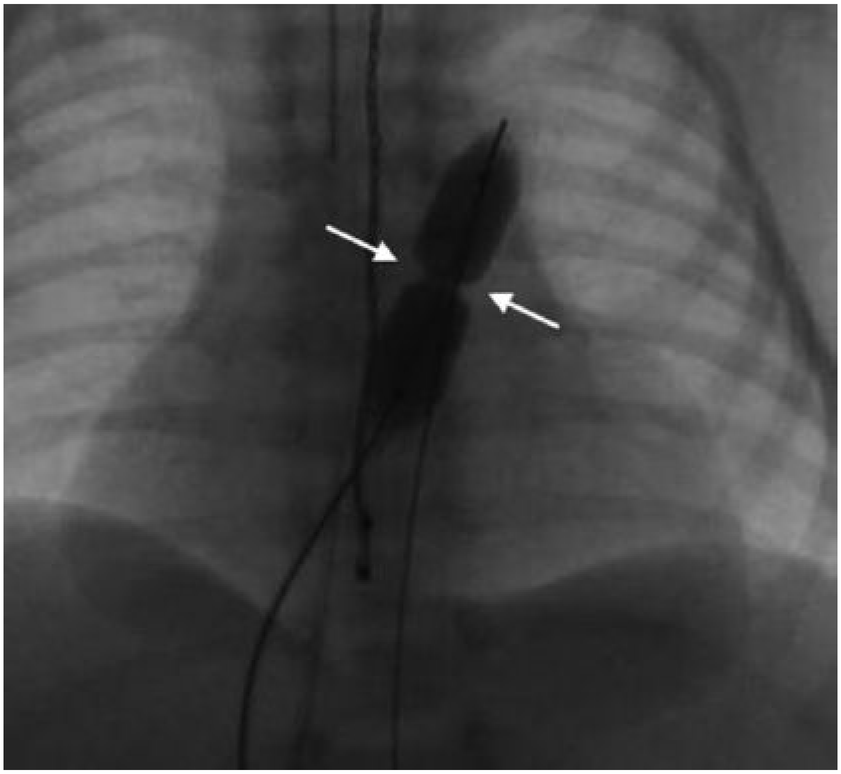

FIGURE 43-5 Balloon valvuloplasty in the cardiac catheterization laboratory in a newborn with critical pulmonary valve stenosis and cyanosis. Note the “waist” in the balloon (arrows) that corresponds to the narrow valve orifice. This will be eliminated with full balloon inflation. (*Used with permission from Athar M. Qureshi, MD.*)

- The final treatment for most common causes of cyanotic congenital heart disease is cardiac surgery. The timing of the surgical procedures is variable depending on the type of lesion. For each of the common lesions the surgical procedure most commonly performed are the following:
  - Tetralogy of Fallot—Ventricular septal defect (VSD) closure and relief of obstruction to pulmonary flow (**Figure 43-6**).

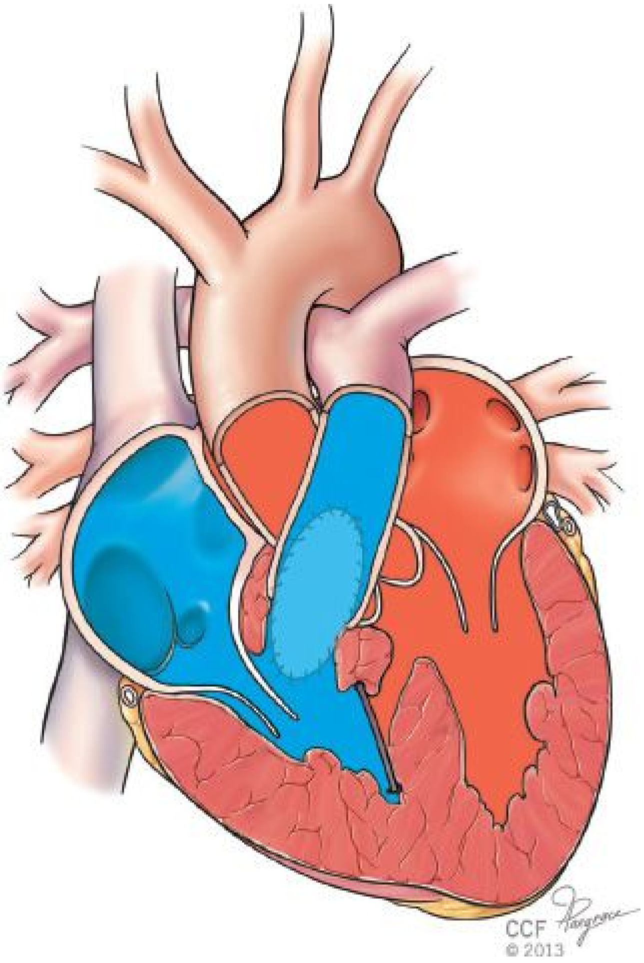

FIGURE 43-6 Complete repair for tetralogy of Fallot, involving VSD closure, and relief of the pulmonary stenosis (in this case with a "transannular patch" across the pulmonary valve annulus). (*Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2012. All Rights Reserved*.)

- Transposition of the great arteries—arterial switch operation (**Figure 43-7**).

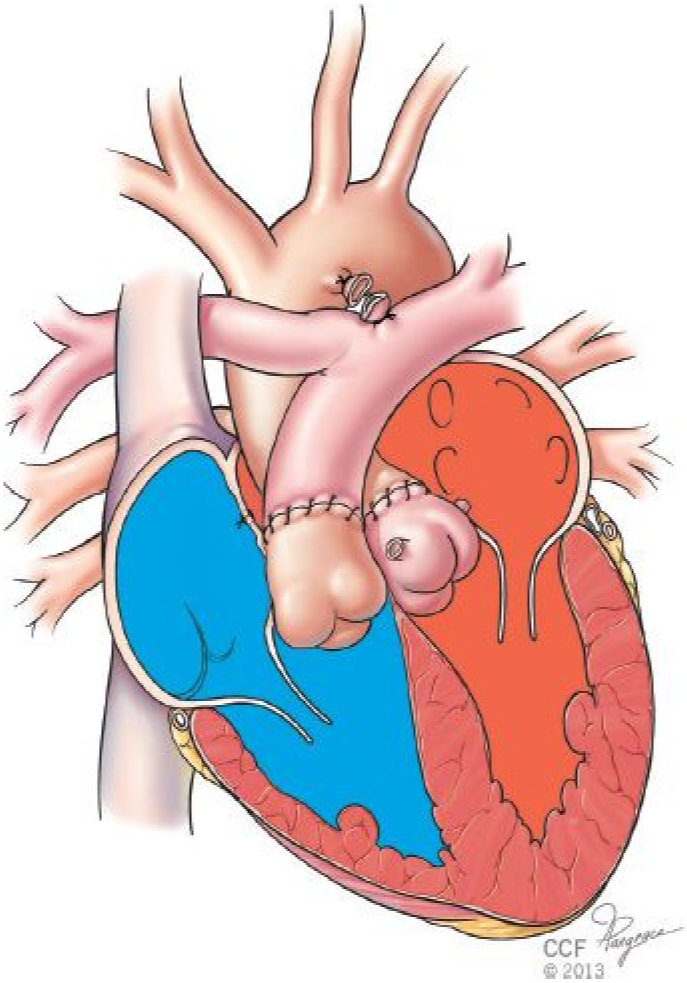

FIGURE 43-7 Surgical correction for transposition of the great arteries (TGA)—the arterial switch operation, which establishes a physiologic and anatomic correction of the defect. The great vessels are “switched” and coronary artery buttons are created and moved over to the “neo” aorta. (*Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography* © *2012. All Rights Reserved*.)

- Tricuspid atresia—Blalock Taussig shunt placement, Glenn operation, and then Fontan operation.
- Total anomalous pulmonary venous return—Redirection of common pulmonary venous confluence to the left atrium.
- Truncus arteriosus—VSD closure with right ventricle to pulmonary artery conduit placement.

REFERRAL

- Pediatric cardiologist, cardiothoracic surgeon, maternal-fetal medicine specialist, obstetrician, neonatologist, or geneticist.

PREVENTION AND SCREENING

PREVENTION

- Preventive measures include genetic counseling, control of maternal disease, and avoiding teratogen exposure during pregnancy.

SCREENING

- Basic obstetrical ultrasound examination should be performed at 18 to 22 weeks of gestation.
- A full fetal echocardiogram is indicated in pregnancies with risk factors (see preceding section) for congenital heart anomalies.
- The identification of a fetal cardiac defect should prompt a search for any associated abnormalities.

PROGNOSIS

- Most cyanotic congenital heart diseases have a poor prognosis if left untreated. With prompt diagnosis and treatment, however, the prognosis is favorable for most lesions.
- Untreated and chronic cyanotic congenital heart diseases have been associated with stroke, organ damage, impaired muscle performance, thrombosis, and vascular damage amongst other devastating consequences.[5]

FOLLOW-UP

Regular and periodic follow-up after surgical or interventional correction is necessary to address continued medical management and long term complications associated with corrected circulations.

PATIENT EDUCATION

Patients with congenital heart disease need complex and multifaceted care in order to ensure their continued survival and improve their quality of life. Teams of specialists are needed to care for families and patients prior to conception, in childhood and in adulthood.

44 BACTERIAL ENDOCARDITIS

Heidi Chumley, MD
Camille Sabella, MD

PATIENT STORY

A 14-year-old girl with a history of mitral regurgitation that complicated rheumatic heart disease was brought in by her parents after two weeks of intermittent low-grade fevers, fatigue, weakness, arthralgias, and myalgias. On examination, she appeared ill, was febrile, and had a heart murmur. Her funduscopic examination revealed Roth spots (**Figures 44-1** and **44-2**). Her blood cultures grew *Streptococcus mitis*. An echocardiogram demonstrated a vegetation on the mitral valve. She was hospitalized and treated for bacterial endocarditis.

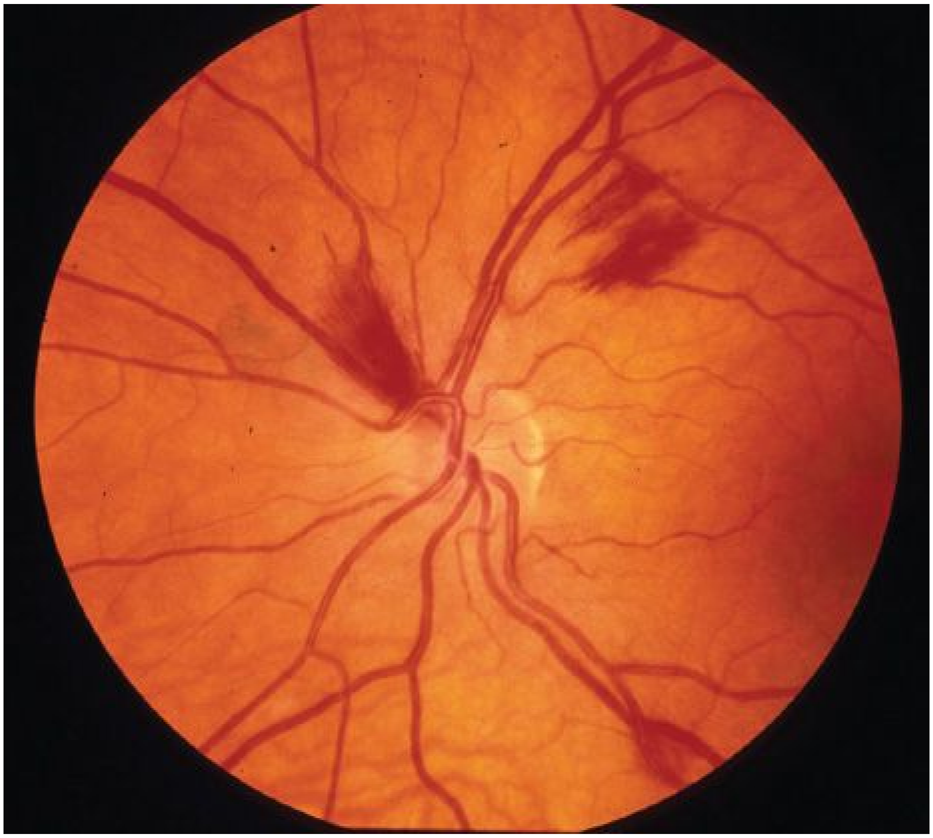

FIGURE 44-1 Roth spots that are retinal hemorrhages with white centers seen in bacterial endocarditis. These can also be seen in leukemia and diabetes. (*Used with permission from Paul D. Comeau*.)

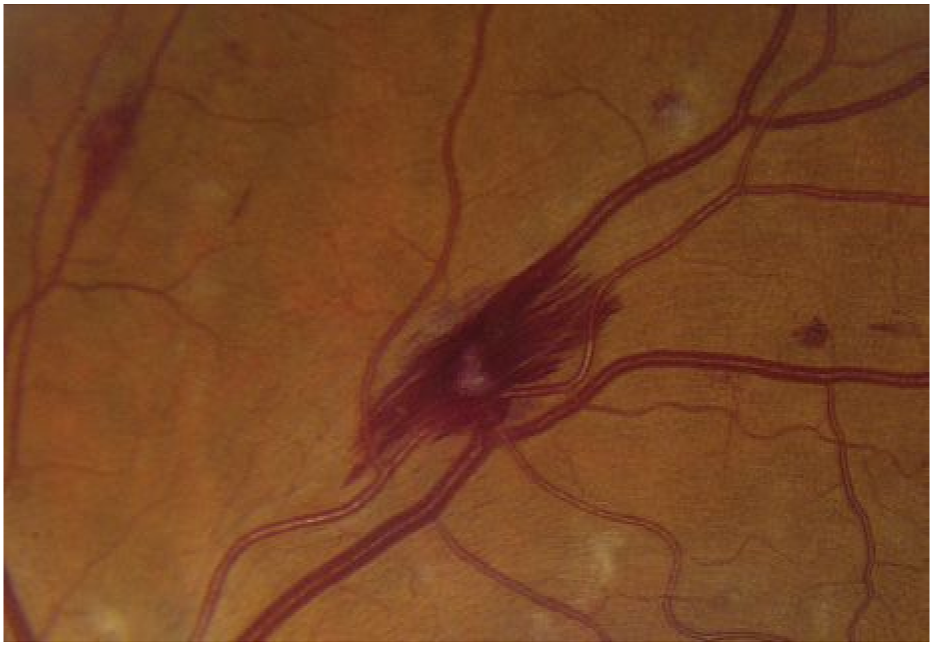

FIGURE 44-2 Close-up of a Roth spot, which is actually a cotton-wool spot surrounded by hemorrhage. The cotton-wool comes from ischemic bursting of axons and the hemorrhage comes from ischemic bursting of an arteriole. (*Used with permission from Paul D. Comeau*.)

INTRODUCTION

Bacterial endocarditis is a serious infection that in the pediatric population is seen most commonly in patients with congenital heart disease, prosthetic valves, injection drug users, and patients with indwelling central venous catheters. The diagnosis is made based on the Duke Criteria. The rate of cure with appropriate antibiotics and surgical management, when indicated, is high, and facilitated by prompt diagnosis and vigilance in recognizing complications.

EPIDEMIOLOGY

- 0.34 to 0.64 cases per 100,000 patient-years.[1]
- 1 case per 1000 pediatric hospital admissions.
- 46 percent of cases in ages 0 to 1, followed by 23 percent, 20 percent, and 12 percent in ages 12 to 18, 5 to 12, and 1 to 5 years, respectively.[2]
- 58 percent of cases in male patients.[2]
- 68 percent of patients hospitalized with infective endocarditis (IE) had some type of congenital heart disease.[2]
- 2007 AHA guidelines for IE prophylaxis have not changed IE admissions.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Flow through an abnormal valve or abnormal communication between systemic and pulmonary circulation (as in various congenital heart diseases) damages endothelium.
- Platelets and fibrin adhere to damaged endothelium initiating a sterile thrombus.
- Microbes adhere to compromised endothelium during transient bacteremia.
- Common organisms include viridans Streptococci (such as *Streptococcus mitis* and *Streptococcus oralis*) *Staphylococcus aureus*, coagulase-negative *Staphylococci, Enterococci, Candida spp*, and rarely *Streptococcus pneumoniae*.
- Viridans streptococci are more commonly associated with rheumatic fever, unrepaired congenital heart disease, and late postoperative endocarditis.
- Staphylococcal species, including methicillin-resistant *S aureus* (MRSA) and coagulase-negative Staphylococci, are commonly associated with endocarditis after cardiac surgery and with prosthetic valves; *S aureus* is also common as a cause of endocarditis in individuals who have normal hearts and in intravenous drug users.
- Fungal causes of endocarditis, such as *Candida* spp., are especially common in those who have hospital-acquired endocarditis, those with central venous catheters, those with prosthetic valves, and in neonates.
- Fastidious agents, known as the HACEK group, are rare causes of endocarditis in the pediatric population and include *Haemophilus, Actinobacillus, Cardiobacterium, Eikenella*, and *Kingella (neonates* and *immunocompromised).*
- Blood contacts subendothelial factors, which promotes coagulation.
- Pathogens bind and activate monocyte, cytokine, and tissue factor production, enlarging the vegetations on the heart valves.
- The vegetations enlarge and damage the heart valves (**Figure 44-3**). This process can lead to death if not treated adequately in time.

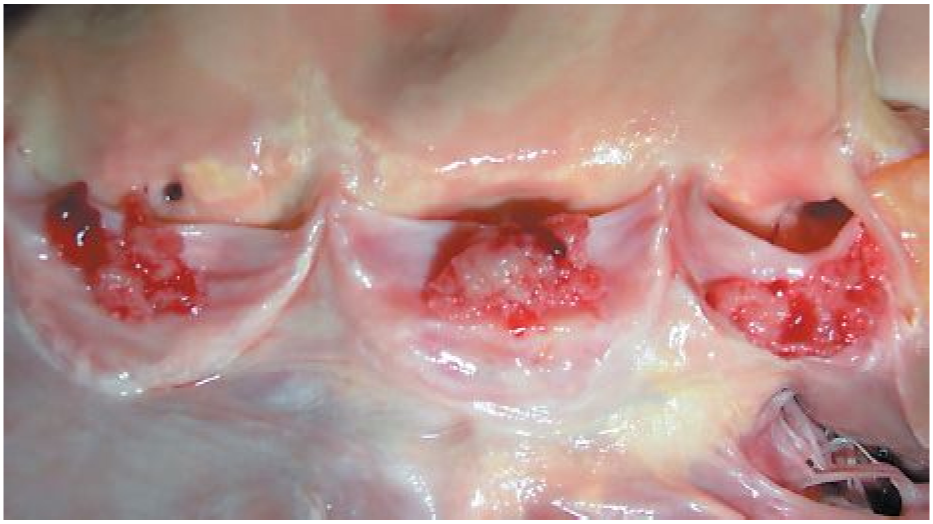

FIGURE 44-3 Pathology specimen of a patient who died of bacterial endocarditis. Bacterial growth can be seen on the three cusps of this heart valve. (*Used with permission from Larry Fowler, MD.*)

- Septic emboli can occur, most commonly in the brain, spleen, or kidney.[3]

RISK FACTORS[4]

- Congenital heart disease.
- Prosthetic valve.
- Injection drug use.
- Rheumatic fever.
- Prior episode of bacterial endocarditis.
- Central venous catheters (neonates).
- Prior heart surgery with resultant valvulopathy or systemic to pulmonary shunt.

DIAGNOSIS

- The Duke criteria use a combination of history, physical examination, laboratory, and echocardiogram findings, and across several studies, have a sensitivity of approximately 80 percent.[5]
- The diagnosis is considered definite when patients have two major, one major and three minor, or five minor criteria.[5]
- The diagnosis is considered possible when one major and one minor or three minor criteria are present.[5]
- Major criteria include:[5]
  - Two separate blood cultures positive with:
    - viridans *Streptococci*, S aureus, HACEK group, or enterococci.
    - Persistently positive blood cultures.
    - Single positive culture or high IgG titer for *Coxiella burnetti* (Q fever).
  - Echocardiogram evidence of vegetation, abscess, or new partial dehiscence of a prosthetic valve.
    - New valvular regurgitation.
- Minor criteria include:[5]
    - Predisposition (e.g., heart condition such as a congenital or acquired valvular defect, injection drug use, prior history of endocarditis).
    - Temperature >38°C (100.4°F).
    - Clinical signs: arterial emboli, septic pulmonary infarcts, mycotic aneurysms, intracranial hemorrhages, splinter hemorrhages, Osler nodes, Roth spots, or Janeway lesions (**Figures 44-1, 44-2**, and **44-4** to **44-7**).

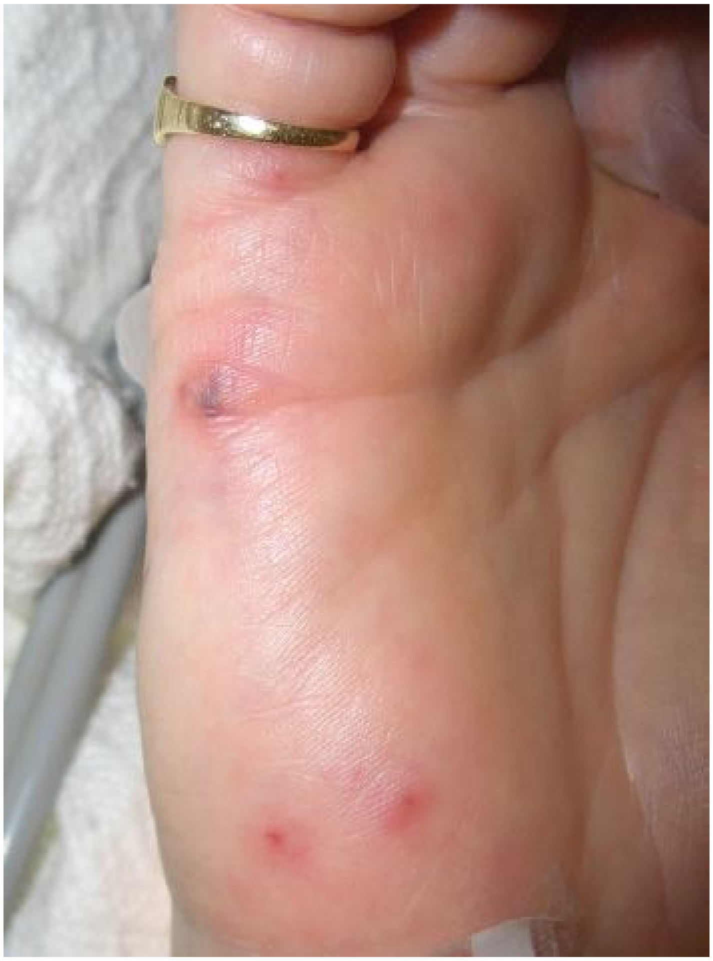

FIGURE 44-4 Janeway lesions on the palm of a woman hospitalized with acute bacterial endocarditis. These were not painful. (*Used with permission from David A. Kasper DO, MBA*.)

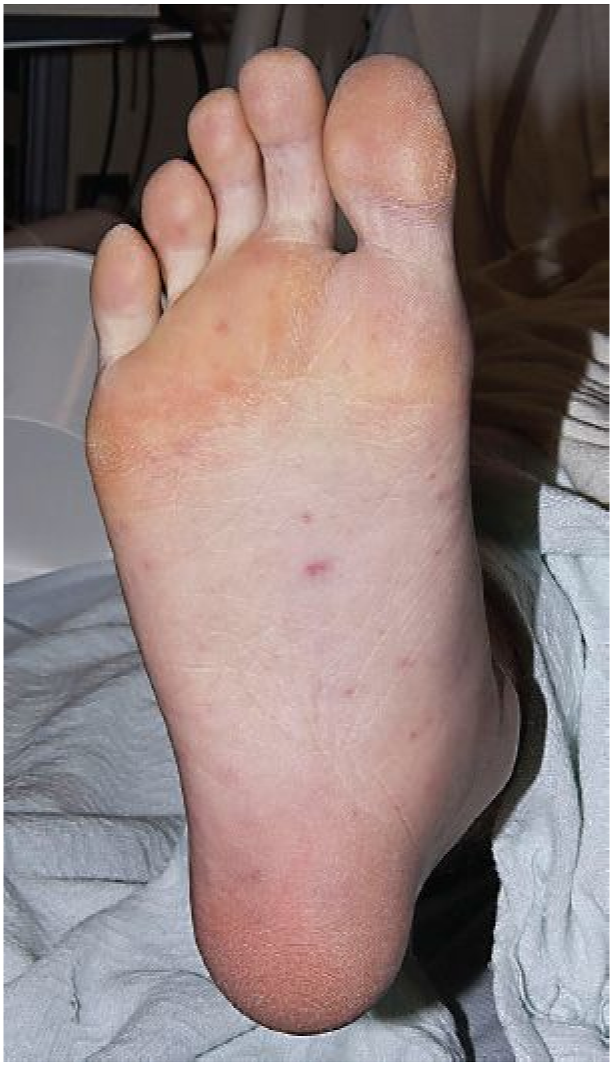

FIGURE 44-5 Janeway lesions and petechial lesions on the sole of a 17-year-old boy who was hospitalized with *S aureus* bacteremia and endocarditis. (*Used with permission from Blanca Gonzalez, MD*.)

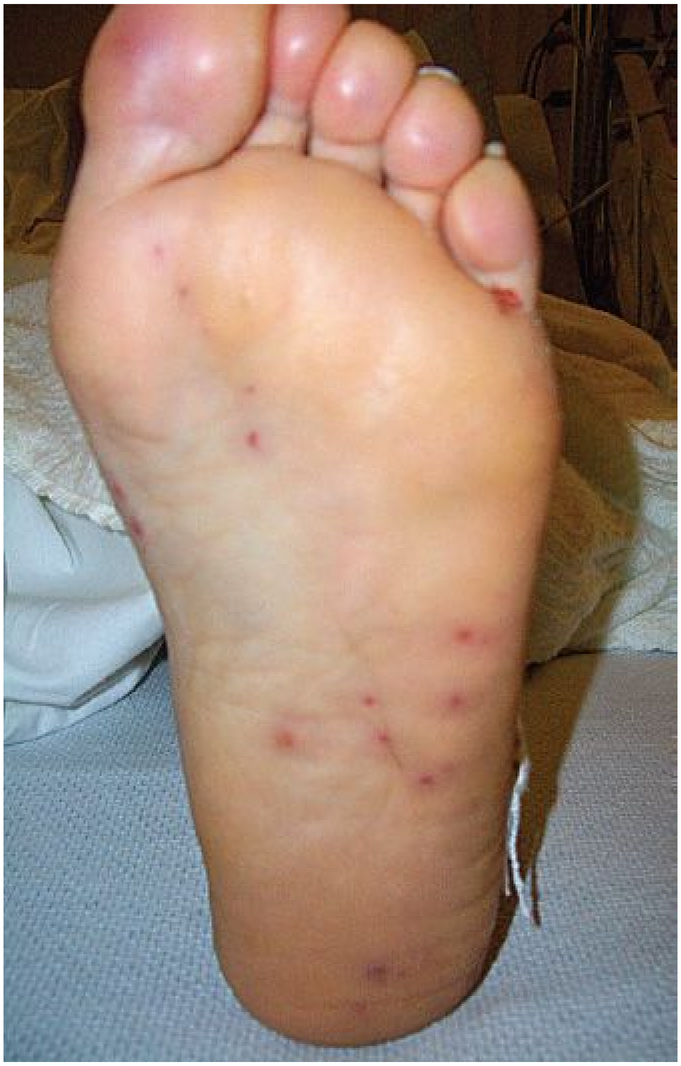

FIGURE 44-6 Osler node causing pain within pulp of the big toe in the same woman hospitalized with acute bacterial endocarditis. (Osler nodes are painful—remember “O” for Ouch and Osler.) Note the multiple painless flat Janeway lesions over the sole of the foot. (*Used with permission from David A. Kasper DO, MBA*.)

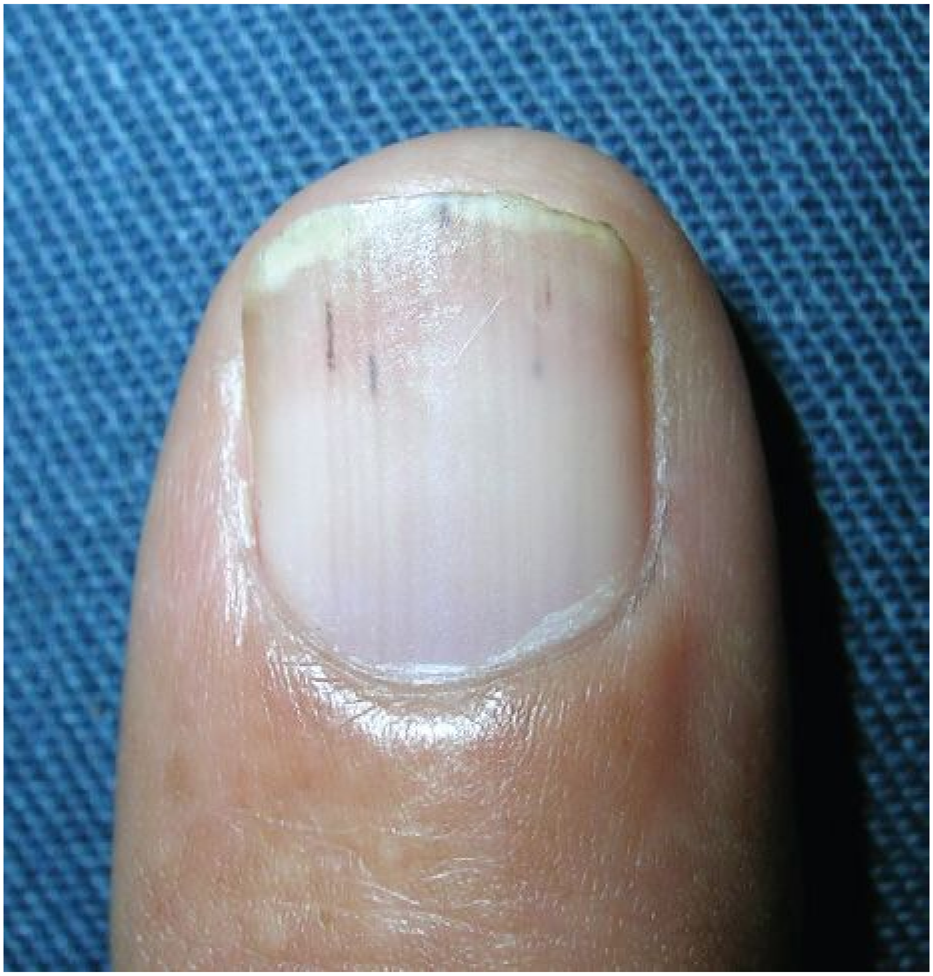

FIGURE 44-7 Splinter hemorrhages appearing as red linear streaks under the nail plate and within the nail bed. Although endocarditis can cause this, splinter hemorrhages are more commonly seen in psoriasis and trauma. (*Used with permission from Richard P. Usatine, MD.*)

- Glomerulonephritis.
- Positive rheumatoid factor.
- Positive blood culture not meeting major criteria.
- Echocardiographic findings consistent with infective endocarditis that do not meet major criteria.

CLINICAL FEATURES

- Fever—Seen in 75 to 99 percent of patients, and is typically low-grade.

- New or changing heart murmur—Seen in 20 to 80 percent of patients.
- Splenomegaly may be in 50 to 75 percent of patients.
- Petechiae seen in up to 50 percent of patients (**Figure 44-5**).
- Septic emboli—Seen in up to 50 percent, largely dependent on the size (>10 mm) and mobility of the vegetation.
- Intracranial hemorrhages—Seen in 30 to 40 percent of patients, bleeding from septic emboli or cerebral mycotic aneurysms.
- Mycotic aneurysms—Aneurysms resulting from infectious process in the arterial wall, most commonly in the thoracic aorta, also found in the cerebral arteries.
- Splinter hemorrhages—Red, linear streaks in the nail beds of the fingers or toes (**Figure 44-7**).
- Janeway lesions—Very rare, flat, painless, red to bluish-red spots on the palms, and soles (**Figures 44-4** and **44-5**).
- Glomerulonephritis—Immune mediated that can result in hematuria and renal insufficiency, occurs in approximately 15 percent of patients with endocarditis.
- Osler nodes—Tender, subcutaneous nodules in the pulp of the digits (**Figure 44-6**).
- Roth spots—Retinal hemorrhages from microemboli, seen in approximately 5 percent of cases of endocarditis (**Figures 44-1** and **44-2**).

TYPICAL DISTRIBUTION

- Native endocarditis—Mitral valve (prior rheumatic fever or mitral valve prolapse), followed by aortic (prior rheumatic fever, calcific aortic stenosis of bicuspid valve).
- Prosthetic valve endocarditis—Site of any prosthetic valve.
- In IV drug users—Tricuspid valve, followed by aortic.

LABORATORY AND ANCILLARY TESTING

- Positive blood cultures (75% to 100% of patients), anemia (75% to 90%) and an elevated erythrocyte sedimentation rate (ESR) (seen in 75% to 100%) are the most common laboratory findings.
- A positive rheumatoid factor is found in 25 to 50 percent of patients with endocarditis.
- Hematuria is found in 25 to 50 percent of patients with endocarditis.
- Positive blood culture—First two sets of cultures are positive in 90 percent.[3]

IMAGING

- Abnormal transthoracic echocardiogram.
- Transthoracic echocardiogram has a sensitivity of 80 percent in children under 60 kg; Transesophageal echocardiogram is rarely indicated in the pediatric population but is occasionally required for adolescent and young adults[6](**Figure 44-8**).

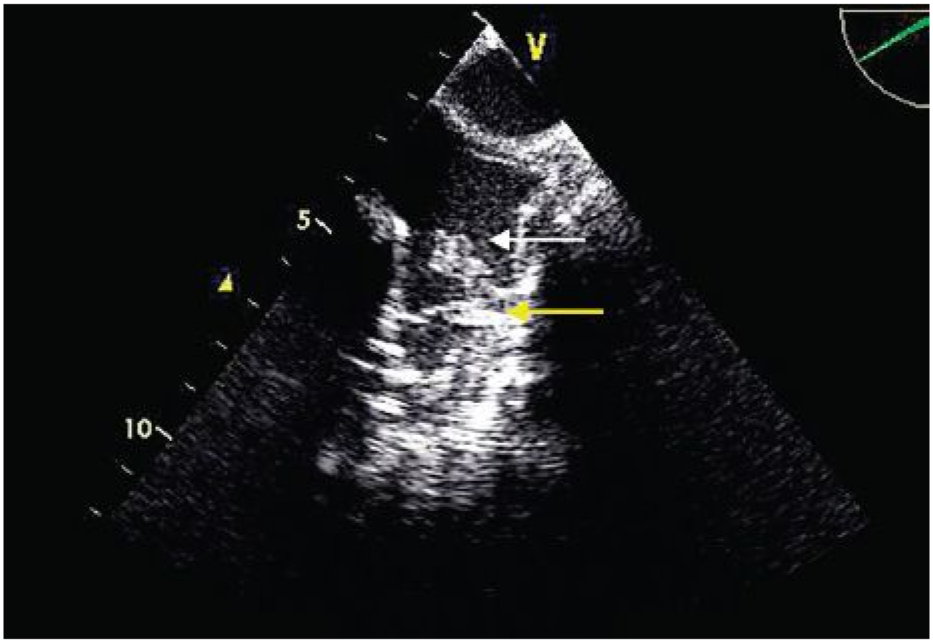

FIGURE 44-8 Transesophageal echocardiogram in a teenage boy with endocarditis of a prosthetic right ventricle to pulmonary artery conduit. Note the vegetation (white arrow) attached to the pulmonary valve leaflets (yellow arrow). (*Used with permission from Athar Qureshi, MD.*)

DIFFERENTIAL DIAGNOSIS

Fever without a clear cause may be seen with:

- Connective tissue disorders—Typically with other signs depending on the disorder, negative blood cultures, normal echocardiogram.
- Fever of unknown origin—Negative blood cultures or positive cultures with atypical organisms, normal echocardiogram in noncardiac causes.
- Intraabdominal infections—Fever and positive blood cultures, normal echocardiogram.
- Acute leukemias—Fever and systemic symptoms, abnormal CBC

Echocardiogram findings similar to bacterial endocarditis may be seen with:

- Noninfective vegetations—No fever and negative blood cultures.
- Cardiac tumors—Embolic complications, right or left heart failure, often located off valves in cardiac chambers, negative blood cultures.
- Cusp prolapse—No fever and negative blood cultures.
- Myxomatous changes—Extra connective tissue in the valve leaflets.
- Lamb excrescences—Stranding from wear and tear on the valve, most commonly aortic, no fever, and negative blood cultures.

MANAGEMENT

- Two or three sets of blood cultures should be obtained when the diagnosis is suspected. Patients with suspected endocarditis should be admitted to the hospital.
- The decision to give antibiotics empirically depends on the clinical findings and suspicion for endocarditis. It is critical that appropriate blood cultures are obtained prior to the start of intravenous antibiotics. SOR C

MEDICATIONS

- Empiric coverage for endocarditis must take into account the most likely organism based on the age, risk factor, preexisting heart disease, recent surgery, clinical presentation, and most likely mode of acquisition.
- Coverage for viridans Streptococci in native valve endocarditis usually includes penicillin G with or without gentamicin. The treatment duration is 2 to 4 weeks.
- Coverage for *Staphylococcus* in IV drug abusers includes nafcillin with or without gentamicin; Vancomycin should be given instead of nafcillin when there is concern about methicillin-resistant *Staphylococcus aureus* (MRSA) or when a prosthetic valve in involved (with gentamicin). The typical treatment duration is 4 to 6 weeks.
- Definitive antimicrobial therapy should be based on culture and susceptibility results.
- Treatment of Gram-positive infections should include a β-lactam when the organism is susceptible; current evidence does not support adding an aminoglycaside.[7] SOR A
- Surgical consultation should be obtained when:
    - Congestive heart failure is severe with mitral or aortic regurgitation.
    - Fever and/or bacteremia persist for 7 to 10 days despite adequate antibiotic therapy, abscesses or perivalvular involvement occurs, or fungal organisms are identified.
    - Embolic events recur on adequate antibiotic therapy or the risk of embolic events is high because of vegetations larger than 10 mm.

SOR C

- Anticoagulation and aspirin are not indicated for infective endocarditis and are contraindicated with cerebral complications or aneurysms.

PREVENTION

- Bacterial endocarditis is a serious life-threatening disease requiring long-term antibiotics and close follow-up.
- Patients who are at high risk for endocarditis should be educated regarding the importance of prophylactic antibiotics before certain procedures. The following are the 2007 American Heart Association recommendations:[8]
    - Prophylactic antibiotics should be prescribed only to patients at the highest risk: SOR B
        - Patients with prosthetic cardiac valves.
        - Patients with previous bacterial endocarditis.
        - Cardiac transplant recipients with cardiac valvuloplasty.
        - Patients with these congenital heart defects (CHDs): unrepaired cyanotic CHD; CHD repaired with prosthetic material within the last 6 months; repaired CHD with a residual defect at or adjacent to the site of a prosthetic device.
    - Prophylactic antibiotics are *no longer recommended* for patients with mitral valve prolapse.
    - Prophylactic antibiotics should be prescribed only to patients undergoing one of the following:
        - Any dental procedure that involves manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa. SOR C
        - Respiratory procedures involving incision or biopsy of the respiratory mucosa such as a tonsillectomy or adenoidectomy. SOR C
        - Procedures on infected skin or musculoskeletal tissue.
    - Endocarditis prophylaxis is *no longer recommended* for patients undergoing gastrointestinal or genitourinary procedures. SOR B

  - A one-dose regimen to be taken 30 minutes to 1 hour before the procedure should be prescribed:[8]
    - Amoxicillin 50 mg/kg up to 2.0 g orally.
    - If unable to take oral medications: ampicillin 50 mg/kg up to 2.0 g IM or IV 30 minutes before the procedure; *or* cefazolin or ceftriaxone 50 mg/kg up to 1 g IM or IV.
    - Penicillin allergic: clindamycin 20 mg/kg up to 600 mg po, IM, or IV; *or* azithromycin or clarithromycin 15 mg/kg up to 500 mg po. If allergy to penicillin is *not* anaphylaxis, angioedema, or urticaria, may also use cephalexin 50 mg/kg up to 2.0 g po; *or* cefazolin or ceftriaxone 50 mg/kg up to 1 g IM or IV.

PROGNOSIS

Bacterial endocarditis requires early detection and aggressive antibiotic therapy to decrease mortality. Overall mortality varies according to the pathogen and underlying condition but may be as high as 16 to 25 percent.

FOLLOW-UP

- Most patients with bacterial endocarditis will require 4 to 6 weeks of IV antibiotics.
- Depending on the antibiotics, some patients will need to have medication levels monitored.
- Repeat blood cultures are important to ensure response to therapy.
- An echocardiogram at the end of treatment provides baseline imaging, as patients with endocarditis are at risk for another episode.[9] SOR C

PATIENT EDUCATION

- Bacterial endocarditis is a serious disease with a significant mortality rate.
- Finish all antibiotics and keep follow-up appointments to ensure adequate treatment.
- Mortality remains elevated even 6 months after an episode.
- Recurrence is common, especially if risk factors remain (i.e., continued immunosuppression or IV drug use).

PATIENT RESOURCES

- The American Heart Association has information about who is at risk for bacterial endocarditis and a printable wallet card for at-risk patient, available in English or Spanish—**www.heart.org/HEARTORG/Conditions/CongenitalHeartDefects/TheImpactofCongenitalHeartDefects/Infective-Endocarditis_UCM_307108_Article.jsp**.

45 ACUTE RHEUMATIC FEVER

Abbas H. Zaidi, MB, BS
Athar M. Qureshi, MD

PATIENT STORY

An 11-year-old girl was referred for evaluation of a heart murmur. She has right knee pain and swelling that was preceded by right ankle pain and swelling. Three weeks prior to the presentation, she had a fever and sore throat. On exam, she has swelling and tenderness of her right knee, a hyperdynamic precordium with a pansystolic murmur heard best at the apex. She has an elevated Anti-streptolysin O (ASO) titer. Her echocardiogram confirms severe mitral regurgitation (**Figure 45-1**). She was diagnosed with acute rheumatic fever and admitted to the hospital. She was treated with penicillin, aspirin, and bed rest with significant clinical improvement. She was discharged from the hospital within a week and over the course of the next few months, her mitral regurgitation improved.

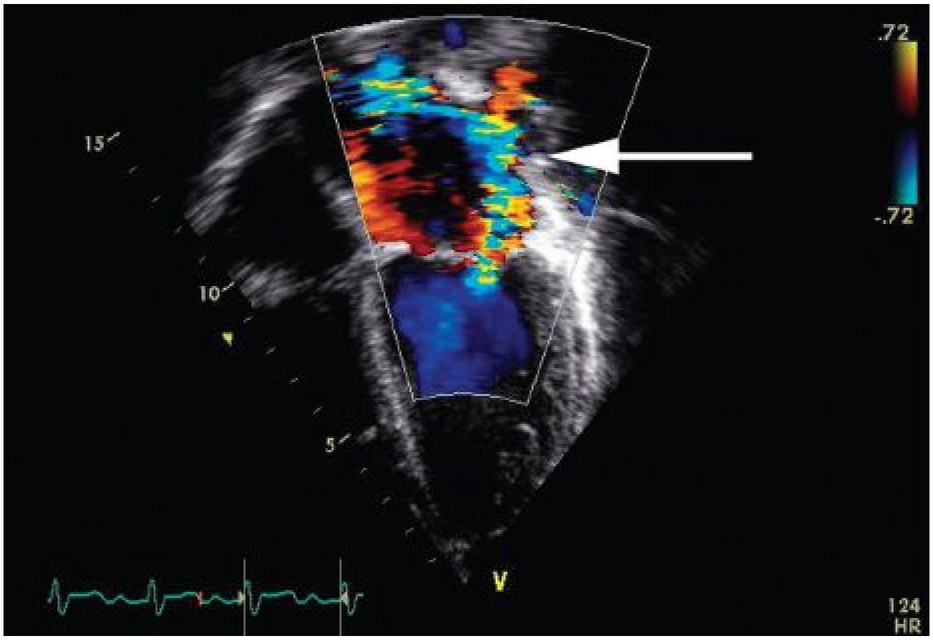

FIGURE 45-1 Transthoracic echocardiogram (apical four-chamber view) in an 11-year-old with acute rheumatic fever and severe mitral regurgitation (arrow). (*Used with permission from Athar M. Qureshi, MD*.)

INTRODUCTION

Acute rheumatic fever (ARF) is an inflammatory disease that affects susceptible children and adolescents, (most commonly aged 3 to 19 years). It is mediated by humoral and cellular autoimmune responses that occur as delayed sequelae of *Streptococcus pyogenes* (group A) (GAS) pharyngitis. The manifestations of ARF usually manifest 2 to 4 weeks after the initial infection.

SYNONYMS

- Sydenham’s chorea is also called St. Vitus’ dance. It is only one manifestation of ARF and is addressed in the following section.

EPIDEMIOLOGY

- Rheumatic heart disease has a prevalence of at least 15.6 million cases, with 282,000 new cases and 233,000 deaths each year.[1]
- The disease today mostly occurs in developing countries.
- There has been a dramatic decline in the incidence of ARF in the US over the past few decades. Although the reasons for this decline are not entirely clear, a shift in the prevalence from circulating rheumatologic to nonrheumatologic strains of GAS likely has played an important role.[2]

- Nevertheless, outbreaks of acute ARF have continued to occur in the US over the past three decades.[3,4]

ETIOLOGY AND PATHOPHYSIOLOGY

- Mimicry between group A streptococci and host antigens has been proposed as a mechanism for the development of the manifestations observed in ARF.
- GAS possess antigens and superantigens, which stimulate B and T cells to respond to self.

RISK FACTORS

Risk factors for RF can be categorized as being:

- Socioeconomic factors such as poverty, crowding, lack of education, and poor access to health care.
- Biological factors such as failure to diagnose the infection and genetic susceptibility.
- Lifestyle factors, such as poor nutrition.

DIAGNOSIS

CLINICAL FEATURES

According to revised Jones criteria,[5,6] the diagnosis can be made when two major criteria, or one major and two minor criteria are present, along with evidence of streptococcal infection, that is, elevated or rising ASO titer or DNAase.

Major criteria

- Polyarthritis—A migrating and temporary inflammation of joints, which usually starts in the legs and involves large joints.
- Carditis—Inflammation of the heart, which may present as valvular heart disease (**Figure 45-1**), pericarditis, or congestive heart failure due to myocarditis.
- Subcutaneous nodules (**Figure 45-2**).

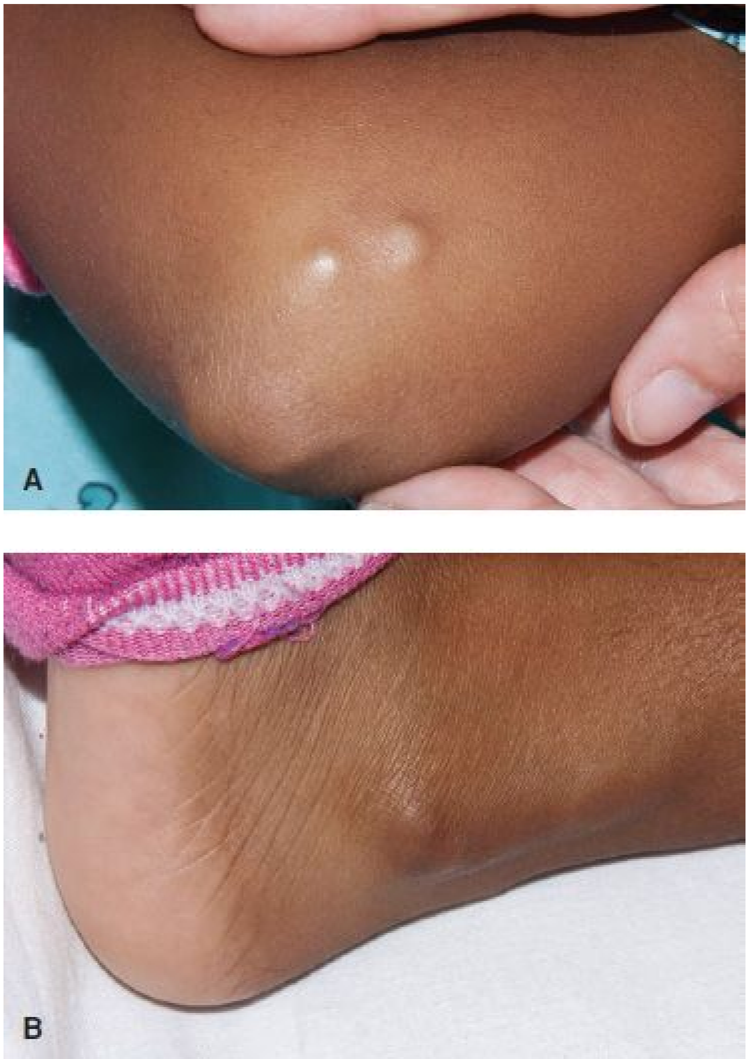

FIGURE 45-2 Painless subcutaneous nodules of acute rheumatic fever over the dorsal forearm/elbow (A) and lateral foot (B) in a 3-year-old girl who presented with fever, migratory arthritis, new-onset mitral regurgitation,

elevated erythrocyte sedimentation rate and very elevated anti-streptolysin O titer. (Used with permission from Blanca Gonzalez, MD)

- Erythema marginatum (**Figure 45-3**).

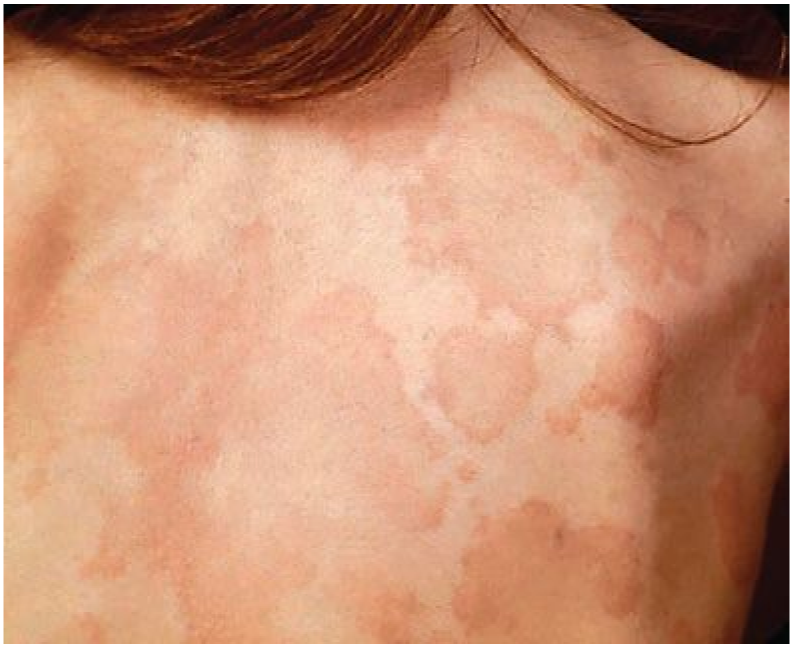

FIGURE 45-3 Erythema marginatum. This photosensitive rash begins on the central areas of the body as macules, and spreads more distally. The macules clear out from the center to form rings, which can sometimes coalesce to form a serpentine pattern on the body. (*Used with permission from Cleveland Clinic Hospital Photo File*.)

- Sydenham's chorea (St. Vitus' dance)—A characteristic rapid movement of the extremities, which is involuntary and may be associated with facial grimacing. This can occur late in the disease up to a few months from the onset of the infection.

▶ Minor criteria

- High fever ranging from 38.2 to 38.9 °C (101 to 102°F).
- Arthralgia—Joint pain without any significant signs of swelling or redness. (A diagnosis of polyarthritis eliminates arthralgia from the criteria.)

- Elevated erythrocyte sedimentation rate or C-reactive protein.
- Leukocytosis.
- Electrocardiogram (ECG) with features of heart block, that is, a prolonged PR interval (**Figure 45-4**). (Cannot be included if carditis is a major finding.)

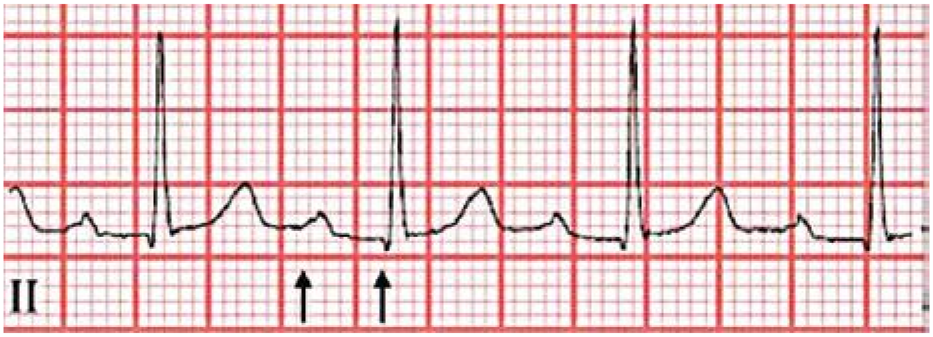

FIGURE 45-4 First-degree heart block with prolonged PR interval (interval between arrows), which may be present as a minor criterion for acute rheumatic fever. (*Used with permission from Athar M. Qureshi, MD.*)

- Prior episode of rheumatic fever or inactive heart disease.

LABORATORY TESTING

- Throat culture for GAS.
- ASO titer or DNAse titer.
- Erythrocyte sedimentation rate and C-reactive protein.

IMAGING

- CXR is recommended to evaluate heart size.
- ECG is recommended to assess for PR prolongation.
- Echocardiography is recommended to confirm and characterize cardiac involvement.

DIFFERENTIAL DIAGNOSIS

- Poststreptococcal reactive arthritis—Typically occurs after a shorter latent period (7 to 10 days) and is usually not migratory in nature.
- Infectious arthritis—Monarticular arthiritis with a positive joint aspirate fluid analysis and culture for organisms (not present in ARF).
- Rheumatoid arthritis—Longer lasting and commonly also involves small joints (see Chapter 172, Juvenile Rheumatoid Arthritis).

MANAGEMENT

NONPHARMACOLOGIC

- Avoidance of vigorous activity during the acute phase is recommended. SOR Ⓒ
- If the patient presents with congestive heart failure, management involves salt and water restriction, and upright posture.
- Injury protection during episodes of chorea.

MEDICATIONS

- Patients with ARF should be treated with antibiotics to eradicate GAS carriage regardless of culture status.[7] SOR Ⓐ
- Patients should receive either 10 days of oral penicillin or a single intramuscular injection of benzathine penicillin.[7] SOR Ⓐ
- Household contacts should have throat cultures performed and those with a positive throat culture should be treated with antibiotics. SOR Ⓒ
- Salicylates (i.e., aspirin) are the major anti-inflammatory agents for relief of arthritis symptoms due to acute rheumatic fever.[8] This results in the

prompt relief of arthritis symptoms. SOR Ⓐ

- Patients with significant heart failure from carditis should be treated with conventional therapy for heart failure.
- Anti-inflammatory agents such as aspirin are used in the acute management of rheumatic carditis. The role of corticosteroids and other anti-inflammatory agents in rheumatic carditis is uncertain.[9] SOR Ⓒ
- The rash associated with ARF is temporary and does not require specific treatment, although antihistamines may help to alleviate pruritus.
- Although chorea is a self-limited disease, the emotional distress can be alleviated with valproic acid, phenobarbital, or valium. SOR Ⓒ

SURGERY/INTERVENTIONAL CARDIOLOGY TREATMENT

Cardiac surgery or percutaneous treatment via cardiac catheterization is usually not needed in the acute phase, but may be needed for chronic valvular heart disease.[10,11]

REFERRAL

- Pediatric Cardiology, Infectious Disease and Rheumatology referral is warranted for most cases of ARF.

PREVENTION AND SCREENING

PRIMARY PREVENTION

- Prompt diagnosis and treatment of streptococcal pharyngitis is the key to primary prevention.

- Any child presenting with manifestations of GAS pharyngitis should have a throat culture performed, and if GAS is isolated, should be treated with antibiotics.

SECONDARY PREVENTION

- Patients who have a history of ARF and develop subsequent GAS pharyngitis are at high risk for rheumatic heart disease or exacerbation of existing rheumatic heart disease.[7]
- Thus, patients with a history of ARF should receive prophylactic antibiotics to prevent streptococcal pharyngitis.[7]
- Duration of antibiotic prophylaxis for those with a history of ARF depends on whether or not cardiac involvement was present initially and whether there is active cardiac disease.

PROGNOSIS

- The cardiac manifestations of ARF are associated with significant morbidity and mortality.
- Noncardiac manifestations of ARF ultimately resolve without sequelae.

FOLLOW-UP AND PATIENT EDUCATION

Patients should be educated about ARF and on the consequences of not treating acute streptococcal pharyngitis. After the diagnosis of ARF is made, patients should be counseled about the need for prevention of acute streptococcal pharyngitis and the need for long term follow-up for rheumatic carditis.

46 COMMON DYSRHYTHMIAS

Asif Padiyath, MD
Peter Aziz, MD

Three important dysrhythmias in the pediatric population include:

- Wolff-Parkinson-White syndrome.
- Long QT syndrome.
- Complete Heart Block.

All three conditions will be covered sequentially in this chapter.

WOLFF-PARKINSON-WHITE SYNDROME

PATIENT STORY

A previously healthy 14-year-old female presents with a 1-month history of rapid onset, rapid offset palpitations without any identifiable precipitating factors. The physical examination is unremarkable. The electrocardiogram (ECG) showed a delta wave, wide QRS, and short PR interval (**Figure 46-1**).

INTRODUCTION

Wolff-Parkinson-White (WPW) syndrome is a congenital abnormality involving the presence of abnormal conduction tissue, or accessory pathway, between the atria and the ventricles in association with supraventricular tachycardia (SVT).[1]

SYNONYM

Pre-excitation or WPW syndrome.

EPIDEMIOLOGY

- In large-scale general population studies involving children and adults, the prevalence of WPW is estimated to be 1 to 3 in 1000.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Ventricular pre excitation occurs due to electrical conduction down an accessory pathway (AP).
- AP conduction circumvents the usual conduction delay between the atria and ventricles, which occurs at the AV node (AVN), and predisposes the patient to develop reentrant tachycardia.
- The most common type of supraventricular tachycardia seen in patients with WPW is orthodromic reentrant tachycardia (ORT; **Figure 46-2**).

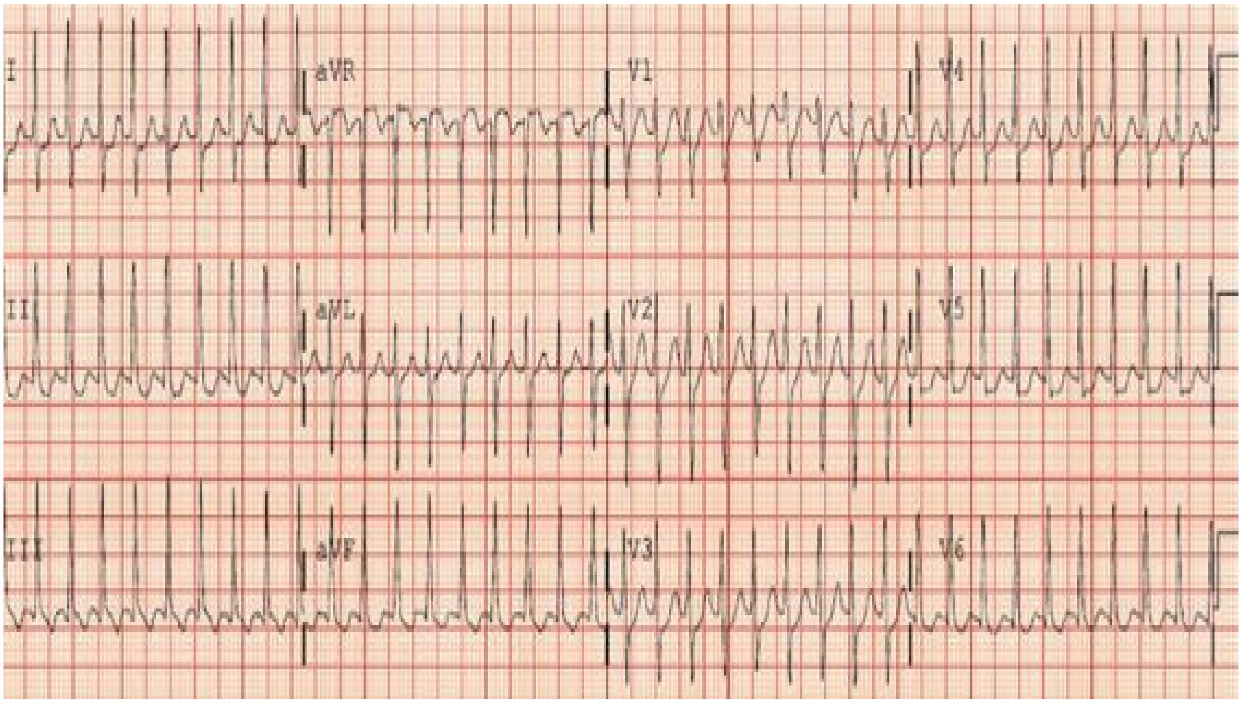

FIGURE 46-2 Orthodromic reciprocating tachycardia (ORT) via a left lateral pathway. Note the narrow complex QRS seen in patients during supraventricular tachycardia. (*Used with permission from Peter Aziz, MD*.)

- Most commonly precipitated by a premature atrial contraction (PAC), the cardiac impulse travels down the AV node to the ventricles and then back to the atria via the accessory pathway. Rarely, antidromic reciprocating tachycardia (ART) occurs due to antegrade conduction down the accessory pathway and retrograde conduction up the AVN.

RISK FACTORS

- Mutations in the PRKAG2 gene can cause familial WPW syndrome.
- Congenital anomalies such as Ebsteins and hypertrophic cardiomyopathy are associated with WPW.

DIAGNOSIS

CLINICAL FEATURES

- Patients with WPW can be asymptomatic.
- The most common clinical manifestation is palpitations.
- Syncope or sudden death is rare and associated with rapid ventricular conduction of atrial fibrillation.
- Physical exam is usually unremarkable. During periods of SVT, tachycardia can be noted with a decrease in blood pressure. If the episode has been untreated for several hours, patients can manifest poor perfusion, hepatomegaly, and cardiac failure.
- Stigmata of associated congenital anomalies such as Ebstein anomaly should be excluded.

IMAGING

- The ECG will show classic findings of WPW: (1) short PR interval, (2) delta wave, and (3) wide QRS complex.
- In patients with atrial fibrillation and rapid accessory pathway conduction, an ECG will show an irregularly, irregular, wide complex tachycardia (**Figure 46-3**). This is the cause of sudden death in patients with WPW.

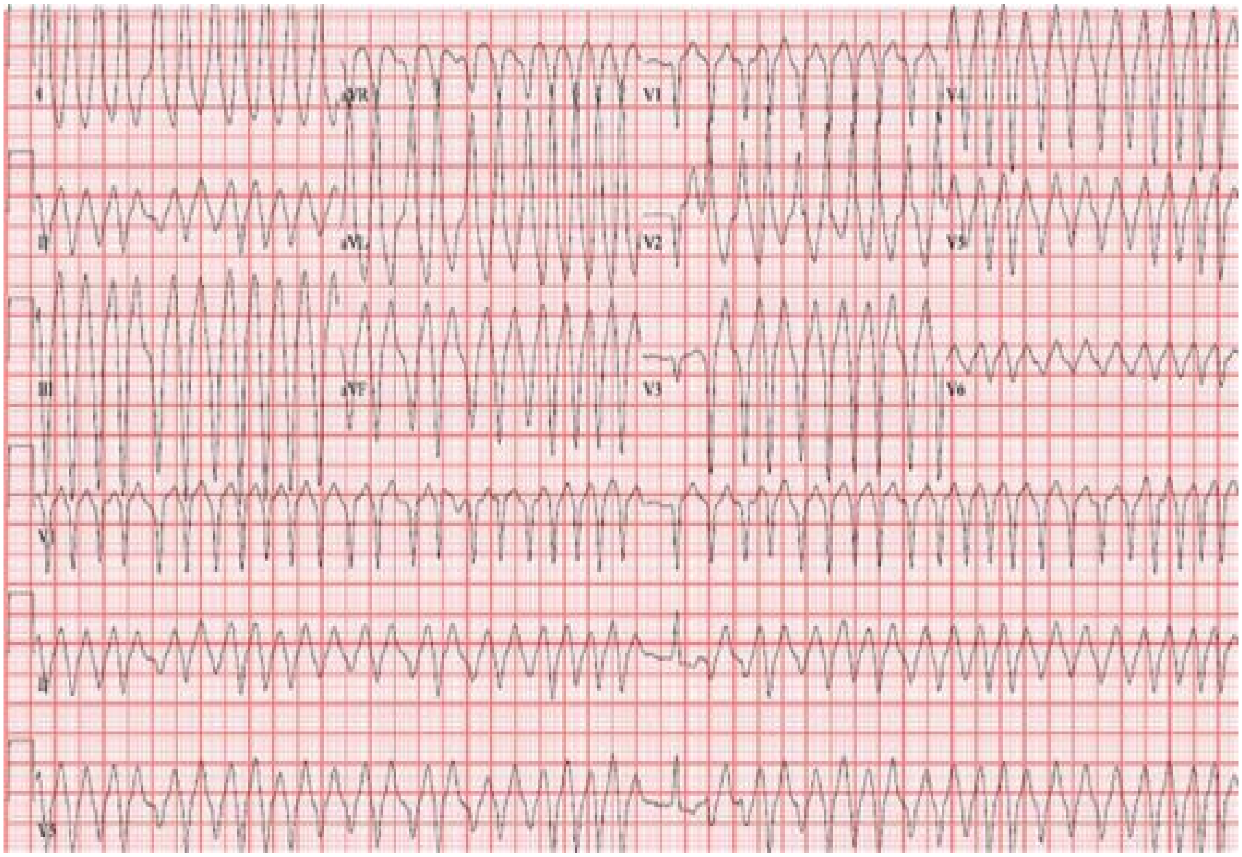

FIGURE 46-3 Atrial fibrillation with rapid ventricular response in a patient with WPW. ECG shows an irregularly irregular wide complex tachycardia. This phenomenon is the cause of sudden cardiac death in WPW patients. (*Used with permission from Peter Aziz, MD*.)

DIFFERENTIAL DIAGNOSIS

- Other types of arrhythmias (AVNRT, atrial tachycardia, or ventricular tachycardia) are typically excluded by an ECG during the tachycardia.
- Other rare pre-excitation subtypes (Mahain fibers, permanent junctional reciprocating tachycardia) can also be distinguished by ECG findings.

MANAGEMENT

- Treatment must be individualized for each patient and should include individual risk assessment.
- Reentrant SVT will terminate with vagal maneuvers (Valsalva or carotid message) or adenosine.
- Two main treatment approaches to WPW syndrome are pharmacotherapy and electrophysiology study (EPS) with catheter ablation.
    - EPS with catheter ablation is the first-line treatment for symptomatic WPW syndrome.[3] SOR A
    - AVN blocking agents (digoxin, calcium channel blockers) are contraindicated in patients with WPW.[3,4] SOR B

REFERRAL

- Patients with WPW require an evaluation by a pediatric electrophysiologist.

PREVENTION AND SCREENING

- No preventive modalities currently exist since mostly WPW is congenital in origin.
- No established screening is being currently used in the US.

PROGNOSIS

- Once identified and appropriately treated, WPW syndrome has an excellent prognosis.
- Mortality is rare and is related to Sudden Cardiac Death (SCD). Incidence of mortality in SCD in WPW syndrome is found to be 1 in 100 symptomatic patients when followed up to 15 years.[5]

FOLLOW-UP

- Regular follow-up is needed to assess for recurrence of arrhythmia, adverse reaction to medicines, and to assess the effectiveness of therapy.

PATIENT EDUCATION

- Close follow-up with patients diagnosed with WPW syndrome is essential to assess the need and timing of interventions.

LONG QT SYNDROME

PATIENT STORY

A 12-year-old female presents with recent syncope. She was swimming during a family vacation on a beach. She lost consciousness and was unresponsive for 30 seconds. She does not recall a prodrome prior to the syncopal event. She had started a decongestant medication for Upper respiratory tract infection symptoms the day prior. Her mother and grandmother have also had syncopal events in the past associated with exercise. Her ECG shows QTc prolongation (**Figure 46-4**).

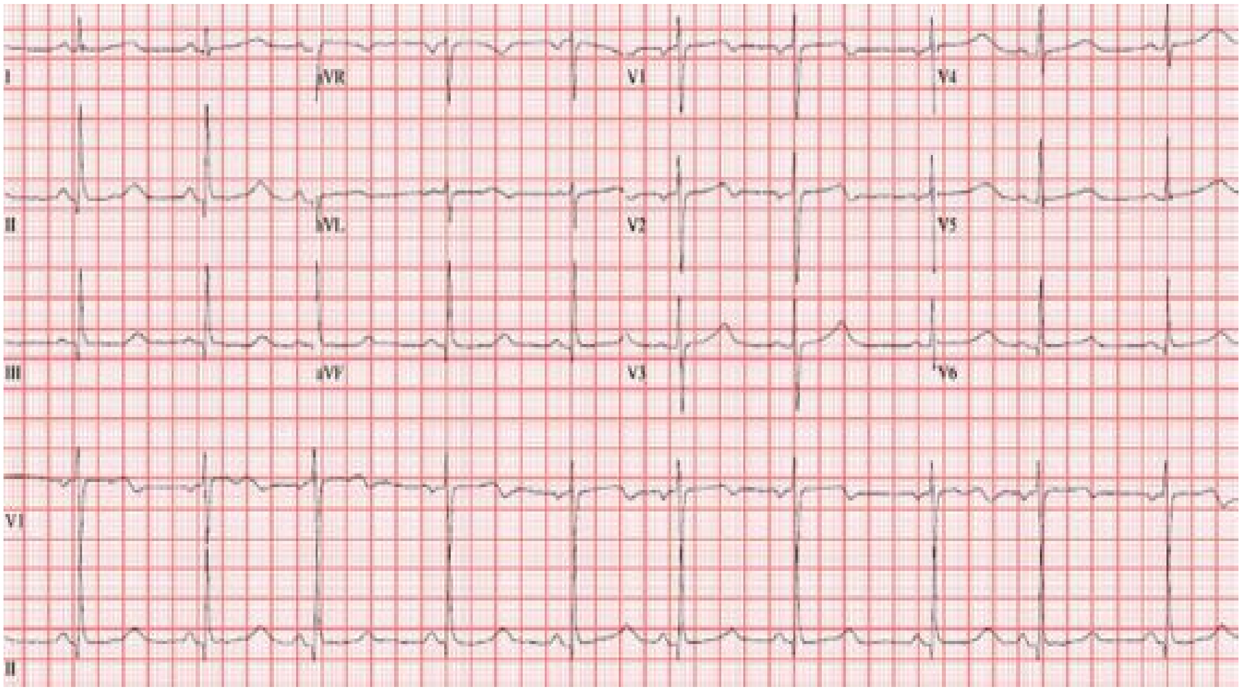

FIGURE 46-4 ECG showing QTc prolongation (QTc=570ms). This patient had the classic long QT syndrome presentation of syncope during swimming consistent with long QT type 1. (*Used with permission from Peter Aziz, MD.*)

INTRODUCTION

Long QT syndrome (LQTS) is an ion channelopathy characterized by a prolonged QTc interval, syncope, ventricular arrhythmias and sudden death.[6,7]

SYNONYMS

Jervell and Lange-Nielson syndrome and Romano Ward Syndrome refer to specific types of LQTS.

EPIDEMIOLOGY

- The estimated prevalence of LQTS is about 1:5000.[8]
- There are presumably many patients with LQTS that are asymptomatic or have not yet been diagnosed.

ETIOLOGY AND PATHOPHYSIOLOGY

- LQTS is caused by ion channel mutations that result in delayed ventricular repolarization.
- This delay in ventricular repolarization subjects myocardial cells to arrhythmias as after depolarizations are propagated between cells.
- Catecholamines play an important role in precipitating these after depolarizations and patients with LQTS are particularly at risk during periods of exercise or excitement.

- The hallmark arrhythmia for LQTS is torsade de pointes (**Figure 46-5**).

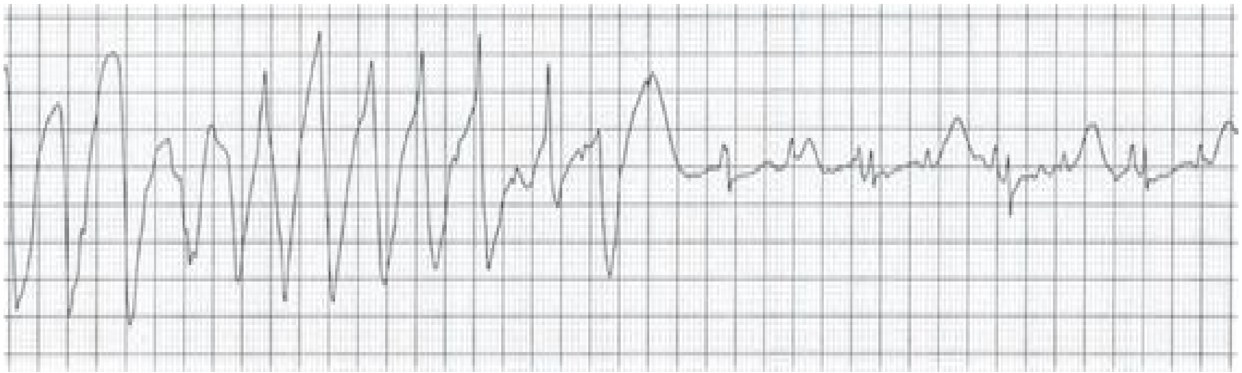

FIGURE 46-5 Rhythm strip showing torsade de pointes in an infant with long QT syndrome. The rhythm disturbance spontaneously terminated in this patient. (*Used with permission from Peter Aziz, MD*.)

RISK FACTORS

- The majority of LQTS cases are inherited in an autosomal dominant fashion. As such, children of parents with LQTS have a 50 percent chance of having the same gene defect.
- Patients with syncope, particularly during exertion, should under an ECG to assess for LQTS.
- Though uncommon, an autosomal recessive form of LQTS (Jervell and Lange-Nielson syndrome) is associated with congenital deafness therefore patients with hearing loss should also undergo ECG evaluation.

DIAGNOSIS

- The ECG is the hallmark of the diagnosis in LQTS and should be performed in any patient with a family history of LQTS or with symptoms of LQTS. The ECG has important limitations, however.

- Some patients with LQTS (depending on the specific genotype) will have abnormal repolarization responses to exercise. Therefore, the exercise stress test has been employed as a diagnostic tool.[9]
- The Schwartz criteria provide a point system based on various risk factors known to be associated with LQTS.[7]
- Genetic testing has become commercially available for LQTS and most insurance companies provide coverage for testing. There are currently 13 identified LQT genes.

DIFFERENTIAL DIAGNOSIS

- All causes of syncope and sudden cardiac death should be considered including hypertrophic cardiomyopathy, anomalous coronary origin, Wolff-Parkinson-White syndrome, catecholaminergic polymorphic ventricular tachycardia (CPVT), Brugada syndrome, and arrhythmogenic right ventricular cardiomyopathy (ARVC).
- These diagnoses can typically be excluded during the evaluation by a cardiologist or electrophysiologist.

MANAGEMENT

- The management of LQTS is predicated on beta-blocker therapy, specifically nonselective types such as nadolol or propranolol.[10] SOR Ⓐ
- Patients who continue to have symptoms (syncope or aborted cardiac arrest) while on therapy should undergo implantation of an implantable cardioverter-defibrillator (ICD).[11] SOR Ⓐ
- Other therapies such as ganglionectomy have also been used in high-risk patients.[12] SOR Ⓑ

REFERRAL

- Patients with long QT syndrome need a referral to a pediatric electrophysiologist.

PREVENTION AND SCREENING

- All drugs known to cause a prolongation in the QT interval should be avoided. A current list of these drugs can be found on www.qtdrugs.org.
- If congenital long QT syndrome is suspected, all first degree relatives should undergo genetic screening.[13,14] SOR Ⓐ

PROGNOSIS

- Generally, the prognosis for LQTS patients who are compliant with medication is excellent. Few patients considered high-risk will continue to have symptoms despite therapy.

FOLLOW-UP

- Patients with Long QT syndrome need to be followed up closely by a pediatric electrophysiologist.

PATIENT EDUCATION

- Patients with long QT syndrome should be educated appropriately to avoid QTc prolonging drugs.

- They should also be encouraged to have their immediate family members screened for Long QT syndrome.

PATIENT RESOURCES

- **http://my.clevelandclinic.org/heart/disorders/electric/longqtsyndrome.aspx**.

- 2013 HRS/EHRA/APHRS Expert Consensus Statement on the Diagnosis and Management of Patients with Inherited PrimaryArrhythmia Syndromes. Developed in partnership with the Heart Rhythm Society (HRS), the European Heart Rhythm, Association (EHRA), a registered branch of the European Society of Cardiology, and the Asia Pacific Heart Rhythm Society (APHRS); and in collaboration with the American College of Cardiology Foundation (ACCF), the American Heart Association (AHA), the Pediatric and Congenital Electrophysiology Society (PACES) and the Association for European Pediatric and Congenital Cardiology (AEPC).

COMPLETE HEART BLOCK

PATIENT STORY

A 15-month-old boy is seen by his pediatrician for failure to thrive. The patient has had poor growth since a viral infection consisting of rhinorrhea and cough about 4 months ago. His activity level has decreased. His physical examination is remarkable for hepatomegaly and bradycardia (heart rate 50 beats per minute). An ECG is performed showing AV dissociation (**Figure 46-6**).

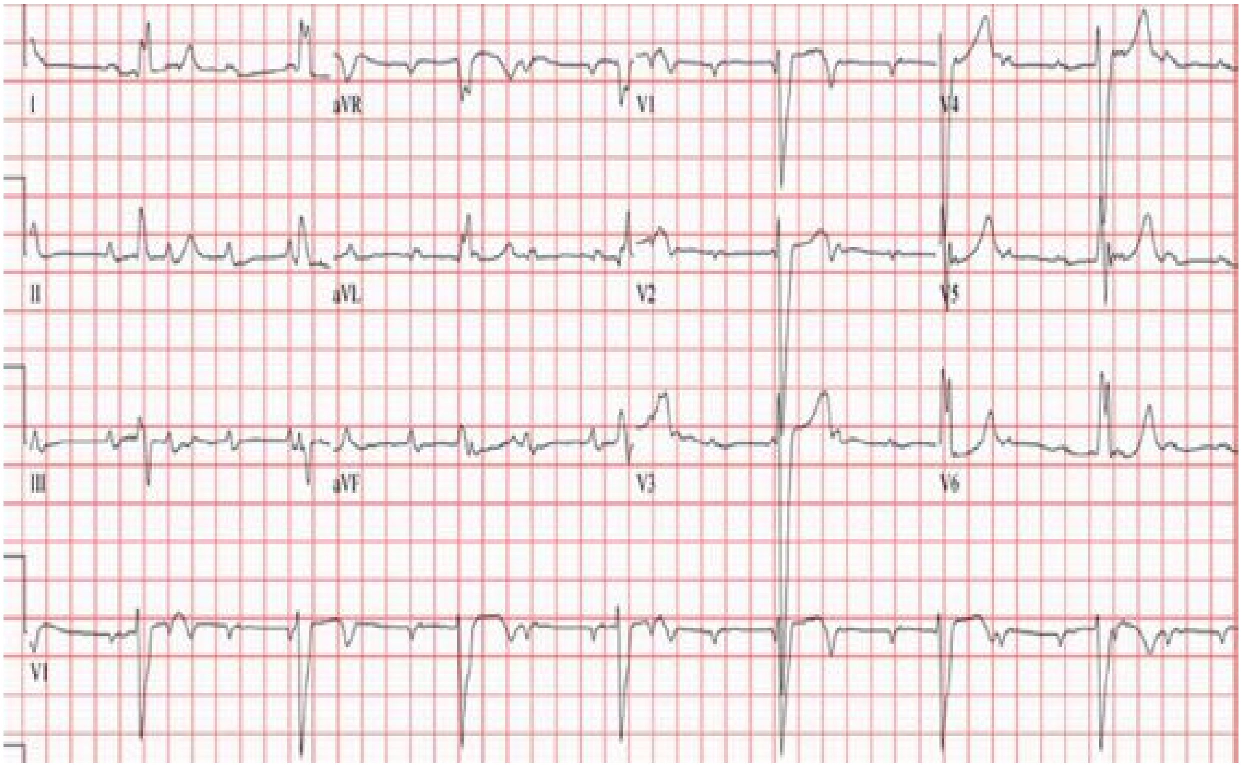

FIGURE 46-6 ECG showing complete heart block. The ECG is notable for bradycardia, AV dissociation, and a wide complex ventricular escape rhythm. (*Used with permission from Peter Aziz, MD*.)

INTRODUCTION

Complete heart block (CHB) occurs when the atrioventricular node (AVN) is unable to conduct an electrical impulse from the atrium to the ventricle. Congenital complete heart block is the most common indication for pacemaker implantation in the pediatric population in the absence of congenital heart disease. Approximately 20 to 30 percent of pacemakers in the pediatric population are implanted for this indication. Although maternal lupus antibody exposure is the most common cause of CHB, most cases are idiopathic. Isolated CHB in the absence of congenital heart disease carries an excellent prognosis.[15,16]

SYNONYM

Atrioventricular dissociation or atrioventricular block.

EPIDEMIIOLOGY

The prevalence of CHB is between 0.04 and 0.02 percent.[17]

ETIOLOGY AND PATHOPHYSIOLOGY

- Fibrosis or scarring of the AVN can occur for a variety of reasons.
- In the absence of structural heart disease, lupus antibodies SS-A (Ro) and SS-B (La) cause damage to the AVN resulting in complete heart block.
- Mothers can transmit these antibodies through the placenta causing fetal AVN damage.
- Acquired CHB can occur spontaneously in patients with specific types of congenital heart disease (see the following section) or as the result of surgical correction of congenital heart disease.
- Occasionally acquired CHB is the sequelae of viral infections as in the patient described in this scenario.
- CHB is also a known, though transient, consequence of Lyme disease.

RISK FACTORS

- Infants at risk for CHB include those exposed to maternal lupus antibodies.

- Children undergoing surgical correction of heart disease, particularly those with ventricular septal defects, are at risk for developing acquired CHB.
- Patients with L-transposition of the great arteries (L-TGA), heterotaxy syndrome and atrioventricular canal defects can develop CHB spontaneously, in the absence of surgical manipulation of the AVN.

DIAGNOSIS

- The ECG is diagnostic of complete heart block.
- Ambulatory monitoring (Holters) can offer insight into the severity of disease.
- Echocardiograms should be performed in any patient with CHB to assess for congenital heart disease and cardiomyopathy.

DIFFERENTIAL DIAGNOSIS

- The differential for bradycardia in the absence of complete heart block includes hypervagatonia, which is common in young athletes.

MANAGEMENT

- Complete heart block requires a thorough investigation by a pediatric electrophysiologist.
- The acute management of CHB depends on symptoms. In a symptomatic patient, administration of isoproterenol or atropine can increase the ventricular escape rate and relieve symptoms.[18] SOR Ⓐ Transcutaneous pacing is rarely indicated.
- Typically an asymptomatic patient does not require acute treatment. SOR Ⓒ

- Pacemaker implantation depends on disease severity and the presence of congenital heart disease. Most patients that are asymptomatic with normal cardiac function can be followed closely.
- Patients with low average heart rates or a wide escape rhythm should undergo pacemaker implantation (**Figures 46-7** and **46-8**).[19] SOR B

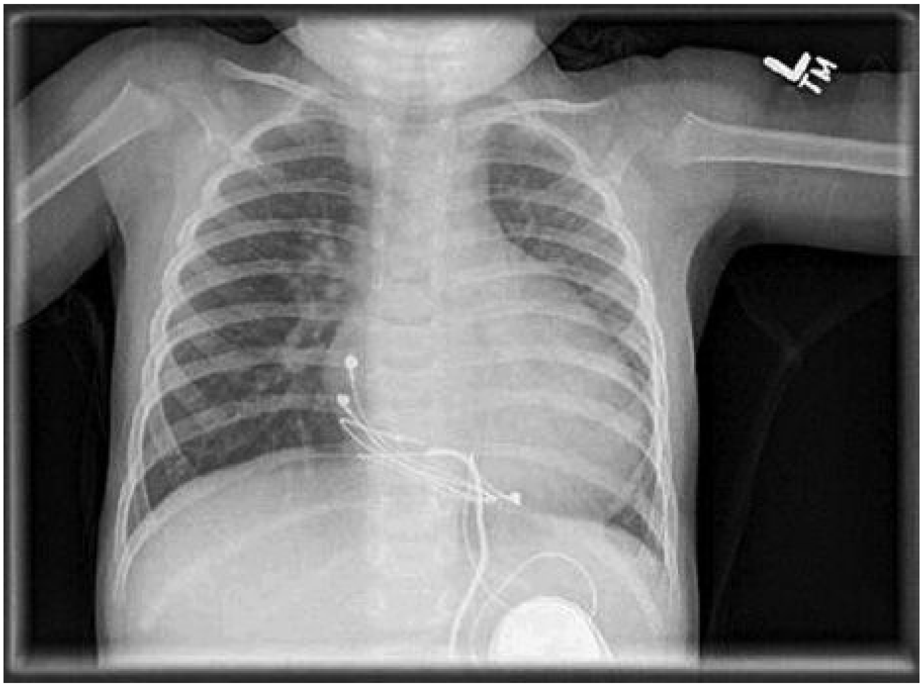

FIGURE 46-7 Chest radiograph post-implantation of an epicardial, dual-chamber pacemaker. The chest radiograph is significant for cardiomegaly. The pacemaker is implanted surgically in the abdomen and the pacemaker leads are sutured on the surface of the atrial and ventricular myocardium. (*Used with permission from Peter Aziz, MD*.)

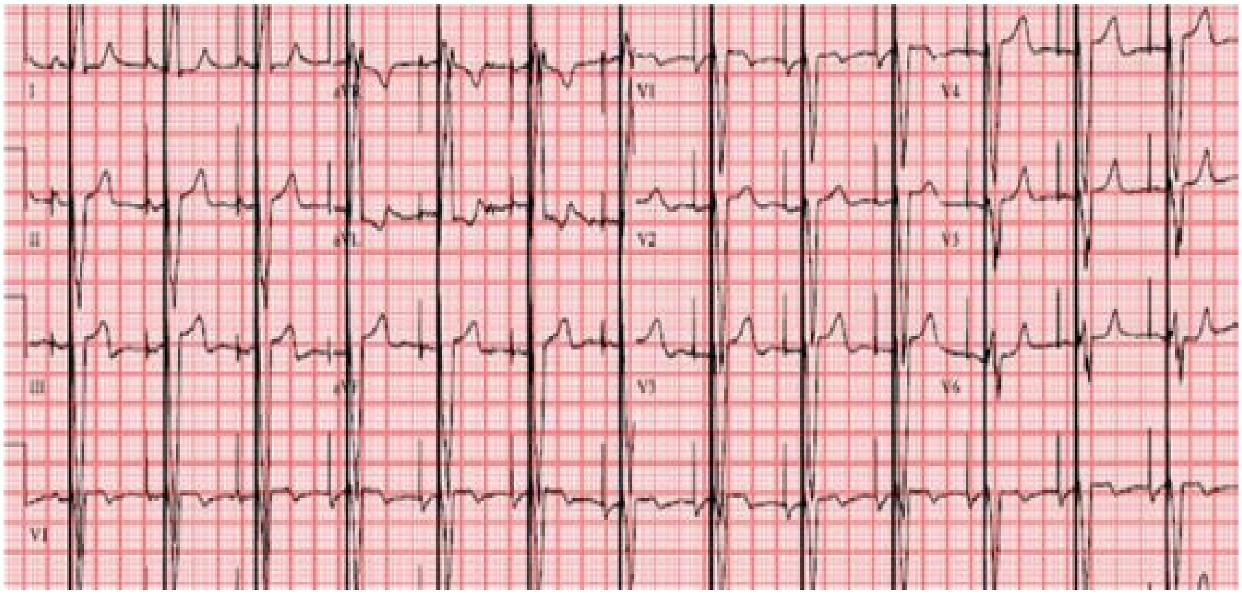

FIGURE 46-8 ECG after pacing of patient in Figure 46-7 showing sequential atrioventricular pacing denoted by the large pacing spikes prior to the P wave and the QRS. This patient has sinus node dysfunction in addition to complete heart block. (*Used with permission from Peter Aziz, MD*.)

- Patients with post-surgical heart block can be monitored for 7 to 10 days as spontaneous resolution can occur.[20] SOR A

REFERRAL

- Patients diagnosed with CHB irrespective of the etiology, need immediate referral, evaluation, and management by a pediatric electrophysiologist.

PREVENTION AND SCREENING

- Patients with known risk factors such as maternal history of lupus should be screened with a post natal ECG.
- Use of steroids prenatally in SLE in the setting on maternal SLE has been evaluated but has not been found to be effective.[21]

PROGNOSIS

- Short-term prognosis is generally good in newborns with CHB born to mothers with Lupus antibodies unless the clinical picture is complicated by prematurity, development of hydrops or abnormal cardiac anatomy.[22] But in the long term, 32 percent of the unpaced eventually develop symptoms, including 5 percent who experience sudden cardiac death.[23]
- Prognosis of CHB secondary to an open heart surgery, is mostly transient but can be permanent depending on the degree of the damage to the AV node during surgery.

FOLLOW-UP

- Close follow-up is needed once the diagnosis is made. Patients with CHB need routine assessment including cardiac examinations, echocardiograms and ECGs.

PATIENT EDUCATION

- Appropriate anticipatory counseling should be offered to a pregnant mother with a fetus diagnosed with CHB.

47 SYNDROMES ASSOCIATED WITH HEART DISEASE

Asif Padiyath, MD
Peter Aziz, MD

Infants and children with genetic syndromes frequently have associated cardiovascular abnormalities. It is important to recognize the cardiovascular anomalies associated with these genetic syndromes, as they account for significant morbidity and mortality. In this chapter, important genetic syndromes that are associated with cardiovascular manifestations are presented successively and include:

- Down syndrome.
- Turner syndrome.
- DiGeorge syndrome.
- Williams syndrome.
- Marfan syndrome.

The focus of this chapter is on the cardiovascular abnormalities. For further clinical information on these genetic syndromes, please refer to Chapters 216, DiGeorge Syndrome; 221, Down Syndrome; 222 Turner Syndrome; and 223, Marfan Syndrome.

DOWN SYNDROME

PATIENT STORY

A 35-week premature infant of a 42-year-old mother is delivered due to premature labor. A prior fetal echocardiogram showed an atrio-ventricular (AV) canal defect. The patient's mother had denied amniocentesis and chromosomal testing during pregnancy. Post-natal examination of the infant reveals simian creases, macroglossia and sandal gap toe. The diagnosis of Down syndrome is made clinically and the diagnosis of AV canal defect is confirmed on echocardiogram (**Figure 47-1**). Surgery to repair the AV canal defect was scheduled at 3 to 6 months of age.

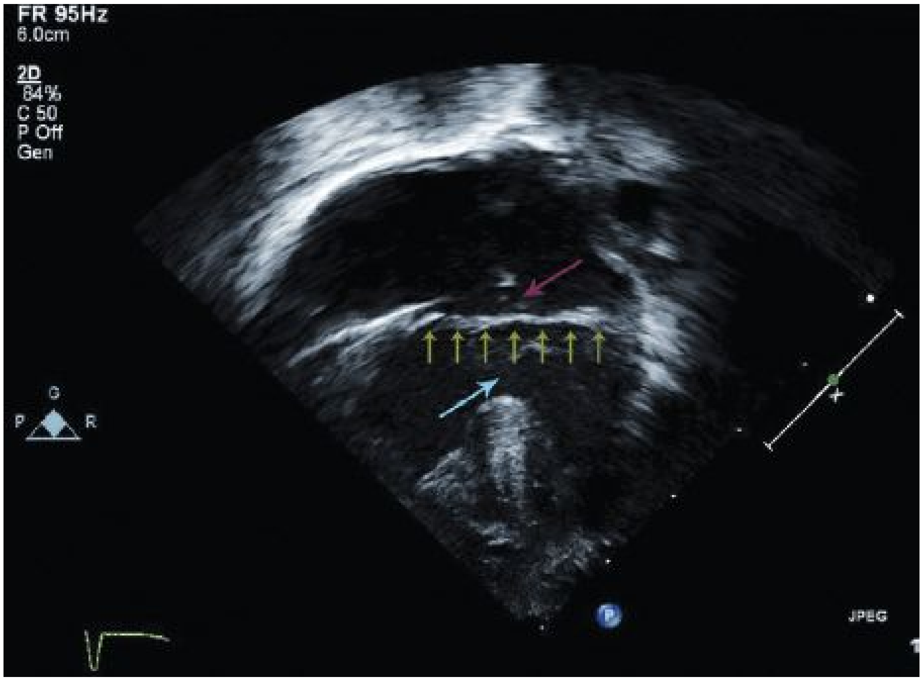

FIGURE 47-1 Apical four chamber view of a complete atrio-ventricular canal defect in an infant on echocardiogram. Note the atrial and ventricular septal defects (red and blue arrows respectively). The common atrioventricular valve (green arrows) sits in a horizontal plane along the atrioventricular groove which is characteristic of this defect. (*Used with permission from Peter Aziz, MD.*)

INTRODUCTION

Down syndrome (Trisomy 21) is associated with a significant risk of congenital heart disease. Every infant with Down syndrome must be evaluated for the presence of congenital heart disease.

SYNONYMS

Trisomy 21

EPIDEMIOLOGY

- Cardiovascular malformations are found in 40 to 50 percent of individuals with Down syndrome.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- A spectrum of endocardial cushion defects is common in Down syndrome and its prevalence is higher in patients with Down syndrome compared to that of general population.
- The most common cardiac anomalies associated with Down syndrome include common AV canal, ventricular septal defect (VSD), tetralogy of Fallot and patent ductus arteriosus.

RISK FACTORS

- Advanced maternal age.

DIAGNOSIS

- The diagnosis of Down syndrome is frequently made antenatally with first trimester screening lab tests and ultrasound appearance of increased nuchal cord thickness.
- Diagnosis is often confirmed by chromosomal analysis from amniocentesis.
- Antenatal diagnosis of cardiac defects in Down syndrome fetuses is accomplished by fetal echocardiography in the second trimester.
- Newborn infants with AV canal defects are typically asymptomatic. They typically manifest symptoms at 3 to 6 months of age when the pulmonary vascular resistance decreases.

IMAGING

- Electrocardiogram should be obtained and will reveal abnormalities associated with the specific cardiac defects (**Figure 47-2**).

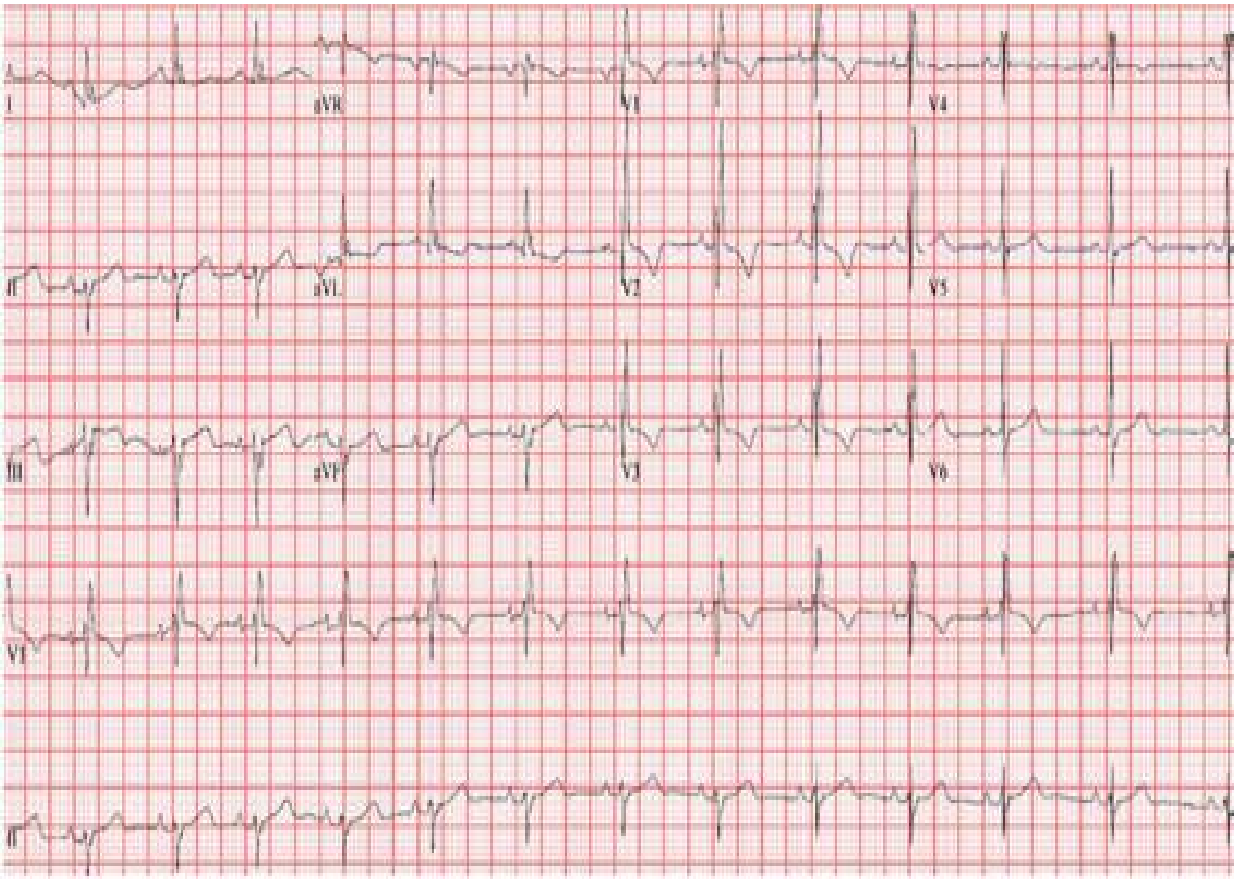

FIGURE 47-2 Superior axis (negative QRS in aVF), characteristic of common atrioventricular canal defect on electrocardiogram. The patient also has a right bundle branch block (RSR’ in V1 and wide QRS) as the result of surgical closure of the canal type ventricular septal defect. (*Used with permission from Peter Aziz, MD.*)

- Echocardiography.

MANAGEMENT

- Management of each cardiac lesion in Down syndrome is addressed in Chapter 42, Acyanotic Congenital Heart Disease, and Chapter 43, Cyanotic Congenital Heart Disease.

REFERRAL

- Many of the cardiac defects are detected by antenatal screening ultrasounds and appropriate referral to a fetal cardiologist for further evaluation with a fetal echocardiogram is commonplace.

PREVENTION AND SCREENING

- Screening for a cardiac anomaly is usually performed by prenatal ultrasounds in the second trimester.

PROGNOSIS

- The prognosis depends on the specific cardiac anomaly detected.

FOLLOW-UP

- Once a cardiac anomaly is detected prenatally or postnatally, careful follow-up by a pediatric cardiologist is required.

PATIENT RESOURCES

TURNER SYNDROME

PATIENT STORY

A 16-year-old female is seen by her primary care physician for primary amenorrhea. On examination she is noted to have short stature, a webbed neck, and widely spaced nipples. Her upper limb blood pressures are above the 95th percentile for her height and four-extremity blood pressures show a systolic gradient of 50 mm Hg between the upper and lower limbs. She has brachiofemoral delay. On chest auscultation she has a grade II/VI systolic ejection murmur in the base of the heart and in the left interscapular region. She also has a continuous murmur audible almost all over the rib cage. A diagnosis of coarctation of the aorta is made via echocardiography and CT angiography (**Figure 47-3**). Chromosomal testing confirms the diagnosis of Turner syndrome. She undergoes surgical repair of the coarctation without complications.

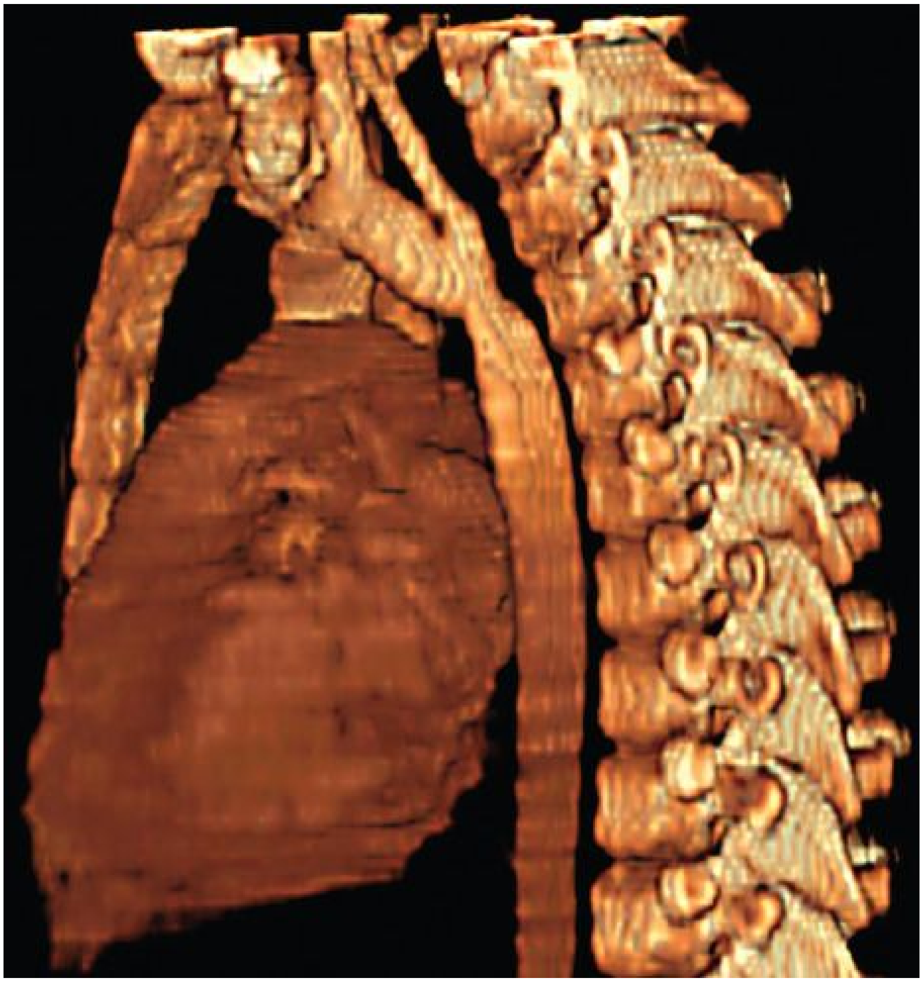

FIGURE 47-3 Discrete coarctation of the aorta just distal to the left subclavian artery on CT angiogram in a patient with Turner syndrome. (*Used with permission from Kenneth Zahka, MD*.)

INTRODUCTION

Turner syndrome is caused by an absence of one sex chromosome yielding the 45, X genotype. Turner syndrome is associated with coarctation of the aorta.

SYNONYMS

45X syndrome, Bonnevie-Ullrich syndrome, Monosomy X, Ullrich-Turner syndrome.

EPIDEMIOLOGY

- The incidence of Turner syndrome is approximately 1 in 2000 liveborn female infants[2]
- Twenty to 40 percent of girls born with Turner syndrome have cardiovascular anomalies.

ETIOLOGY AND PATHOPHYSIOLOGY

- The most common cardiovascular malformation is coarctation of the aorta, although bicuspid aortic valve and aortic stenosis are also common.
- Patients with Turner syndrome can have a spectrum of left heart obstructive lesions ranging from bicuspid aortic valve to hypoplastic left heart syndrome, although the latter is quite rare.

DIAGNOSIS

- Unlike Down syndrome, Turner syndrome is usually diagnosed postnatally. Once the diagnosis of Turner syndrome is made, a clinical and echocardiographic evaluation for cardiac defects should be performed.
- Complete or near complete obstruction occurring from coarctation of the aorta can result in left sided heart failure.
- Milder forms of coarctation may go unnoticed for many years and become apparent during evaluation of “primary” hypertension.

- As described in the case, uncomplicated coarctation of the aorta will have clinical signs of hypertension, lower blood pressures in the lower limbs, brachiofemoral delay and a systolic ejection murmur in the left interscapular region.
- A long-standing coarctation can cause collateral flow through the intercostal arteries resulting in continuous murmurs.
- Patients with a bicuspid aortic valve can have a systolic click and/or a systolic ejection murmur in the aortic area radiating to the carotid arteries.

IMAGING

- A chest radiograph can show rib notching due to collateral artery formation in aortic coarctation. This finding is uncommon in young children.
- An echocardiogram offers definitive diagnosis of the cardiac manifestations, although MRI and CT angiography may be utilized to help demonstrate the level of the obstruction, especially in older patients.

DIFFERENTIAL DIAGNOSIS

- Associated left-sided cardiac anomalies should be excluded when a coarctation is diagnosed in a patient with Turner syndrome.

MANAGEMENT

- The mainstay of management is surgical repair of aortic coarctation.[3] SOR Ⓐ
- Balloon angioplasty or stent placement can also be used in select patient groups.[4] SOR Ⓑ

REFERRAL

- All patients with Turner syndrome should have evaluation performed by a pediatric cardiologist.

PROGNOSIS

- The prognosis is excellent following successful complete surgical repair.
- Sports participation is generally permitted with the exception of high static (isometric) activities.[6] SOR Ⓑ
- Systolic blood pressures should be monitored closely after coarctation repair, as hypertension may develop.

FOLLOW-UP

- Depending on the diagnosis and timing of repair, close follow-up with a pediatric cardiologist is required to look for a recurrence or for development of complications such as hypertension.

PATIENT EDUCATION

- A collaborative approach of management in this patient group involving a geneticist, pediatric endocrinologist and general pediatrician should be planned and patients should be provided with anticipatory information regarding prognosis and follow-up.

PATIENT RESOURCES

DIGEORGE SYNDROME

PATIENT STORY

A 38-week gestation infant girl who was diagnosed antenatally with Truncus arteriosus (**Figure 47-4**) is transferred to the neonatal intensive care unit for stabilization soon after delivery. At 3 hours of life, the girl has a generalized seizure and is found to have serum calcium level of 4.5 mg/dL. The diagnosis of DiGeorge syndrome is suspected based on the cardiac lesion and the hypocalcemia, and confirmed by chromosomal testing. She undergoes surgical repair of her heart lesion at 8 days of life and recovers after a long hospitalization.

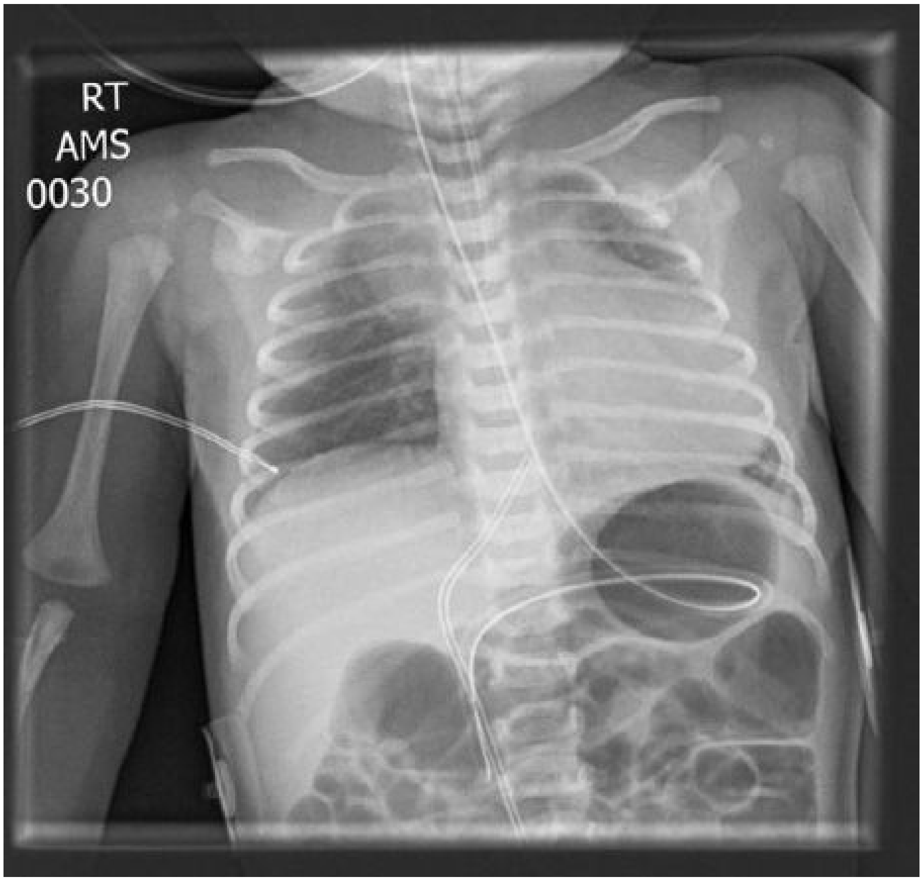

FIGURE 47-4 Profound cardiomegaly and right sided aortic arch in a newborn infant with Truncus arteriosus and DiGeorge syndrome. (*Used with permission from Camille Sabella, MD*.)

INTRODUCTION

DiGeorge syndrome (DGS) is caused by deletion or mutation of the long arm of chromosome 22 (22q1 1.2).

SYNONYMS

Velo-cardio-facial syndrome, Shprintzen syndrome, conotruncal anomaly face syndrome, Strong syndrome, congenital thymic aplasia/hypoplasia.

EPIDEMIOLOGY

- The incidence of DGS in the general population is 1 in 2000 to 4000 persons.
- Congenital heart defects are observed in 74 to 80 percent of affected patients.[7]

ETIOLOGY AND PATHOPHYSIOLOGY

- DiGeorge syndrome results from deletion of the 22q11.2 segment.
- Most of the manifestations of this syndrome are a result of defective migration of neural crest cells.
- Since neural crest cells contribute to the formation and septation of the outflow tract of the heart, lack of migration results in a spectrum of conotruncal malformations.

RISK FACTORS

- Gestational diabetes is thought to be associated with DiGeorge syndrome.[8]

DIAGNOSIS

- The most common cardiac anomalies associated with DGS include truncus arteriosus, tetralogy of Fallot, and interrupted aortic arch.
- These cardiac anomalies, especially when they are associated with craniofacial features should make one suspect DGS.

- Rarer cardiac anomalies associated with DiGeorge syndrome include vascular ring anomaly, transposition of great arteries with VSD, coarctation of the aorta, atrial septal defect (ASD), pulmonary stenosis, hypoplastic left heart syndrome, and patent ductus arteriosus.
- Neonatal hypocalcemia and absence of a thymic shadow on chest x-ray also warrants genetic evaluation for DiGeorge syndrome.

DIFFERENTIAL DIAGNOSIS

- Cayler syndromes—Caused by paresis of the depressor anguli oris muscle and can also be associated with cardiac anomalies.

MANAGEMENT

- The management of the cardiac manifestations of DGS depends on the specific heart lesion.

REFERRAL

- All patients clinically suspected of having DGS should have an evaluation by a pediatric cardiologist.

PREVENTION AND SCREENING

- An echocardiogram to screen for cardiac anomalies is required for all patients with DGS.

PROGNOSIS

The prognosis of patient with a cardiac anomaly in the setting of DGS varies widely and depends on the severity of the defect.

FOLLOW-UP

- Close outpatient follow-up is needed by a pediatric cardiologist; the frequency determined based on the severity of the lesion.

PATIENT EDUCATION

Ongoing genetic counseling should be offered to educate parents about possible recurrence with future pregnancies.

PATIENT RESOURCES

- **http://ghr.nlm.nih.gov/condition/22q112-deletion-syndrome**.

PROVIDER RESOURCES

- Practical Guidelines for Managing Patients with 22q11.2 Deletion Syndrome—**www.sciencedirect.com/science/article/pii/S0022347611002447**.

WILLIAMS SYNDROME

PATIENT STORY

A 10-year-old girl with failure to thrive is referred to a pediatric cardiologist because of asystolic murmur heard during a routine physical examination. She was small for gestational age (SGA) at birth and was born at 38 weeks gestation. She has history of multiple ear infections in the past. On exam she has facial features consisting of a short upturned nose, flat nasal bridge, long philtrum, and wide mouth (**Figure 47-5**). On cardiovascular exam, she has an ejection systolic murmur in the right 2nd intercostal space, which radiates to the carotids. An echocardiogram revealed supravalvular aortic stenosis. Based on the cardiac findings, a diagnosis of Williams syndrome was suspected and confirmed with chromosomal testing. She is scheduled for very close follow-up with the pediatric cardiologist.

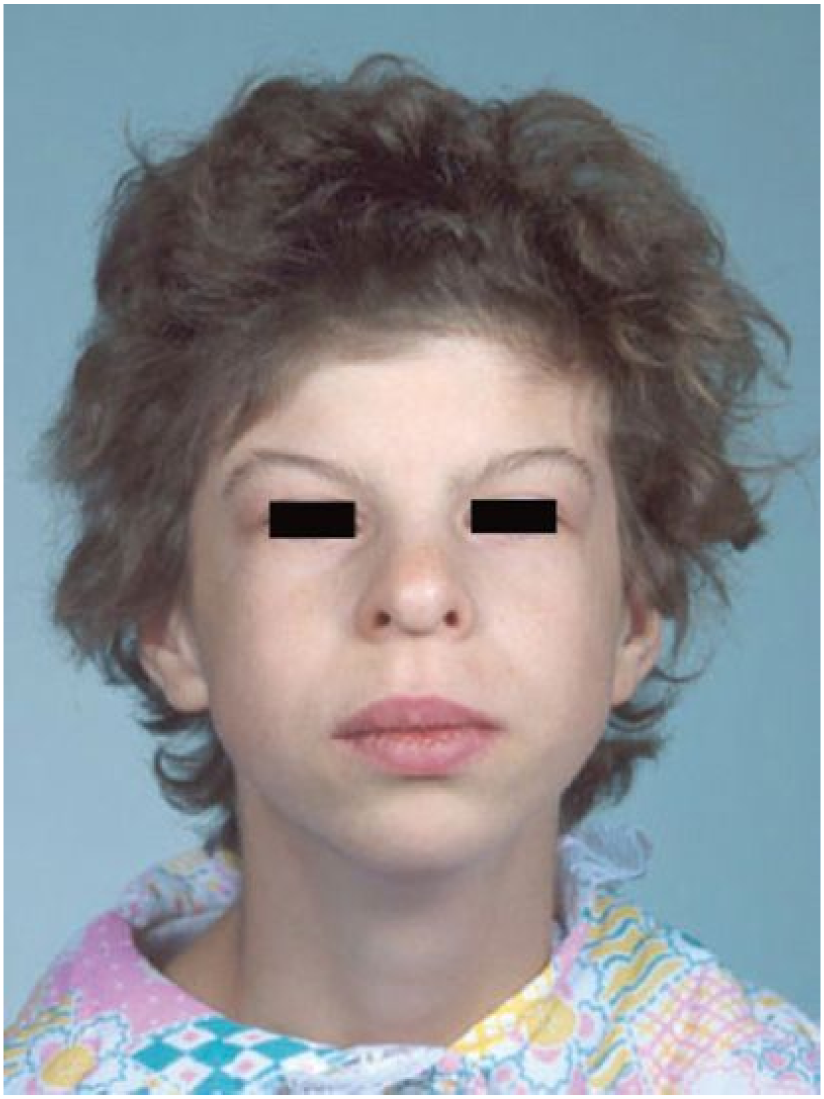

FIGURE 47-5 Typical facies of a patient with Williams syndrome. Note the presence of a short upturned nose, flat nasal bridge, long philtrum, and wide mouth. (*Used with permission from Cleveland Clinic Children's Hospital photo file*.)

INTRODUCTION

Williams syndrome is characterized by a distinct facial appearance, supravalvular aortic stenosis, idiopathic hypercalcemia, and a characteristic neurodevelopmental and behavioral profile.

SYNONYMS

Williams–Beuren syndrome (WBS), Elfin facies syndrome.

EPIDEMIOLOGY

- The reported prevalence of Williams syndrome is 1 per 7,500 to 20,000 births.[10]

ETIOLOGY AND PATHOPHYSIOLOGY

- Haploinsufficiency (loss of 1 of 2 copies) due to a deletion at chromosome band 7q11.23 that involves the elastin gene (ELN) is implicated in the etiology of Williams syndrome.[11]
- Cardiac defects account for most of the morbidity and mortality in this syndrome.

DIAGNOSIS

- Chromosomal testing showing a 7q11.23 deletion provides a confirmatory diagnosis.
- Clinical features include prenatal and postnatal growth delay, short stature, mild to moderate mental retardation, facial features as described in the case, hypercalcemia, developmental delay, learning disabilities, excessive social personality, and interest and enthusiasm for music.
- Cardiac manifestations include diffuse stenosis of medium sized or large sized arteries, most commonly involving the ascending aorta

(supravalvular aortic stenosis), or pulmonary arteries.

- Coronary artery involvement leading to myocardial ischemia and brachiocephalic and cerebral artery involvement leading to stroke in young patients can occur.[12,13]
- Hypertension occurs in 50 percent of patients, which may be secondary to renal artery involvement.[14]
- QTc prolongation is also reported in patients with Williams syndrome.[15]

DIFFERENTIAL DIAGNOSIS

- Isolated aortic valve stenosis—May be seen without Williams syndrome. The distinguishing features of Williams syndrome are absent.
- Attention deficit hyperactivity disorder—These children do not have the clinical, genetic, cardiovascular, and metabolic manifestations of Williams syndrome.

MANAGEMENT

- Management of the cardiac manifestations of Williams syndrome depends on the extent of supravalvular aortic stenosis and other cardiac manifestations.
- Treatment of hypertension will depend on the cause and the presence of co-morbid cardiovascular problems.

REFERRAL

- Patients diagnosed with Williams syndrome require evaluation and follow-up with a pediatric cardiologist.

- Patients with hypercalcemia and renal artery stenosis often require referral and follow-up with a pediatric nephrologist and/or pediatric endocrinologist.

PREVENTION AND SCREENING

- Close monitoring of blood pressures should be performed during office visits as patients with Williams syndrome can have hypertension from renal artery involvement.
- Screening and surveillance with serial echocardiograms should be performed.

PROGNOSIS

- Patients with supravalvular aortic stenosis have good long-term prognosis if gradients during infancy are low. Those with gradients above 20 mm Hg tend to have an increase in gradient as they grow and 60 percent of them require surgical relief.[16] SOR A
- Sudden cardiac death is also a well-known risk in patients with William Syndrome.

FOLLOW-UP

- Annual or more frequent follow-up is needed with a pediatric cardiologist.
- Follow-up with a pediatric nephrologist or pediatric endocrinologist will depend on the presence and extent of renal and metabolic problems.

PATIENT EDUCATION

- Parents need to be given anticipatory counseling about the possibility of having renal artery involvement in future.
- Education regarding the risk of sudden cardiac death should also be discussed with the family.

PATIENT RESOURCES

MARFAN SYNDROME

PATIENT STORY

A 16-year-old previously healthy boy presenting for a sports physical to his pediatrician is found to have a mid to late systolic murmur in the apex with a mid-systolic click, which becomes more prominent with standing. The family history is significant for sudden death in a paternal uncle. His height is at the 99th percentile for his age, he is slender, has long fingers, hypermobile joints, and pectus excavatum (**Figures 47-6** and **47-7**). The diagnosis of Marfan syndrome was suspected and he was referred to a geneticist and cardiologist. He was found to have a mutation in the fibrillin-1 gene and dilatation of the aorta.

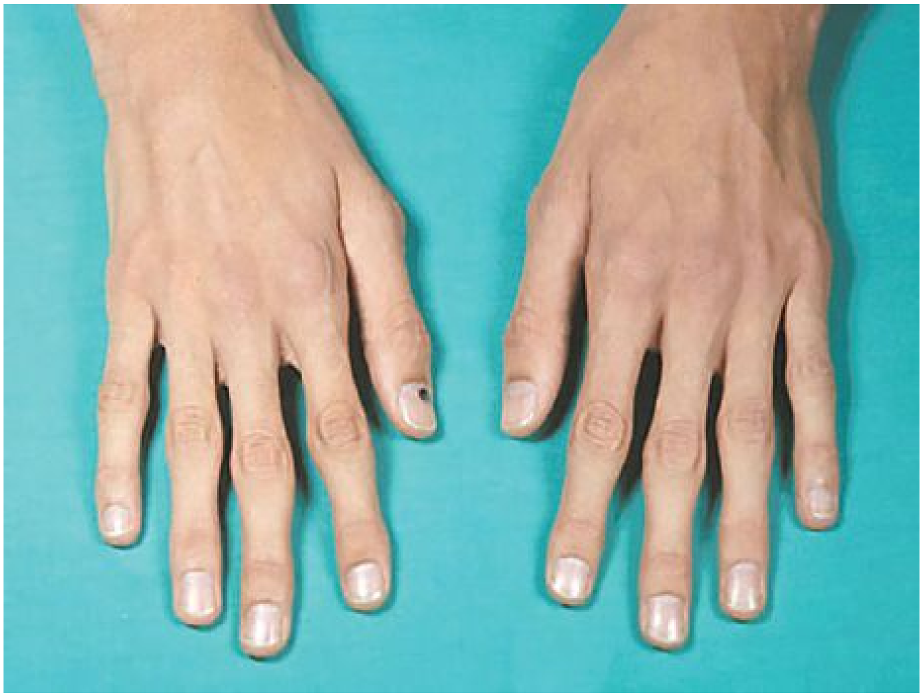

FIGURE 47-6 Arachnodactyly (long, slender fingers) in a patient with Marfan syndrome. (*Used with permission from Cleveland Clinic Children's Hospital photo file*.)

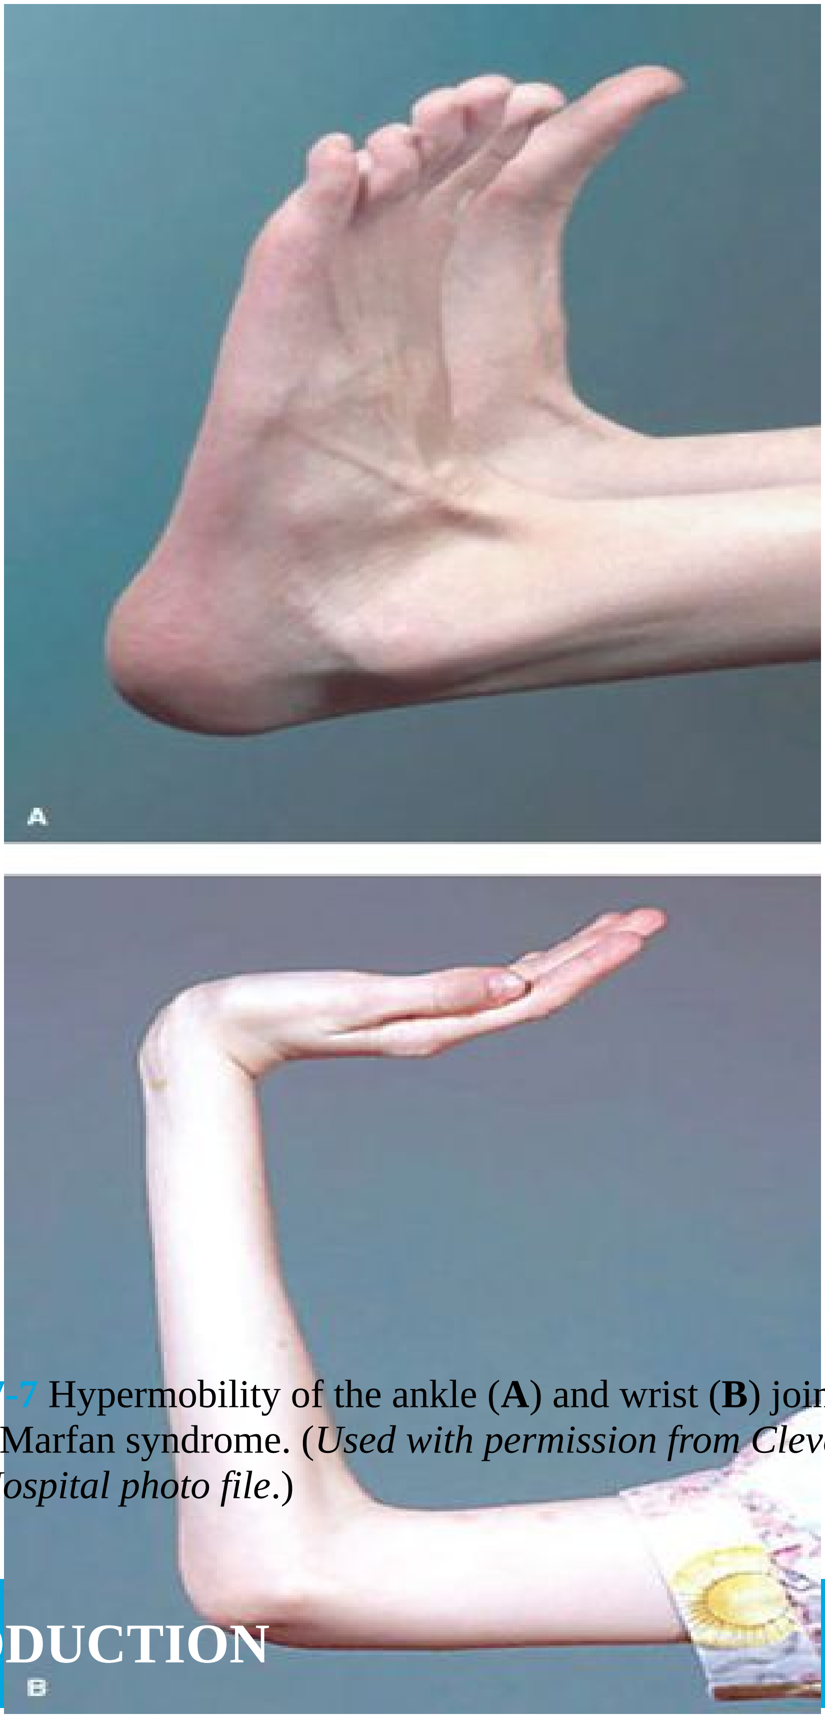

FIGURE 47-7 Hypermobility of the ankle (**A**) and wrist (**B**) joints in a patient with Marfan syndrome. (*Used with permission from Cleveland Clinic Children's Hospital photo file*.)

INTRODUCTION

Marfan syndrome is the most common and best characterized form of connective tissue disorder and is associated with serious cardiovascular manifestations.

EPIDEMIOLOGY

- The estimated incidence of Marfan syndrome is 1 in 5,000 to 2 to 3 in 10,000 persons.[17]

ETIOLOGY AND PATHOPHYSIOLOGY

- Autosomal dominant inherited, multisystem disorder with serious cardiovascular manifestations.[18]
- Mutations involving the FBN1 gene for the connective tissue protein fibrillin-1 have been identified as the genetic defect causing Marfan syndrome.

RISK FACTORS

- Family history of Marfan syndrome.
- Autosomal dominant inheritance.

DIAGNOSIS

- The clinical diagnosis of Marfan syndrome is usually made using the revised Berlin criteria, or Ghent criteria, both of which take into consideration skeletal, cardiovascular, ocular, skin and integumental, pulmonary system and family history.[19,20]

- Confirmatory diagnosis is usually made with gene testing for a mutation in the FBN1 gene.
- Cardiovascular manifestations include:
  - Dilation of the ascending aorta (**Figure 47-8**) with or without regurgitation.

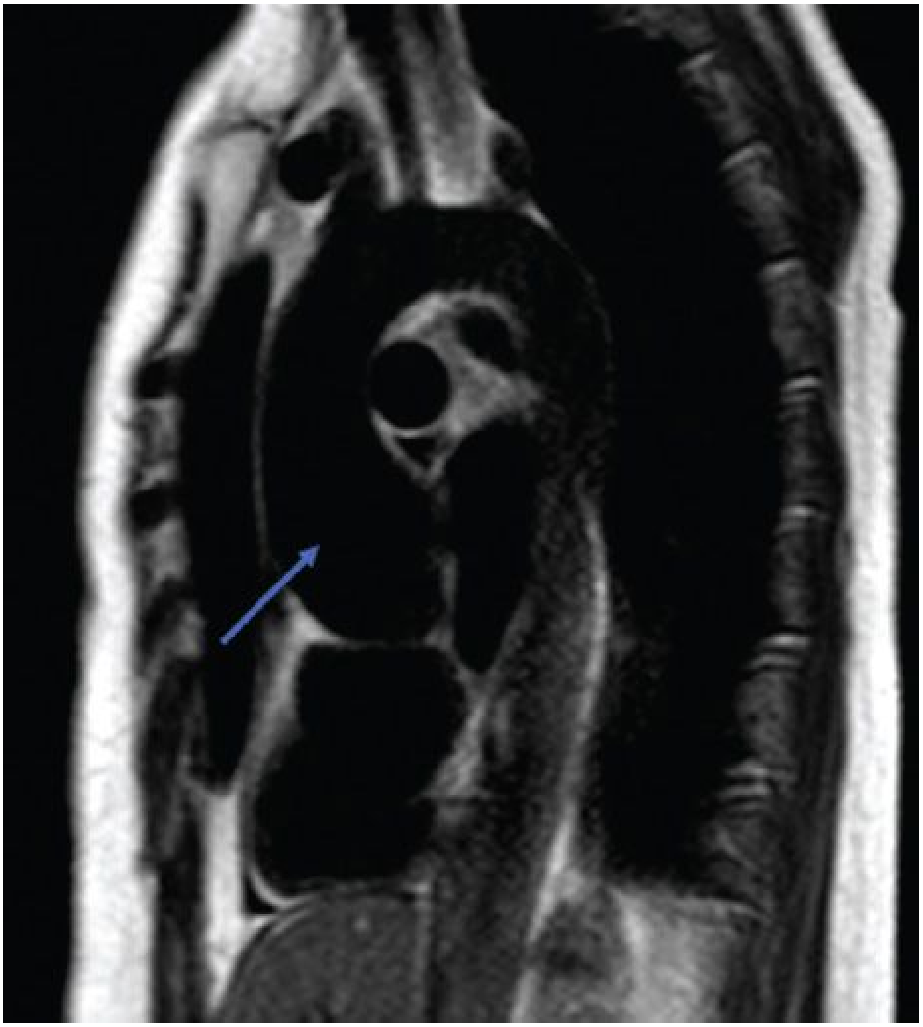

FIGURE 47-8 Sagittal plane MRI image of the aorta (arrow) in a patient with Marfan syndrome. The aorta is dilated at the level of the sinuses of valsalva while the remainder of the aorta is normal in size. (*Used with permission from Peter Aziz, MD*.)

  - Dissection of the ascending/thoracic/abdominal aorta.
  - Mitral valve prolapse with or without regurgitation.
  - Dilatation of main pulmonary artery in the absence of valvular or peripheral pulmonary stenosis or any other obvious causes and calcification of mitral valve annulus.

DIFFERENTIAL DIAGNOSIS

- Loeys-Dietz syndrome can present with aortic root dilation similar to Marfan syndrome and is caused by mutation of transforming growth factor beta receptor 1 (TFFBR1) or 2 (TFFBR2).[21]
- Ehlers Danlos syndrome can also manifest with aortic root dilation and mitral regurgitation[22](see Chapter 224, Ehlers Danlos Syndrome).

MANAGEMENT

- B-blockers, which reduce hemodynamic stress on the aortic wall, are often prescribed for patients with Marfan syndrome. SOR Ⓒ
- Afterload reduction agents can be used to decrease the stress on the aortic and mitral valves and aortic roots.[23] SOR Ⓑ
- Animal studies and a small clinical study have shown that Losartan can improve the contractile function of the aorta.[24,25]SOR Ⓑ
- Clinically significant mitral valve prolapse would necessitate replacement of the valve.[26] SOR Ⓐ
- Similarly, dilated ascending aorta/root >5.5 cm in those without family history of dissection and >5 cm in those with family history of dissection (applies to adults only) may require surgical repair as well.[27] SOR Ⓑ

REFERRAL

- Patients suspected of having Marfan syndrome patients should be managed using a multidisciplinary approach involving a pediatrician, pediatric cardiologist, pediatric ophthalmologist, geneticists, and pediatric surgeon.
- Referral to a pediatric cardiologist should be made if diagnosis is suspected.

PREVENTION AND SCREENING

- Genetic counseling should be provided to families who have a child with Marfan syndrome.

PROGNOSIS

- Patients with Marfan syndrome have a life expectancy similar to that of persons without Marfan because of advancement in pharmacotherapy and improvement in surgical outcome. However, cardiovascular compromise is the most common cause of patient death from sudden death in a previously undiagnosed patient.

FOLLOW-UP

- Close follow-up with a pediatric/adult cardiologist is needed to closely follow-up the status of aortic root to determine need for a surgical repair.

PATIENT EDUCATION

- Patients need to be educated about having other family members screened for Marfan and to have them undergo an evaluation by a cardiologist.

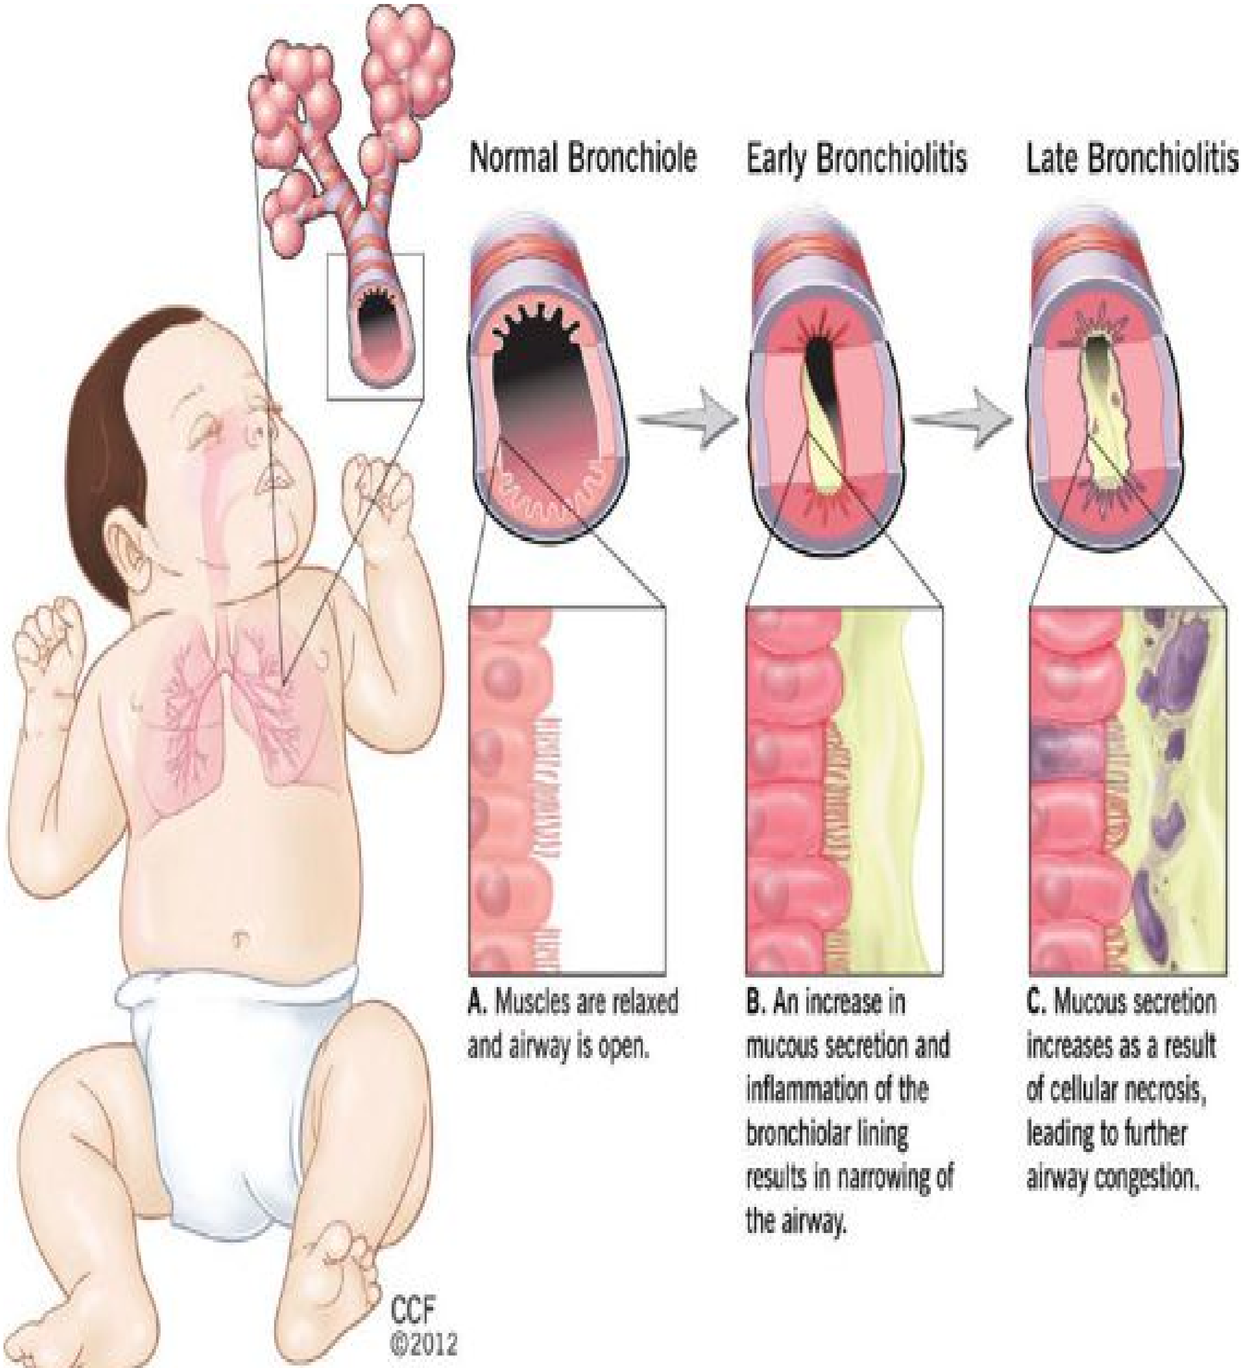
48 BRONCHIOLITIS

Rachna May, MD, FAAP
Julie Cernanec, MD, FAAP

PATIENT STORY

A 5-month-old full-term female infant presents to your office with 3 days of fever and cough. On examination, you note a frequent wet cough and appreciate bilateral wheezes. Pulse oximetry reveals a normal oxygen saturation. You reassure the mom that her daughter has bronchiolitis and needs supportive care only (**Figure 48-1**). She agrees to follow up with you in 1 to 2 days.



Normal Bronchiole
Early Bronchiolitis
Late Bronchiolitis
A. Muscles are relaxed and airway is open.
B. An increase in mucous secretion and inflammation of the bronchiolar lining results in narrowing of the airway.
C. Mucous secretion increases as a result of cellular necrosis, leading to further airway congestion.
CCF

INTRODUCTION

Bronchiolitis is inflammation of the bronchioles typically caused by a viral illness that frequently affects young children.[1]

SYNONYMS

Respiratory Syncytial Virus (RSV) or lower respiratory tract infection (LRTI).

EPIDEMIOLOGY

- Most common lower respiratory tract infection in children less than 1 year of age.[1]
- Annual hospitalizations for bronchiolitis account for greater than half a billion dollars in health care expenditures.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Viral etiology, most frequently RSV.
- Other viruses implicated include influenza, parainfluenza, adenovirus, and human metapneumovirus.
- Inflammation, edema, and necrosis of epithelial cells lining bronchioles (**Figure 48-1**).
- Leads to increased mucus production and bronchospasm.

RISK FACTORS

- Up to 90 percent of infants will have had an RSV infection by the age of 2 years.[1]
- Infants with exposure to child care center populations, school-aged siblings, and smoke are at higher risk for developing bronchiolitis.[3]
- Risk factors for severe disease include:
    - Prematurity of less than 35 weeks gestation.
    - Chronic lung disease or congenital airway malformations.
    - Cyanotic congenital heart disease.
    - Severe neuromuscular disease.
    - Immunocompromised state.[4]

DIAGNOSIS

CLINICAL FEATURES

- Bronchiolitis is a clinical diagnosis.
- Signs and symptoms include rhinorrhea, cough, tachypnea, bilateral wheezing, and signs of increased work of breathing such as use of accessory muscles and/or nasal flaring.

LABORATORY TESTING

- Laboratory testing is not routinely indicated.
- Respiratory viral testing can be obtained if necessary for epidemiologic surveillance and research but the results do not change the management of the disease.

IMAGING

- As most chest x-rays obtained in patients with bronchiolitis are found to be normal, routine chest radiography is *not* recommended for patients with bronchiolitis (**Figure 48-2**).

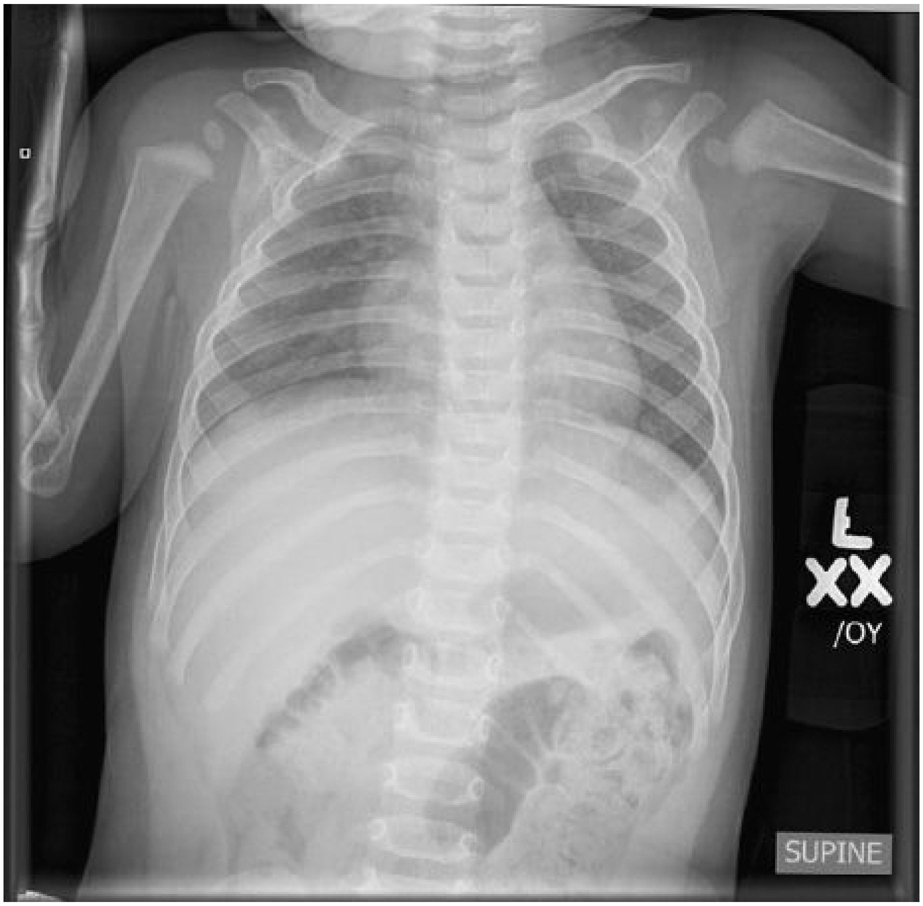

FIGURE 48-2 Normal chest x-ray of an 8-month old infant. (*Used with permission from Rachna May, MD*.)

- Nonspecific findings such as hyperinflation, perihilar markings, or central bronchial thickening can be seen in some patients (**Figure 48-3** to **48-5**).

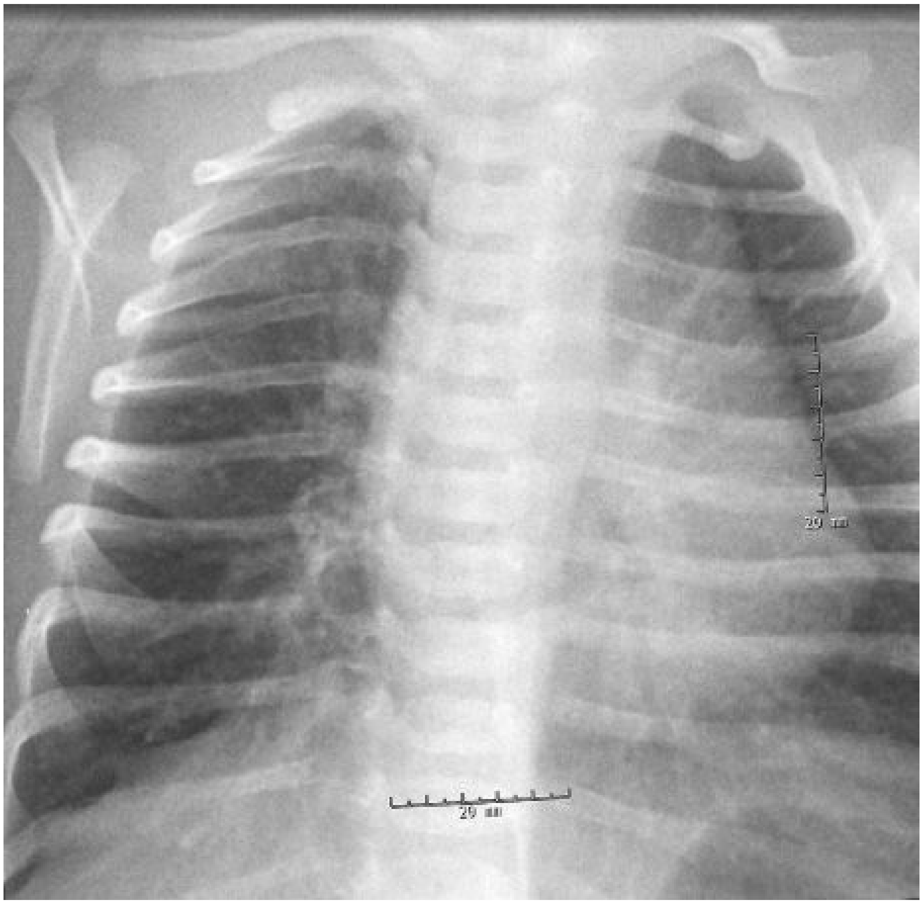

FIGURE 48-3 Hyperinflation secondary to air trapping and mild atelectasis seen in some patients with bronchiolitis. (*Used with permission from Rachna May, MD.*)

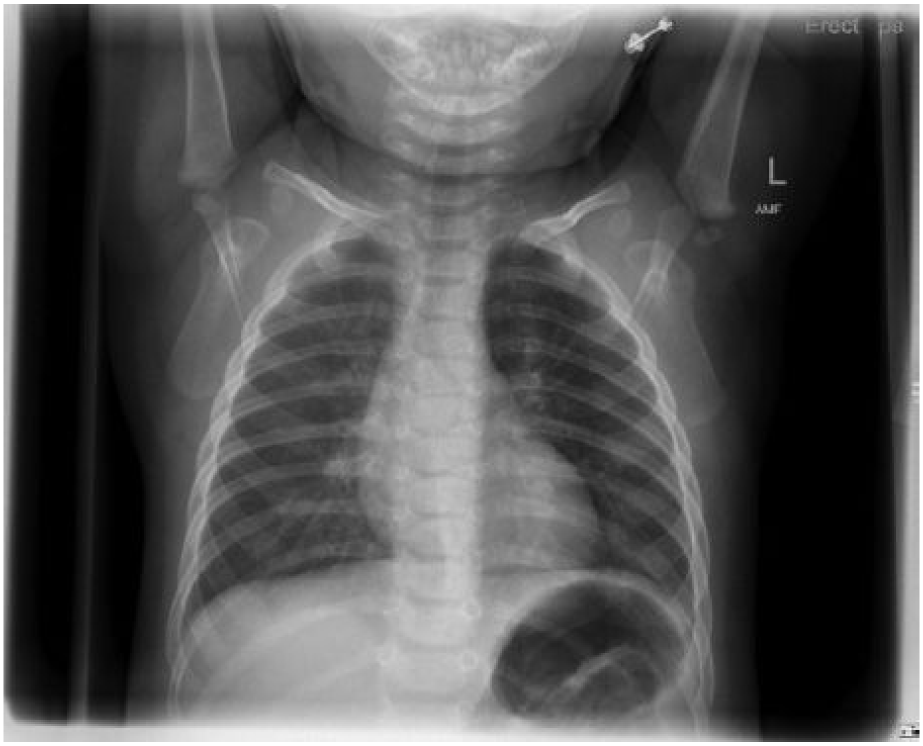

FIGURE 48-4 Increased perihilar markings, a non-specific sign often seen with viral infections. (*Used with permission from Rachna May, MD*.)

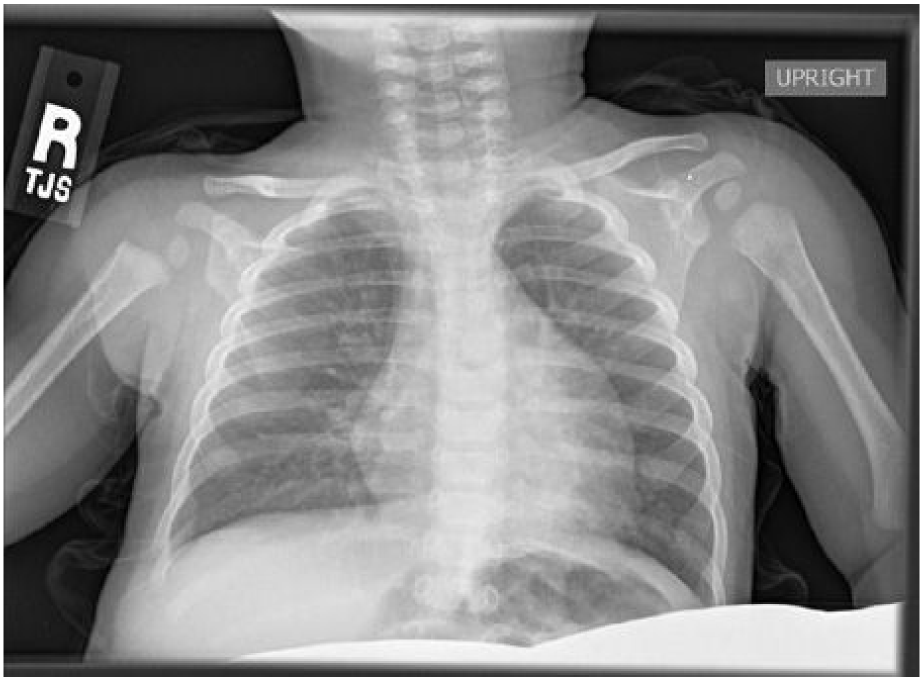

FIGURE 48-5 Central bronchial thickening, a nonspecific sign often seen with viral infections. (*Used with permission from Rachna May, MD*.)

- Chest radiography may be necessary if the patient experiences a severe course or does not improve as expected based on the natural history of disease.

DIFFERENTIAL DIAGNOSIS

- Reactive Airway Disease—Asthma-like condition in toddlers, presenting with wheezing and airway hyperreactivity, and may be exacerbated by viral illness (see Chapter 49, Asthma).
- Pneumonia—Infection of the lung most commonly caused by viral or bacterial infection (see Chapter 50, Community-Acquired Pneumonia).

MANAGEMENT

NONPHARMACOLOGIC

- Supportive care with supplemental oxygen, suction, and fluid resuscitation as indicated by the patient's clinical status is the mainstay of treatment.
- IV fluid therapy is usually indicated when feeding is compromised in the setting of severe tachypnea.

MEDICATIONS

- Bronchodilators are not routinely recommended for wheezing in bronchiolitis. However, it is reasonable to attempt a single dose to assess the patient's response, after which the decision can be made to continue the therapy. Studies suggest that up to 25 percent of patients may benefit from bronchodilator treatment.[1] SOR Ⓑ
- Systemic or high-dose inhaled steroids are also not recommended for treatment of bronchiolitis.[1] SOR Ⓑ

- The use of hypertonic saline is controversial and requires further study.[2]

REFERRAL

- Inpatients that require supplemental oxygen beyond the typical length of stay of approximately 3 days may benefit from a pulmonology consultation for further evaluation of underlying reactive airway disease or structural abnormality.

PREVENTION AND SCREENING

- Effective handwashing is the best prevention for viral respiratory infections that cause bronchiolitis.[1]
- Palivizumab, a monoclonal antibody against RSV, may be given to infants who qualify based on risk factors for severe RSV infection, including but not limited to prematurity, chronic lung disease, and cyanotic congenital heart disease.[1] Palivizumab has been shown to reduce the risk of hospitalization in infants who are at risk for severe RSV infection.[5–7] SOR Ⓐ

PROGNOSIS

Most infants and children recover without long-term adverse effects.

FOLLOW-UP

- Most children who are otherwise healthy may continue routine follow-up with their primary care pediatrician.

- Children with underlying medical conditions such as chronic lung disease or reactive airway disease will benefit from follow-up with the appropriate subspecialist.

PATIENT EDUCATION

- If the diagnosis of bronchiolitis is made in the outpatient setting, parents should be counseled on reasons to seek further emergency medical care, including tachypnea, retractions, cyanosis, and dehydration.

49 ASTHMA AND PULMONARY FUNCTION TESTING

Mindy A. Smith, MD, MS

PATIENT STORY

A 7-year-old boy with a history of atopic dermatitis as an infant, presents with an episode of continued cough and wheezing 2 weeks following a recent cold. The cough is keeping the family up at night. This is his third episode this winter and has gone on longer than the others. He has otherwise been quite healthy. He appears comfortable but is coughing intermittently. His examination is significant for mild inspiratory and expiratory wheezing but no crackles. His mother mentions that she had asthma as a child and is worried that this might be asthma. The pediatrician prescribes an inhaled bronchodilator and refers the child for spirometry before and after an inhaled bronchodilator.

The spirometry results in **Table 49-1** show a mild to moderate baseline defect with marked improvement post bronchodilator. The flow volume loops provide graphical demonstration of the same data (**Figure 49-1**). This confirms the diagnosis of asthma and an asthma treatment plan is developed.

TABLE 49-1 Pulmonary Function Tests: 7-year-old boy. Weight 30.7 Kg; Height 131 cm (see Table 49-2 for key to abbreviations)

	Predicted	Pre-bronchodilator	% Predicted	Post-bronchodilator	% Predicted

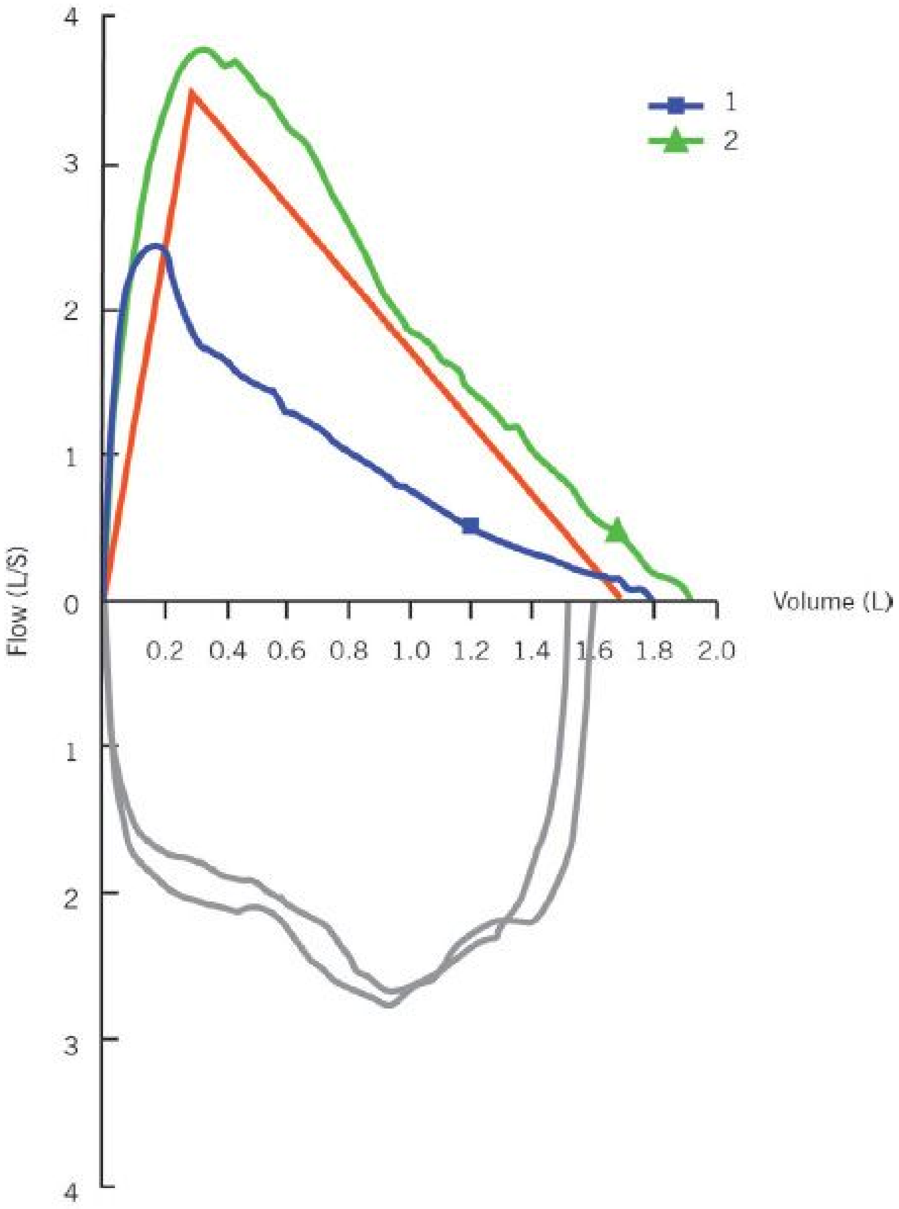

FIGURE 49-1 Pulmonary Function Tests (PFTs) showing flow volume loop in a 7-year-old boy with newly diagnosed asthma. He has a mild to moderate baseline defect with marked improvement post bronchodilator. See **Table 49-1** for specific numbers.
Blue—pre-bronchodilator. Green—post-bronchodilator. Red—predicted.

Interpretation: mild to moderate baseline defect with marked improvement post bronchodilator.

INTRODUCTION

Asthma is a chronic inflammatory airway disorder with variable airflow obstruction and bronchial hyperresponsiveness that is at least partially reversible, spontaneously or with treatment (e.g., beta-2 agonist treatment). Patients with asthma have recurrent episodes of wheezing, breathlessness, chest tightness, and cough (particularly at night or in the early morning).

EPIDEMIOLOGY

- About one in 12 people (25 million or 8% of the population) had asthma in 2009, including about one in 10 children.[1] Rates of asthma are increasing; the greatest rise in rates is among black children, an almost 50 percent increase between 2001 and 2009.[1]
- The number of deaths linked to asthma in 2007 was 3,447.[1] Using the 2006 to 2008 Nationwide Emergency Department (ED) Sample database, the estimated overall annual number of in-hospital asthma-related deaths was 1,144 (0.06%).[2] Most patients died as inpatients (N = 1043) but 101 died in the ED. There were 37 asthma-related deaths per year among children.
- Asthma was the first-listed diagnosis for 479,000 hospital discharges in 2009 with an average length of stay of 4.3 days.[1]
- Asthma-associated medical expenses increased from $48.6 billion in 2002 to $50.1 billion in 2007.[1] Many uninsured people with asthma (about 40%) and about 1 in 9 insured people could not afford their prescription drugs.[1] In one retrospective study based on insurance claims for children with asthma who initiated asthma control therapy between 1997 and 2007 (N = 8834), the mean annual out-of-pocket asthma medication cost was $154 (95% CI, $152-$156) among children aged 5 to 18 years and slightly lower (mean $151) among younger children.[3] In this study, asthma-related hospitalization was higher for children aged 5 to 18 years who were in the

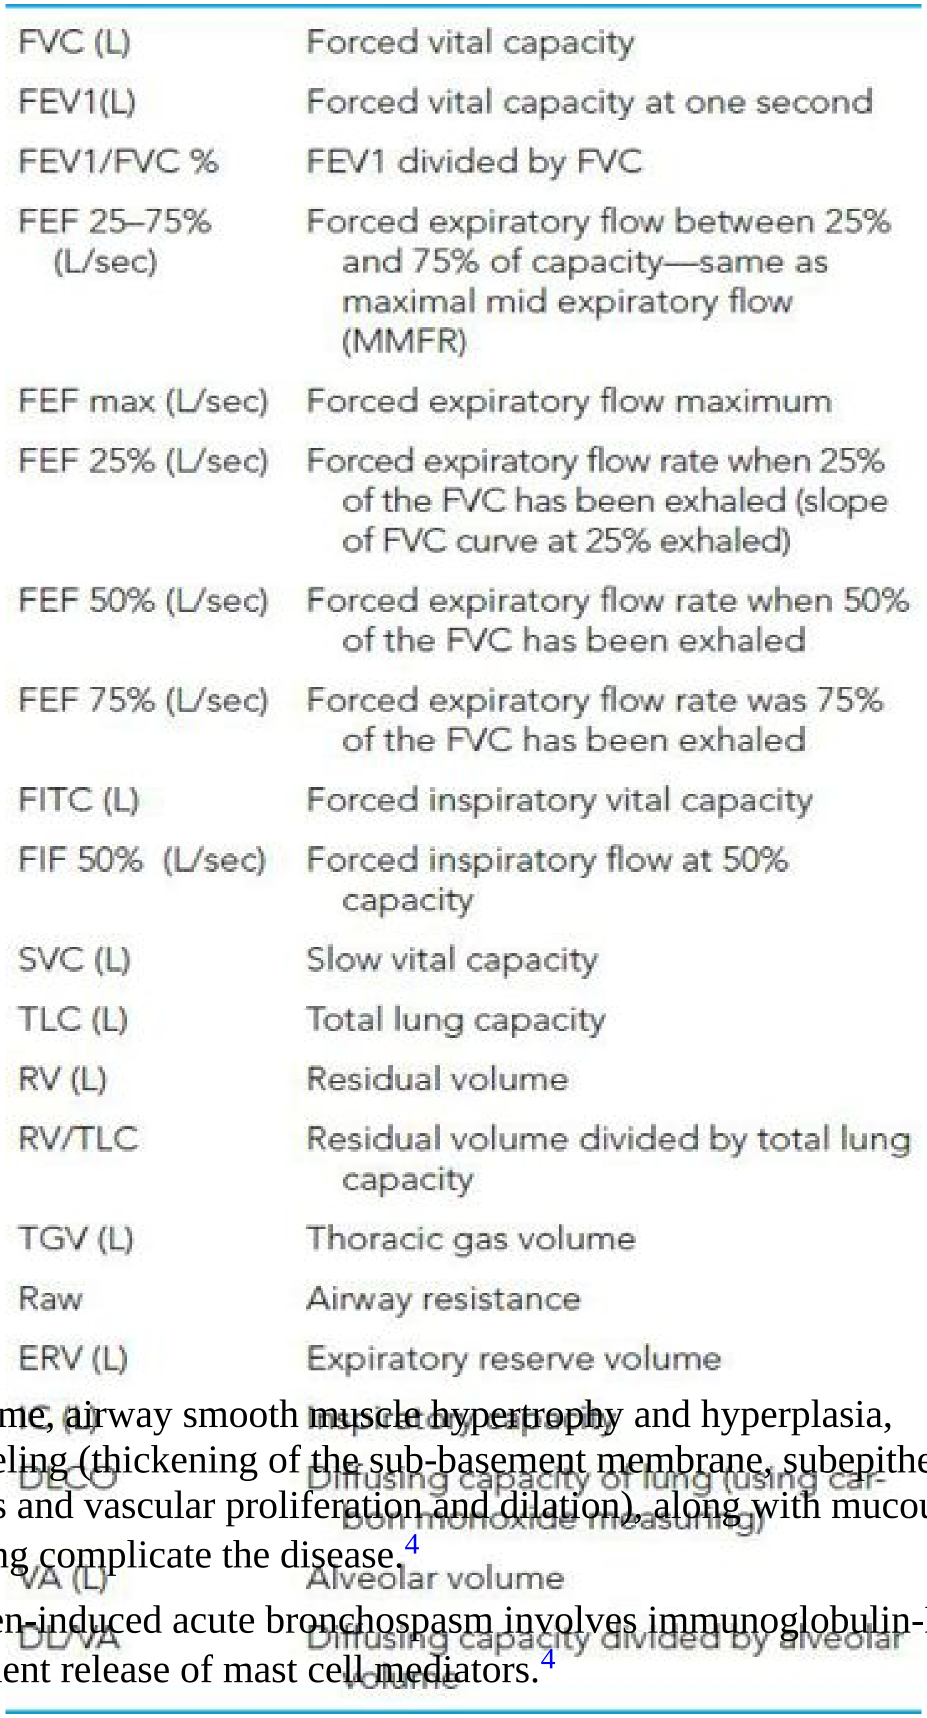
top quartile of out-of-pocket costs (2.4 [95% CI, 1.9 to 2.8] hospitalizations per 100 children versus 1.7 [95% CI, 1.3 to 2.1] per 100 in the bottom quartile).

- More than half (59%) of children and 1/3 (33%) of adults who had an asthma attack missed school or work because of asthma in 2008; on average, children missed 4 days of school.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Although the precise cause is unknown, early exposure to airborne allergens (e.g., house dust-mite, cockroach antigens) and childhood respiratory infections (e.g., respiratory syncytial virus, parainfluenza) are associated with asthma development. In one prospective cohort study, 50 percent of children who experienced severe RSV bronchiolitis at age 12 months or less had a subsequent asthma diagnosis.[4]
- In addition to environmental factors, asthma has an inherited component, although the genetics involved remain complex.[5] The gene ADAM 33 (A Disintegrin And Metalloproteinase) may increase risk of asthma as metalloproteinases appear to effect airway remodeling.[6] A recent nested case-control study found that genetic variation in the ATPAF1 gene predisposed children of different racial backgrounds to asthma.[7]
- In the Copenhagen Prospective Studies on Asthma in Childhood (N = 411 at-risk children followed prospectively from birth using spirometry), children with asthma by age 7 years (14%) had a significant airflow deficit as neonates.[8] It was estimated that approximately 40 percent of the airflow deficit associated with asthma was present at birth and the remainder developed with clinical disease.
- The pulmonary obstruction characterizing asthma results from combinations of mucosal swelling, mucous production, constriction of bronchiolar smooth muscles and neutrophils (the latter, particularly important in smokers or those with occupational asthma).[4] The smaller airways of children make them particularly susceptible.

TABLE 49-2 Pulmonary Function Tests (Key to Abbreviations)



FVC (L)	Forced vital capacity
FEV1(L)	Forced vital capacity at one second
FEV1/FVC %	FEV1 divided by FVC
FEF 25–75% (L/sec)	Forced expiratory flow between 25% and 75% of capacity—same as maximal mid expiratory flow (MMFR)
FEF max (L/sec)	Forced expiratory flow maximum
FEF 25% (L/sec)	Forced expiratory flow rate when 25% of the FVC has been exhaled (slope of FVC curve at 25% exhaled)
FEF 50% (L/sec)	Forced expiratory flow rate when 50% of the FVC has been exhaled
FEF 75% (L/sec)	Forced expiratory flow rate was 75% of the FVC has been exhaled
FITC (L)	Forced inspiratory vital capacity
FIF 50% (L/sec)	Forced inspiratory flow at 50% capacity
SVC (L)	Slow vital capacity
TLC (L)	Total lung capacity
RV (L)	Residual volume
RV/TLC	Residual volume divided by total lung capacity
TGV (L)	Thoracic gas volume
Raw	Airway resistance
ERV (L)	Expiratory reserve volume
IC (L)	Inspiratory capacity
DLCO	Diffusing capacity of lung (using carbon monoxide measuring)
VA (L)	Alveolar volume
DL/VA	Diffusing capacity divided by alveolar volume

- Over time, airway smooth muscle hypertrophy and hyperplasia, remodeling (thickening of the sub-basement membrane, subepithelial fibrosis and vascular proliferation and dilation), along with mucous plugging complicate the disease.[4]
- Allergen-induced acute bronchospasm involves immunoglobulin-E (IgE)-dependent release of mast cell mediators.[4]

RISK FACTORS

Based on a cohort study, early life (first 5 years) risk factors for diagnosed asthma at age 10 years includes:[9]

- Family history of asthma (maternal [odds ratio (OR) 2.26; 95% confidence interval (CI) 1.24 to 3.73); paternal [OR 2.30; 95% CI 1.17 to 4.52]; sibling [OR 2.00; 95% CI 1.16 to 3.43]).
- Recurrent chest infections at 1 year of age (OR 2.67; 95% CI 1.12 to 6.40) and 2 years of age (OR 4.11; 95% CI 2.06 to 8.18).
- Atopy at 4 years of age (OR 7.22; 95% CI 4.13 to 12.62).
- Parental smoking at 1 year of age (OR 1.99; 95% CI 1.15 to 3.45).
- Male gender (OR 1.72; 95% CI 1.01 to 2.95).
- Recent use of acetaminophen has also been associated with asthma symptoms in adolescents (OR 1.43; 95% CI 1.33 to 1.53 and OR 2.51; 95% CI 2.33 to 2.70 for at least once a year and at least once a month use versus no use, respectively).[10] One possible mechanism is through acetaminophen reducing the immune response and prolonging rhinovirus infection.[11]
- Environmental mold is also a risk factor; in one study the OR was 1.8 (95% CI 1.5 to 2.2) for asthma diagnosed at age 7 years for a 10-unit increase in the Environmental Relative Moldiness Index value in the child’s home in infancy.[12]
- In one study, consumption of salty snacks (OR 4.8; 95% CI 1.50 to 15.8) was strongly associated with the presence of asthma symptoms, especially in children with television/video-game viewing of >2 hours/day.[13]
- In a prospective study of children following an episode of severe bronchiolitis, risk factors for physician-diagnosed asthma by age 7 years included maternal asthma (OR 5.2; 95% CI 1.7 to 15.9), exposure to high levels of dog allergen (OR 3.2; 95% CI 1.3 to 7.7), aeroallergen sensitivity at age 3 years (OR 10.7; 95% CI 2.1 to 49.0), recurrent wheezing during the first 3 years of life (OR 7.3; 95% CI 1.2 to 43.3), and CCL5 mRNA

expression in nasal epithelia during acute RSV infection (OR 3.8; 95% CI 1.2 to 2.4).[4]

- Obesity has also been associated with risk of wheezing in children (OR 1.62, 95% CI 1.13 to 2.32).[14]
- Not surprisingly, in patients with severe or difficult-to-treat asthma, recent exacerbation history was the strongest predictor of future asthma exacerbations.[15] High concentrations of pollen also increase the risk of asthma- and wheeze-related ED visits by up to 15 percent.[16]

DIAGNOSIS

The diagnosis of asthma is made on clinical suspicion (presence of symptoms of recurrent and partially reversible airflow obstruction and airway hyperresponsiveness) and confirmed with spirometry.[5] Alternative diagnoses should be excluded.

CLINICAL FEATURES

Asthma’s most common symptoms are recurrent wheezing, difficulty breathing, chest tightness, and cough. An absence of wheezing or normal physical exam does not exclude asthma.[3] In fact, up to 25 percent of patients with asthma have normal physical examinations even though abnormalities are seen on pulmonary function testing.[4] As part of the diagnosis of asthma, ask about the following:[3]

- Pattern of symptoms and precipitating factors. Symptoms often occur or worsen at night and during exercise, viral infection, exposure to inhalant allergens or irritants (e.g., tobacco smoke, wood smoke, or airborne chemicals), changes in weather, strong emotional expression (laughing hard or crying), menstrual cycle, and stress.[3]
- Family history of asthma, allergy or atopy in close relatives.
- Social history (e.g., daycare, workplace, or social support).

- History of exacerbations (e.g., frequency, duration, or treatment), and impact on patient and family. The preschool-aged asthmatic population tends to be characterized as exacerbation prone with relatively limited impairment while older children and adolescents have more impairment-dominant disease.[13]

Findings on physical exam may include:[3]

- Upper respiratory tract—Increased nasal secretion, mucosal swelling, and/or nasal polyp.
- Lungs—Decreased intensity of breath sounds is the most common (33% to 65% of patients).[4] Additional findings may include wheezing, prolonged phase of forced exhalation, use of accessory respiratory muscles, appearance of hunched shoulders, and chest deformity. During a severe exacerbation of asthma, minimal airflow may result in no audible wheezing.
- Skin—Atopic dermatitis and/or eczema (see Chapters 130, 132, and 133). There is a strong association between asthma, allergic rhinitis and atopic dermatitis (**Figure 49-3**). The “atopic triad” with the coexistence of all three conditions at one time (Figure **49-3**) is less common. Children with asthma are also more likely to develop pityriasis alba, a chronic skin disorder characterized by patches of lighter skin mainly on the face (**Figure 49-4**). In a US study of children with physician-confirmed atopic dermatitis (N = 2270), 38.0 percent reported symptoms of asthma and allergic rhinitis on a survey;[17] similarly in a population study in Taiwan using the National Insurance register, of the 66,446 individuals diagnosed with atopic dermatitis, about half had a concomitant diagnosis of allergic rhinitis and/or asthma.[18] Data support a sequence of atopic manifestations beginning typically with atopic dermatitis in infancy followed by allergic rhinitis and/or asthma in later stages.[19]

Findings in patients with status asthmaticus (prolonged/severe asthma attack that is not responsive to standard treatment) may include:[4]

- Tachycardia (heart rate >120 beats/minute) and tachypnea (respiratory rate >30 breaths/minute).

- Use of accessory respiratory muscles.
- Pulsus paradoxus (inspiratory decrease in systolic blood pressure >10 mm Hg).
- Mental status changes (due to hypoxia and hypercapnia).
- Paradoxical abdominal and diaphragmatic movement on inspiration.

LABORATORY TESTING

Spirometry is recommended by NAEP for all patients over 4 years of age to determine airway obstruction that is at least partially reversible (**Figures 49-1**, **49-2**, **49-5**, and **49-6**).[3] SOR Ⓑ The British Thoracic Society also recommends an assessment of the reversibility of airway obstruction in response to an inhaled bronchodilator.

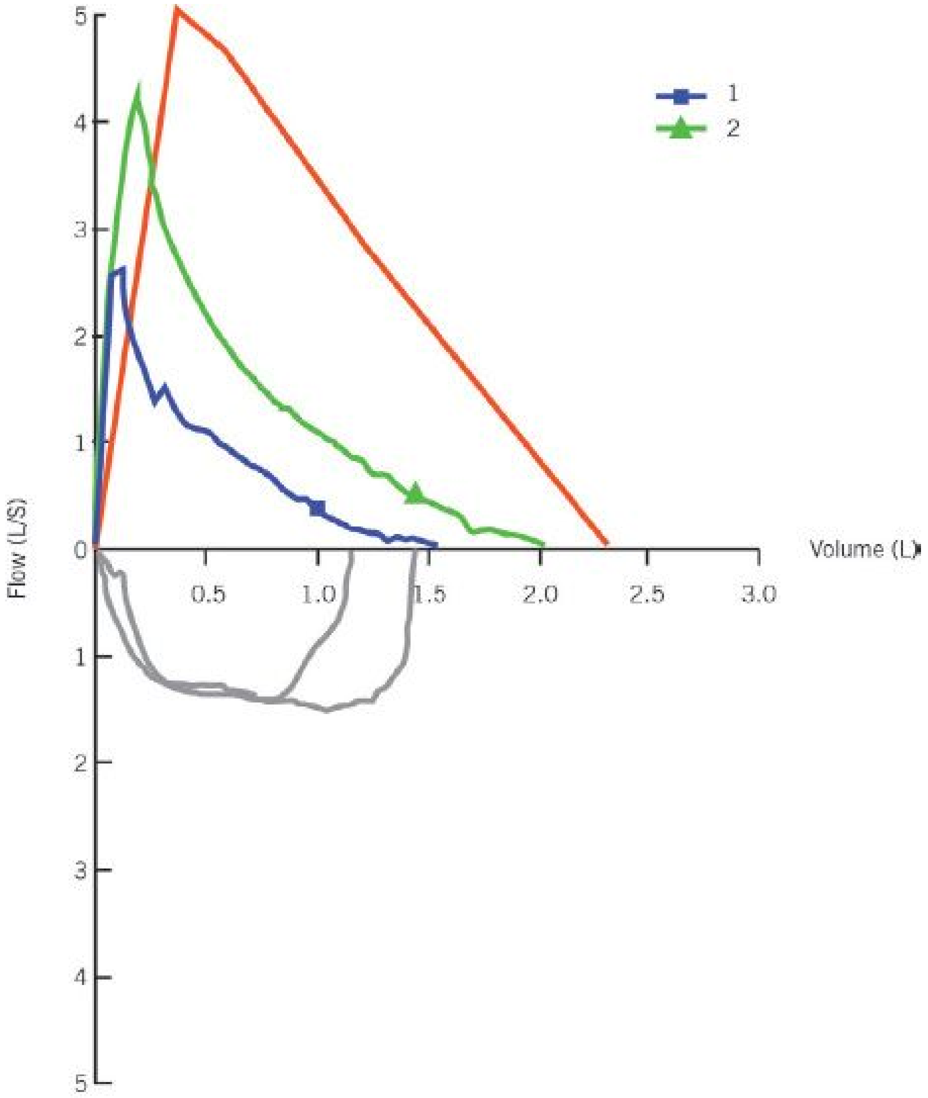


FIGURE 49-2 Pulmonary Function Tests (PFTs) showing flow volume loop in a 9-year-old boy with ongoing asthma. He has a moderate baseline obstruction defect with marked improvement in the FEV1 and FEF 25/75 post-bronchodilator but not to predicted levels.
Blue—pre-bronchodilator. Green—post-bronchodilator. Red—predicted.

- In preschool-aged children diagnosis is most often based on symptom patterns, presence of risk factors, and therapeutic responses.[13]

Assess severity:

- Severity is defined as the intrinsic intensity of the disease process.[3] The NAEP divides severity into four groups for youths age 12 and up and adults: intermittent, persistent-mild, persistent-moderate, and persistent-severe.
- For younger children, the Composite Asthma Severity Index (CASI) has been proposed for assessment of control, including both impairment and risk.[20] CASI was developed by members of the National Institutes of Health-supported Inner City Asthma Consortium through a modified Delphi consensus process and subjected to factor analysis and validation using the Inner City Anti-IgE Therapy for Asthma trial. CASI includes five domains that are scored and summed for a final score of up to 20 points for most severe; scores might be useful for determining treatment and monitoring response to therapy:
    - Day symptoms and albuterol use in the past 2 weeks (scored 0 [0 to 3 symptoms and albuterol use] to 3 [daily symptoms and use]).
    - Night symptoms in the past 2 weeks and albuterol use (scored 0 [0 to 1 night] to 3 [5 to 14 nights]).
    - Lung function (scored 0 [FEV1% >85] to 3 [FEV1% <70]).
    - Controller treatment (scored 0 [none] to 5 [high dose ICS]).
    - Exacerbations (scored 2 for prednisone burst and 4 for prednisone burst plus hospitalization).
- Initially, severity can be assessed in the office, urgent or emergency care setting with predicted forced expiratory volume in 1 second (FEV1) or PEF; a value of <40 percent indicates a severe exacerbation. A value of >=70 percent predicted FEV1 or PEF is a goal for discharge from the emergency care setting.
- Once asthma control is achieved, severity can also be assessed by the step of care required for control (i.e., amount of medication; see the following list).

Additional tests that may be useful include:[3]

- Pulmonary function testing if a diagnosis of restrictive lung disease or vocal cord dysfunction is considered.
- Bronchoprovocation (using methacholine, histamine, cold air or exercise challenge) if spirometry is normal or near-normal and asthma is still suspected; a negative test is helpful in ruling out asthma.
- Pulse oximetry or arterial blood gas if hypoxia is suspected (e.g., cyanosis, rapid or respiratory rate).
- In preschool-aged children, consider allergen sensitization, increased IgE levels, or presence of blood eosinophilia to help in establishing a diagnosis of asthma.[21] In the PARIS birth cohort study, the risk of severe wheeze was increased in infants having eosinophilia (OR 1.76, 95% CI 1.21 to 2.49) or being sensitized to ≥2 allergens (OR 1.88; 95% CI 1.13 to 3.14).[14]
- The fraction of exhaled nitric oxide (FENO), a biomarker for eosinophilic airway inflammation, has also been used to detect future uncontrolled asthma in patients on corticosteroids.[22] In addition, in a post-hoc analysis, daily FENO (performed at home) was shown to increase before moderate (but not severe) exacerbations in children with asthma.[23]

IMAGING

A CXR is not useful for diagnosis but is helpful for excluding other diseases (e.g., pneumonia) or identifying comorbidity (e.g., heart failure). The main finding on CXR is hyperinflation (occurring in about 45% of patients with asthma).[4] Hyperinflation is manifested by the following:

- Lung hyperexpansion and abnormal lucency (**Figure 49-7**).

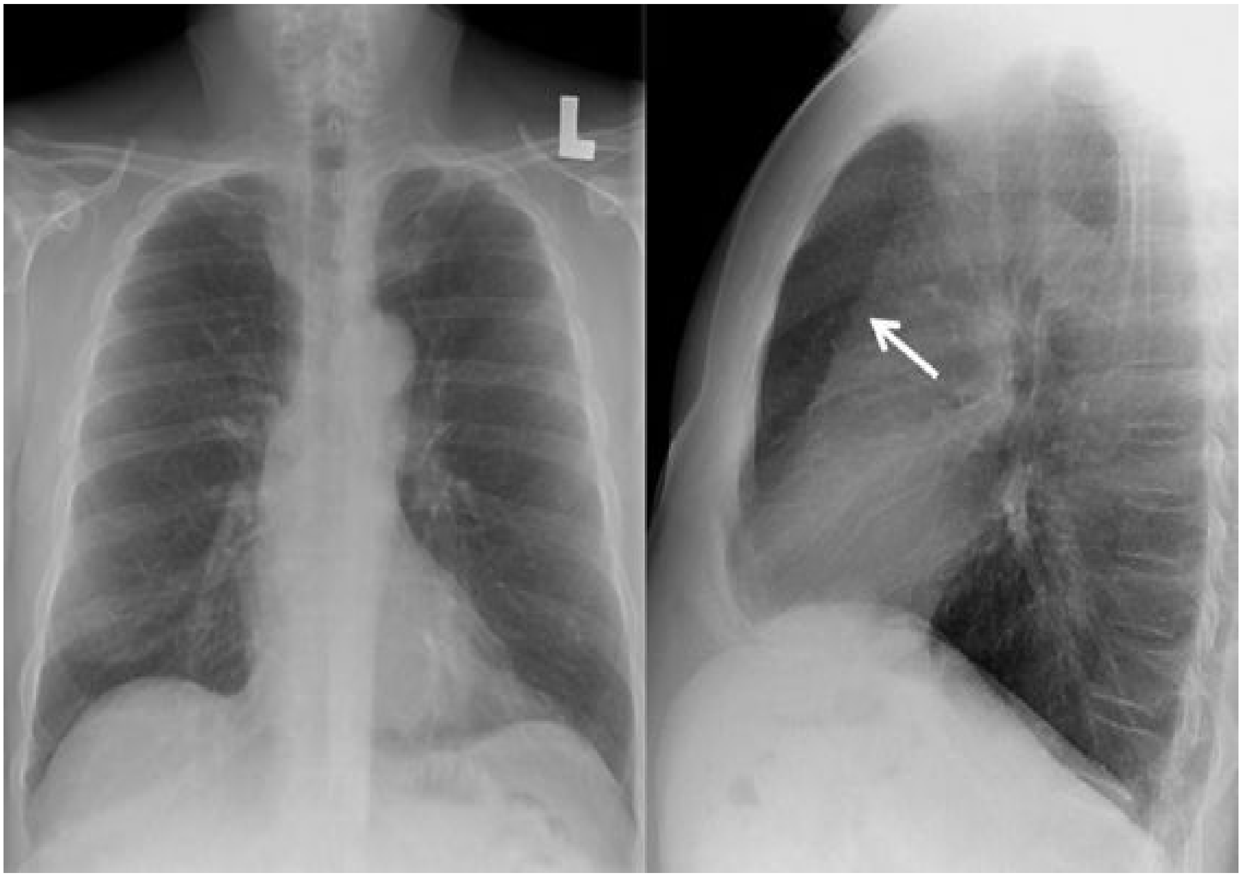

FIGURE 49-7 Acute asthma exacerbation with increased lung volumes on chest x-ray. The lateral projection reveals enlargement of the retrosternal clear space (*arrow*). (*Used with permission from Carlos Santiago Restrepo, MD*.)

- Increased AP diameter.
- Increased retrosternal air space (**Figure 49-8**).

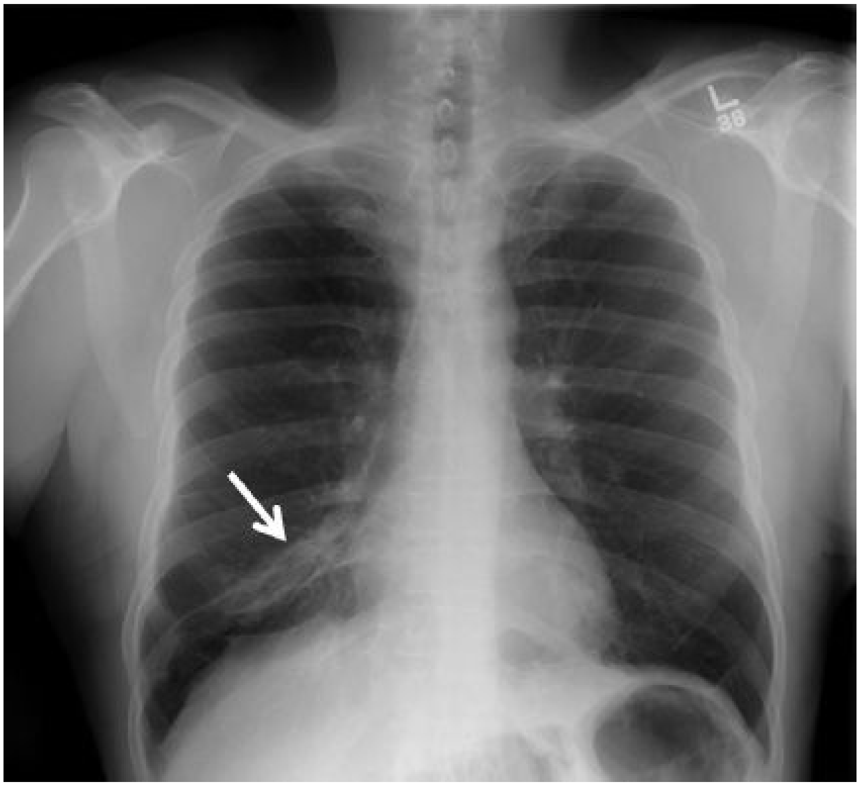

Figure 49-8 Acute asthma exacerbation in a young man. Frontal chest radiograph demonstrates increased lung volumes and ill-defined opacity in the right infrahilar region consistent with middle lobe segmental atelectasis (*arrow*). (*Used with permission from Carlos Santiago Restrepo, MD.*)

- Infracardiac air.
- Low-set flattened diaphragms (best assessed in lateral chest) (**Figure 49-7**).
- Vertical heart (**Figure 49-7**).
- Atelectasis is another finding seen during acute severe episodes (**Figure 49-8**).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of an infant or child with wheezing includes:[3]

- Upper airway disease (e.g., allergic rhinitis, sinusitis)—Exam or imaging helps differentiate.
- Airway obstruction (foreign body, vascular rings, vocal cord dysfunction, tracheal stenosis, enlarged lymph node or tumor, infection, cystic fibrosis, or heart disease)—Imaging helps differentiate.
- Other causes such as recurrent cough or reflux. Cough-variant asthma (only cough) occurs especially in young children.
- Rarely, cardiac causes such as shunts, outflow obstruction, coronary artery disease, and cardiomyopathy can cause exertional dyspnea; electrocardiography and echocardiography can help distinguish these causes.[24]
- Asthma may occur in conjunction with these conditions.

MANAGEMENT

NAEP outlines four components of care: assessment and monitoring, provision of education, control of environmental factors and comorbid conditions, and use of medications.[3] The goals of asthma therapy are twofold:[3]

- Reduce impairment—Prevent chronic symptoms, require infrequent (<= twice weekly) use of rescue inhaler, maintain near normal pulmonary function, maintain normal activity levels, meet patient and family expectations, and satisfaction with care.
- Reduce risk—Prevent recurrent exacerbations and minimize need for emergency or hospital care, prevent loss of lung function (for children, prevent reduced lung growth), and provide optimal pharmacotherapy while minimizing side effects and adverse effects.

In the future, it may be possible to better tailor therapy to asthma phenotype, based on a child’s clinical signs and use of health care resources. Three phenotypes have been recently described—mild, nonatopic severe, and severe atopic.[25] In this study conducted during the 18-month examination (N = 1831), most children (69.4%) had a low prevalence respiratory symptoms or allergy followed by a group of 306 (16.7%) with a mild phenotype, 195 (11%) with nonatopic severe phenotype, including 88 percent of the children with recurrent wheezing, and atopic severe (N = 59 [3.2%]), including 78 percent with atopic dermatitis and 61 percent with allergic sensitization; in the latter group, 49 children also had wheezing.

NONPHARMACOLOGIC

- Exercise should be encouraged. In a randomized clinical trial (RCT) of aerobic exercise in patients with persistent asthma, the group randomized to exercise showed significant improvements in physical limitations, frequency of symptoms, health-related quality of life, number of asthma-symptom-free days, and anxiety and depression levels over the control group (education and breathing exercises only).[26]
- For patients exposed to secondhand smoke in the home, use of high-efficiency, particulate-arresting (HEPA) air cleaners was shown in one RCT to decrease unscheduled asthma visits for children ages 6 to 12 years; there was no difference between groups in parent-reported symptoms.[27]
- Dietary changes may also be useful. In a cross-sectional study of children, greater adherence to a Mediterranean-type diet was associated with a lower prevalence of asthma symptoms.[28]
- Provide patient education. SOR A Pediatric asthma education was shown in a meta-analysis to reduce mean number of hospitalizations and emergency department (ED) visits and the odds of an emergency department visit for asthma;[29] there was no influence of education on the odds of hospitalization or mean number of urgent physician visits. Reduction in hospital and ED visits and missed work/school has also been shown for self-management education with written asthma action plans and physician review.[4]
  - In several RCTs of adolescents, peer-led asthma education was associated with more positive attitudes at 6 months,[30] greater

  improvements in quality of life,[30,31] and greater self-efficacy to resist smoking and knowledge of asthma self-management.[31]
  - In another study, a school-based program for primarily minority race high school students resulted in greater confidence in managing asthma, more preventive steps taken, greater use of controller medication and written treatment plans, and improved control (e.g., fewer night awakenings, days with activity limitation, school absences); in addition, there were fewer asthma acute care visits, ED visits, and hospitalizations.[32] Authors of a meta-analysis of school-based asthma education programs, however, found consistent results demonstrating improved asthma knowledge, self-efficacy, and self-management behaviors but fewer studies showing reduced symptoms days (5 of 11 studies), reduced nights with symptoms (2 of 4 studies), and school absences (5 of 17 studies).[33]

- Consider interventions to control home environmental triggers; comprehensive individual programs may reduce symptom days.[4] SOR B
  - Many people who have asthma are allergic to dust mites (**Figure 49-9**). Two relatively easy interventions to decrease dust mite exposure are: encase pillows and mattresses in special dust-mite proof covers and wash the sheets and blankets on the bed each week in hot water.[3]

Figure 49-9 Dust mites under the microscope. Dust mites are a common allergen for patients who suffer from asthma and allergic rhinitis. Environmental control to minimize dust mite exposure can help control asthma for some individuals. (*Used with permission from Richard P. Usatine, MD.*)

  - Other suggestions for reducing environmental triggers can be found in the NAEP reference.[5]

MEDICATIONS

To determine appropriate medication management, assess severity based on symptoms, medication usage, exacerbations, and lung function (as discussed in Laboratory Testing). For children, severity is usually assessed through symptoms, night-time awakenings, interference with normal activity, and lung function; the latter if over age 4 years. Children are also categorized as controlled, not-well controlled, or very poorly controlled with steps of care associated with each category. Several charts for children are available in the NAEP reference to facilitate these assessments and include treatment protocols by age group divided into 6 steps of care as described in the following:[5]

- **Step 1:** For all aged patients with intermittent asthma, an inhaled short-acting beta-2 agonist (SABA) is recommended. SOR Ⓐ Metered dose inhalers with spacers are at least as effective (with fewer side effects) as nebulized treatment for most patients.
- **Step 2:** Low-dose inhaled corticosteroids (ICS) are the preferred long-term control therapy for all ages with persistent asthma. SOR Ⓐ Alternatives for young children (ages 0 to 4 years) include cromolyn inhaler and montelukast and for older children (ages 5 to 11 years) cromolyn, leukotriene receptor antagonist (LTRA), nedocromil, or theophylline
  - LTRAs are less effective than ICS but better than placebo.[5] SOR Ⓐ
  - In a RCT of preschool-aged children with recurrent wheezing (N = 278), intermittent budesonide inhalation suspension (1 mg twice daily for 7 days, starting early during a predefined respiratory tract illness) was as effective as a daily low-dose regimen (0.5 mg nightly) in preventing

acute exacerbations (about 1 fewer per patient-year) while reducing mean exposure to budesonide.[34]

- **Step 3:** For children ages 0 to 4 years not well controlled on low dose ICS, medium dose ICS is recommended. For children over age 4 years, combination low-dose ICS and long-acting beta-2 agonist (LABA) or medium-dose ICS are equally preferred options.[5] SOR A Alternatives include low-dose ICS plus LTRA (less effective than ICS and LABA), theophylline, or zileuton. Theophylline requires monitoring serum concentration levels. Zileuton is less desirable due to limited supporting data and need to monitor liver function. Authors of a Cochrane review found the combination ICS/LABA modestly more effective in reducing the risk of exacerbations requiring oral corticosteroids than higher dose ICS for adolescents and adults, but a trend toward increased risks of exacerbation and hospitalization among children.[35]
    - For patients ages 4 years and younger, low-dose ICS and LABA can be used followed by increasing ICS dose if persistent low lung function and >2 days per week of impairment;[5] ICS/LABA combination may not reduce exacerbations but appears to improve PEF and growth.[36] Although serious asthma-related events (asthma-related deaths, intubations, and hospitalizations) attributable to LABAs appear to be greatest among children, in a meta-analysis there was no statistically significant difference in serious events by age group for the subgroup on both ICS and LABA.[37]
    - One trial of step-up therapy for children with not-well controlled persistent asthma on ICS found that although combination ICS/LABA was most likely to result in a best response, some children had a best response to doubling ICS or combination ICS/LTRA.[38] In a systematic review of medium (300-400 µg/d) vs. low dose (200 µg/d or less) steroids in children with mild-moderate persistent asthma, although medium dose steroids provided a small but significant improvement in FEV1 (mean difference 0.11 [95% CI, 0.01 to 0.21), there were no differences in any other outcome (e.g., symptom scores).[39]
- **Step 4:** For children with poorly controlled asthma, combination medium-dose ICS and LABA are recommended along with consultation with an asthma specialist. Alternatives are combination medium-dose ICS plus LTRA (or theophylline or zileuton in older children).

- **Step 5:** Combination high-dose ICS and LABA.
- **Step 6:** Combination high-dose ICS and LABA plus oral corticosteroid. For children presenting to the ED with moderate or severe asthma, investigators of an observational study (N = 406) found early administration of systemic corticosteroids reduced the odds of admission by 0.4 (95% confidence interval 0.2 to 0.7) and the length of active treatment by 0.7 hours (95% confidence interval -1.3 to -0.8 hours), with no significant effect on relapse.[40]

Other drug options:

- Omalizumab can be considered for patients over 11 years of age who have allergies.[3] In a RCT with inner-city children, adolescents, and young adults (N = 419) with persistent asthma, omalizumab reduced symptom days and the proportion of subjects who had one or more exacerbations (30.3% versus 48.8% on placebo).[41]
- To assist with smoking cessation, consider nicotine replacement therapy (bupropion [150 mg, twice daily], varenicline [1 mg twice daily], nortriptyline [75–100 mg daily], or nicotine replacement [gum, inhaler, spray, patch]), and supportive counseling and follow-up; using these interventions improves rates of smoking cessation by up to twofold.[42–44] SOR A
- In patients with persistent asthma attributed to allergies, consider allergy immunotherapy.[5] SOR B One meta-analysis concluded that specific immunotherapy for patients with positive skin tests resulted in a reduction in need for increased medications (number needed to treat = 5) and another study in patients with high IgE found immunotherapy reduced exacervations.[4]
- The use of proton-pump inhibitor therapy is not likely to add significant benefit.[45] Among children with uncontrolled asthma on ICS but without gastrointestinal reflux symptoms, the addition of a lansoprazole (versus placebo) resulted in no improvement in symptoms or lung function but increased adverse events.[46]

For patients with an *exacerbation* of asthma, SABAs and sometimes oral corticosteroids are used for home management of patients with a mild exacerbation (dyspnea with activity, PEF >=70 percent predicted or personal best) following their action plan. NAEP does not recommend doubling the dose of ICS for home management versus oral steroids for exacerbations.[3] A Cochrane review concluded that a short course of oral steroids was effective in reducing the number of relapses to additional care, hospitalizations, and use of SABA without an apparent increase in side effects.[47]

- Moderate exacerbation (dyspnea interferes with usually activity, PEF 40% to 69% predicted or personal best)—Usually requires office or ED visit; SABA and oral corticosteroids (typically 40–60 mg prednisone for adults and 1-2 mg/kg/day of prednisolone liquid in two divided doses) are recommended for 3 to 10 days. SOR A SABA can be administered every 20 minutes as needed and the addition of inhaled ipratropium bromide may reduce the need for hospitalization (0.68–0.75).[4] SOR A Symptoms usually abate in 1 to 2 days.
- Severe exacerbation (dyspnea at rest, PEF <40% predicted or personal best)—Usually requires ED visit and hospitalization likely; combination SABA/anticholinergic nebulized treatment hourly or continuously as needed, oral corticosteroids, adjunctive treatment as needed (see the following bullet). Symptoms last for >3 days after treatment begins.
- Life-threatening exacerbation (too dyspneic to speak, diaphoresis, PEF <25% predicted or personal best)—ED/hospitalization, consider intensive care unit; SABA/anticholinergic, intravenous corticosteroids, and adjunctive therapies.
- Oxygen therapy—Use to correct hypoxia in patients with moderate to life-threatening exacerbations; maintain O_2 saturation above 90 percent.[3,4] SOR C
- Consider intravenous magnesium sulfate or heliox-driven albuterol nebulization if severe exacerbation and unresponsive to treatment after initial assessments.
- Monitor response to treatment with serial assessments of FEV1 or PEF. Pulse oximetry may be useful in children for assessing initial severity—A result <92–94 percent after 1 hour is an indication for hospitalization.[3]

- Patients with severe or life-threatening exacerbation unresponsive to initial treatments may require intubation and mechanical ventilation. Drowsiness may be a symptom of impending respiratory failure.
- The following should not be used as they have no supporting evidence and may delay effective treatment: drinking large volumes of liquids; breathing warm, moist air; using nonprescription products, such as antihistamines or cold remedies, and pursed-lip and other forms of breathing.[3] In addition, NAEP does not recommend use of methylxanthines, antibiotics (except as needed for comorbid conditions), aggressive hydration, chest physical therapy, mucolytics, or sedation in the ED or hospital setting.[3]

REFERRAL

- Consider referral to an asthma specialist if signs and symptoms are atypical, there are problems in assessing other diagnoses, or if additional specialized testing is needed.
- Referral or consultation should aalso be considered if there are difficulties achieving or maintaining control of asthma, if the patient required >2 bursts of oral systemic corticosteroids in 1 year or has an exacerbation requiring hospitalization, or if immunotherapy or omalizumab is considered.[3]
- Consultation with an asthma specialist should be conducted for patients with persistent asthma requiring step 4 care or higher and considered if a patient requires step 3 care.[3]

PREVENTION AND SCREENING

- Smoking cessation and avoidance of second-hand smoking, limiting occupational exposures, and exposure to indoor air pollution may be preventive.

- In the Danish National Birth Cohort, maternal intake of peanuts and tree nuts during pregnancy was inversely associated with asthma in children at 18 months (OR 0.79 95% CI, 0.65 to 0.97 OR 0.75; 95 percent CI, 0.67 to 0.84, respectively).[48]
- Breastfeeding protects against asthma, especially among children with atopy; in one study, in children with atopy, exclusive breastfeeding for 3 or more months reduced current asthma at ages 4 to 6 years by more than 50 percent.[49]
- Influenza and pneumococcal vaccination are recommended.[3] SOR Ⓑ
- Despite limited data, vitamins A, D, and E; zinc; fruits and vegetables; and a Mediterranean diet may be useful for the prevention of asthma.[50] In addition, raw cow's milk consumption appears protective (adjusted OR, 0.59; 95% CI, 0.46 to 0.74).[51]

PROGNOSIS

- More than half of children with asthma will no longer have symptoms by age 6 years.[4]
- In a meta-analysis, maternal asthma was associated with an increased risk of low birthweight (RR, 1.46; 95% CI 1.22 to 1.75), small for gestational age (RR, 1.22; 95% CI 1.14 to 1.31), preterm delivery (RR, 1.41; 95% CI 1.22 to 1.61) and pre-eclampsia (RR, 1.54; 95% CI 1.32 to 1.81).[52] The RR of preterm delivery and preterm labor became nonsignificant by active asthma management. Pregnancy does not appear to increase asthma severity, provided women continue to use their prescribed medications.[53]
- Among children, factors predictive of an asthma exacerbation include bronchiolitis or pneumonia during infancy, maternal eczema, paternal history of hay fever, asthma symptoms ≥3 months/year, more than four scheduled physician visits for asthma in the previous year, and use of certain medications (SABAs, antiinflammatory medications, and one or more courses of oral steroids) in the prior year.[36] A 17-item checklist assessing asthma symptoms, use of medications and health care services,

and history has been demonstrated to be helpful for identifying children at high or low-risk for asthma exacerbations.[54]

- For patients with an asthma exacerbation, the following factors place a patient at higher risk of asthma-related death; these patients should be advised to seek medical care early during an exacerbation:[3]
  - Previous severe exacerbation (e.g., intubation or ICU admission for asthma).
  - Two or more hospitalizations or >3 ED visits in the past year.
  - Use of >2 canisters of SABA per month.
  - Difficulty perceiving airway obstruction or the severity of worsening asthma.
  - Low socioeconomic status or inner-city resident.

FOLLOW-UP

- Many patients have asthma that is not well controlled. In a cross-sectional study of 29 pediatric practices (N = 2429), 46 percent reported uncontrolled asthma (defined as a Childhood Asthma Control Test (C-ACT) or the Asthma Control Test (ACT)<or = 19).[55] One of the new aspects of the NAEP 2007 guideline is the focus on monitoring asthma severity and control, the latter defined as the degree to which manifestations of asthma are minimized by therapeutic interventions and the therapy goals are met.
- At each visit, ask about frequency and intensity of symptoms and functional limitations currently or recently experienced (impairment). A self-assessment sheet for follow-up visits is available in the NAEP document and a simple symptom checklist can be downloaded from **www.qvar.com/asthma/asthma-symptoms-checklist.aspx**. SOR Ⓒ
- In addition, at each visit, assess the likelihood of either asthma exacerbations, progressive decline in lung function (or lung growth for children) or risk of medication adverse effects. A patient self-assessment sheet rating asthma control (e.g., symptoms or PEF) and medication use is available in the NAEP reference.[3] Provision of a visually standardized,

interpreted peak flow graph to assist in understanding when to add medication or contact a health provider may reduce need for oral steroids and urgent care visits.[56]

- For patients on medications, monitor treatment effectiveness (“have you noticed a difference, for example less breathlessness”) and side effects. Observe inhaler technique at least once to ensure optimal delivery.
- For smokers, encourage cessation.
- Document exacerbations/hospitalizations—This may indicate a need for additional treatment.
- Monitor for comorbidities (e.g., heart disease, chronic lung disease) and maximize control of those conditions.
- Measurement of fractional nitric oxide (NO) concentration in exhaled breath (Fe(NO)) is a quantitative, noninvasive method of measuring airway inflammation.[57] It is under investigation as a complementary tool to other ways of assessing airways disease, including asthma.
- Post-hospital discharge management was investigated in a recent before and after study of implementing the Joint Commission’s three Children’s Asthma Care (CAC) measures in a tertiary care children’s hospital.[58] The measures were (1) percentage of patients who received beta agonists, (2) percentage of patients who received systemic steroids during their hospital stay, and (3) percentage of patient’s discharged with a home management care plan including quick reliever and controller drugs, follow-up appointment, environmental or other trigger control, and a written action plan. Compliance with the first two measures was extremely high before and after (99% versus 100%, CAC-1; 100% versus. 100%, CAC-2) but compliance with the third measure increased from 0 to 87 percent. There was an associated small but significant decrease in readmissions from an average of 17 to 12 percent post implementation.

For patients who appear well controlled, step-down therapy can be considered. Authors of one study found that although daily ICS was associated with the lowest rates of exacerbations (28%) and treatment failure (2.8%), no daily medication with rescue albuterol and ICS was a reasonable alternative (exacerbations 35%, treatment failure 8.5%) and did not affect linear growth (versus 1.1 cm less).[59] Combined rescue performed better than albuterol rescue alone.

PATIENT EDUCATION

- Smoking cessation should be strongly and repeatedly encouraged; passive smoking can trigger asthma exacerbations.[60] Exercise should also be encouraged along with weight loss, if obese, or maintenance of a healthy weight.
- The NAEP suggests that key educational messages include basic facts about asthma, the role of medications (i.e., rescue/short-term vs. control/long-term), and patient skills (e.g., correct inhaler technique, self-monitoring).
- Creation of an asthma action plan can be helpful in promoting self-management and greater understanding of warning signs of worsening asthma. An example of an action plan can be found in the NAEP document.[3] Asthma action plans usually use three zones, similar to traffic lights, with green zone representing good control (e.g., few symptoms, PEF 80% to 100%), yellow zone representing worsening or not well-controlled asthma (e.g., mild to moderate symptoms, PEF 50% to 80%), and red zone representing an alert or warning (severe symptoms, PEF <50%) with advice to seek emergency care if not better after 15 minutes of rescue medication use and unable to reach their care provider. Each zone contains instructions for management, which the primary care provider can modify.

50 COMMUNITY-ACQUIRED PNEUMONIA

Mindy A. Smith, MD, MS

PATIENT STORY

Max is a 4-year-old boy who presents with a 2-day history of cough, fever, and chills. He tells you that his tummy hurts. On examination, he appears moderately ill and his breathing is rapid (about 55 breaths per minute); his oxygen saturation on room air is 94 percent. You hear decreased breath sounds and crackles on the left side of his chest and possibly on the right. You obtain a chest x-ray which is concerning for bacterial pneumonia. (**Figures 50-1** and **50-2**). You admit him to the hospital with a diagnosis of probable bacterial pneumonia and prescribe intravenous antibiotics. He improves considerably over 48 hours and is discharged home on oral antibiotics.

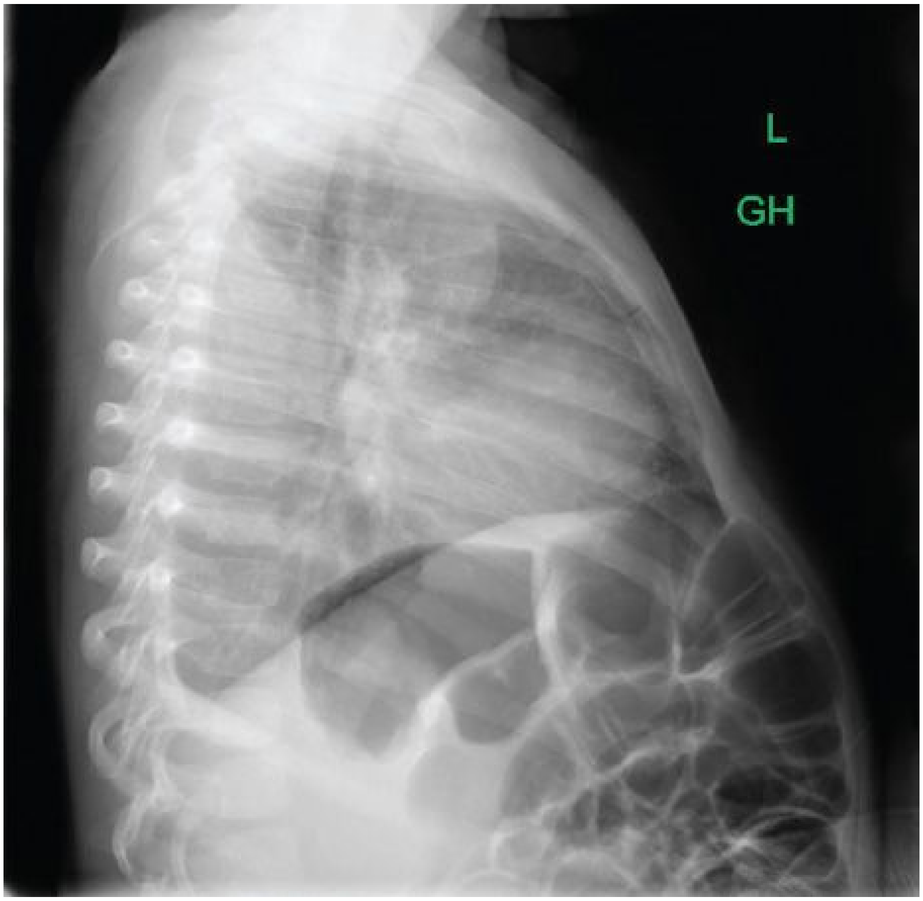

FIGURE 50-2 Lateral chest x-ray in the same child. (*Used with permission from Camille Sabella, MD*.)

INTRODUCTION

Pneumonia refers to an infection in the lower respiratory tract (distal airways, alveoli, and interstitium of the lung). Community-acquired pneumonia (CAP) has traditionally referred to pneumonia occurring outside of the hospital setting. A subgroup of CAP that is associated with health care risk factors (e.g., prior hospitalization, dialysis, immunocompromised state) has been classified as health care-associated pneumonia.

CAP can be caused by a wide variety of viral, bacterial, and “atypical” pathogens. The age and immune status of the host are important in considering the potential causes and management of pneumonia in the pediatric population.

EPIDEMIOLOGY

- The incidence rate of CAP among children in the first 5 years of life is 10 to 40 cases/1000,[1] with an incidence rate of 6 to 12 cases/1000 in children older than 9 years in North America.[2]
- In the National Hospital Discharge Survey (2006) of 1,232 first-listed pneumonia discharges from short-stay hospitals, 172 (14%) were children aged <15 years.[3]
- The distribution of the pneumococcal vaccine in 2000 has resulted in an approximately 35 percent decrease in all-cause pneumonia hospitalizations in US children since 1997–1999, with incident rates in 2005 and 2006 for children aged <2 years of 9.1/1,000 and 8.1/1,000, respectively.[4] For pneumococcal pneumonia, rates of hospitalizations between 1997–1999 and 2004 in an employer-based population study of children <age 2 years declined from 0.6 to 0.3 per 1000 children (57.6% decline) and rates of ambulatory visits declined from 1.7 to 0.9 per 1000 children (46.9% decline).
- CAP is the most frequent cause of death due to infectious disease in the US and the eighth leading cause of death overall (2007).[5,6]
- Deaths in 2009 from influenza and pneumonia occurred in 5.9/50,000 children <age 1 year, 0.9/50,000 for children aged 1 to 4 years, 0.6/50,000 for children aged 5 to 14 years and 1.0/50,000 for those aged 15 to 24 years.[7]

ETIOLOGY AND PATHOPHYSIOLOGY

- *Streptococcus (S) pneumoniae* is the most important pathogen at all ages.[8] Age, however, is an important consideration: in the first 20 days of life, most cases of pneumonia are secondary to Group B *Streptococci* or gram negative enteric bacteria while among young children with CAP, respiratory syncytial virus (RSV), influenza, and rhinovirus are common.[9] *Mycoplasma pneumoniae* and *Chlamydophila pneumoniae* are common in school-aged children and adolescents.[9] *Mycoplasma pneumoniae* is the single most common cause of CAP is school-aged children. Newly identified microbes in childhood pneumonia include human metapneumovirus, human bocavirus, and Simkania negevensis (an intracellular bacterium).[8]
- For children who are immunocompromised, other pathogens such as *Pneumocystis jiroveci* and *Mycobacterium tuberculosis* should be considered.[9]
- In a study of children hospitalized with CAP (N = 254), the cause of the disease (identified in 85% of cases) was most often viral (62%, with 30% having evidence of both viral and bacterial pathogens).[10] The most common identified pathogens were *S. pneumoniae* (37%), RSV (29%), and rhinovirus (24%). Dual bacterial infections were found in 19 patients; only one patient of 125 tested had a positive blood culture.
- In a retrospective study of children with unresponsive or recurrent CAP undergoing flexible bronchoscopy with bronchoalveolar lavage, an infectious agent was detected in the majority (76%) of cases with aerobic bacteria identified in about half including nontypeable *Haemophilus influenzae* (75%), *Moraxella catarrhalis* (28.9%), and *S. pneumoniae* (13.3%).[11]
- The most common route of infection is microaspiration of oropharyngeal secretions colonized by pathogens.[12] In this setting, *S. pneumoniae* and *Haemophilus influenza* are the most common pathogens.
- Pneumonia can also occur secondary to gross aspiration (postoperatively or in those with central nervous system disorders) where anaerobes and gram-negative bacilli are common pathogens.[12]
- Hematogenous spread, most often from the urinary tract, can result in *Escherichia coli* pneumonia and hematogenous spread from intravenous

catheters or in the setting of endocarditis may cause *Staphylococcus aureus* pneumonia.[12]

- *Mycobacterium tuberculosis* (TB), fungi, *legionella*, and many respiratory viruses are spread by aerosolization.
- Etiology is unknown in up to 70 percent of cases of CAP.

RISK FACTORS[13,14]

Among children <5 years of age, risk factors include:

- History of recurrent respiratory infections during the past year (odds ratio [OR] 5.5) or previous chest infections (2.31; 95% confidence intervals [CI], 1.55–3.43).
- History of wheezing episodes (OR 5.3).
- History of otitis media and tympanocentesis before the age of 2 years (OR 3.6).
- Lower weight for height (OR 1.28; 95% CI, 1.10–1.51).
- Spending less time outside (1.96; 95% CI, 1.11–3.47).
- Mold in the child’s bedroom (1.93, 95% CI, 1.24–3.02).

Among older children, risk factors include:

- History of recurrent respiratory infections during the previous year (OR 3.0).
- History of wheezing periods at any age (OR 2.1).

DIAGNOSIS

CLINICAL FEATURES

- Constellation of symptoms includes fever (88% to 96%), cough (76% to 88%), dyspnea (37% to 40%), chills, pleuritic chest pain, and sputum production.[8] Children may also complain of fatigue, myalgia, and headache.[9]
- Patients with viral or atypical pathogens (e.g., mycoplasma or chlamydia) often present with low-grade fever, nonproductive cough, and constitutional symptoms developing over several days.[9]
- About half of children report nonspecific signs like vomiting and abdominal pain.[8]
- Wheezing is most frequently associated with viral or atypical pathogens and bacterial infection is less likely when true wheezing is present.[9]
- Signs of pneumonia include increased respiratory rate, dullness to percussion, bronchial breathing, egophony, crackles, wheezes, and pleural-friction rub. Nonspecific crackles were reported in two recent Italian studies in 1/3 to half of children with CAP.[15,16] Lung findings in atypical pneumonia may be more diffuse. Pleural effusion is common and appears to increase the risk of a bacterial etiology.[9]
- In one emergency department case series of children >12 months of age with suspected pneumonia, respiratory rates >50 breaths per minute and oxygen saturation below 96 percent had a high specificity (97%) for predicting radiographic evidence of pneumonia.[17] In another study, tachypnea was present in 50 percent to 80 percent of pediatric radiologically-confirmed CAP cases.[18]
- Signs of respiratory distress in children include tachypnea (defined as age 0 to 2 months: >60 breaths per minute, age 2 to 12 months: >50 breaths per minute, age 1–5 years: >40 breaths per minute, and age >5 years: >20 breaths per minute), apnea, altered mental status, dyspnea, grunting, nasal flaring, pulse oximetry <90 percent on room air or retractions.[19]

LABORATORY STUDIES[12]

- Routine complete blood count (CBC) and acute phase reactants (e.g., erythrocyte sedimentation rate, C-reactive protein, procalcitonin) are not necessary for children with suspected CAP managed as outpatients but should be considered for children with more serious disease, if deemed useful.[19] SOR C

- In one RCT of hospitalized children with CAP, use of procalcitonin (admission level <0.25 ng/mL) reduced antibiotic prescriptions (85.8% versus 100%).[20]
- Acute phase reactants should not be used as the sole determinant for distinguishing between viral and bacterial CAP.[19] SOR A
- CBC should be obtained in children hospitalized for severe pneumonia (interpreted in the context of other tests).[19] SOR C
- Sputum culture and gram stain should be obtained in hospitalized children who can produce sputum.[19] SOR C Tracheal aspirates for gram stain, culture, and viral pathogens (as appropriate) should be obtained at the time of initial endotracheal tube placement in children requiring mechanical ventilation.[19] SOR C
- Blood cultures are not recommended routinely for nontoxic, fully immunized children with CAP managed in the outpatient setting.[19] SOR B In developing the microbial testing strategy for the Pneumonia Etiology Research for Child Health (PERCH) study, investigators found that only 1 percent to 5 percent of children with CAP have documented bloodstream infections; prevalence is higher among children with severe infection.[21]
- Blood cultures should be obtained in children who fail to demonstrate clinical improvement and in those who have progressive symptoms or clinical deterioration after initiation of antibiotics.[19] SOR B
- Blood cultures are recommended for children requiring hospitalization for presumed bacterial CAP that is moderate to severe, particularly those with complicated pneumonia.[19] SOR C
- Sensitive and specific tests for the rapid diagnosis of influenza virus and other respiratory viruses should be used in the evaluation of children with CAP.[19] A positive influenza test may decrease both the need for additional diagnostic studies and antibiotic use, while guiding appropriate use of antiviral agents in both outpatient and inpatient settings.[19] SOR A Serology

(fourfold rise in IgM titer) may also be useful in diagnosing *Mycoplasma pneumoniae*, *Chlamydophilaia pneumoniae*, legionnaires, and other viral pneumonia.[19] SOR C

- Urinary antigen detection tests are not recommended for the diagnosis of pneumococcal pneumonia in children, as false-positive tests are common.[19] SOR A
- Pulse oximetry should be performed in patients with pneumonia and suspected hypoxemia. The presence of hypoxemia should guide decisions regarding site of care and further diagnostic testing.[19] SOR B

IMAGING

- Routine chest x-ray (CXR) is not necessary for the confirmation of suspected CAP in children treated in the outpatient setting.[19] SOR A
- CXR, posteroanterior and lateral, should be obtained in patients with suspected or documented hypoxemia, significant respiratory distress, those who failed initial antibiotic therapy, and hospitalized patients.[19] SOR B
- In one RCT in Pakistan of treatment of CAP in young children (2 to 59 months), CXRs were normal in most children (82%) with a clinical diagnosis of pneumonia.[22]
- There are four general patterns of pneumonia seen on CXR;[12] however, they do not differentiate causative agents in CAP[19]:
    - Lobar—Consolidation involves the entire lobe (**Figures 50-1** to **50-5**). Early, especially with pneumococcal pneumonia in children, infiltrates can appear as round and can be mistaken for a pulmonary or mediastinal mass (**Figures 50-6** and **50-7**).[23] In young children, the thymic shadow can be mistaken as a pneumonic infiltrate (**Figure 50-8**).

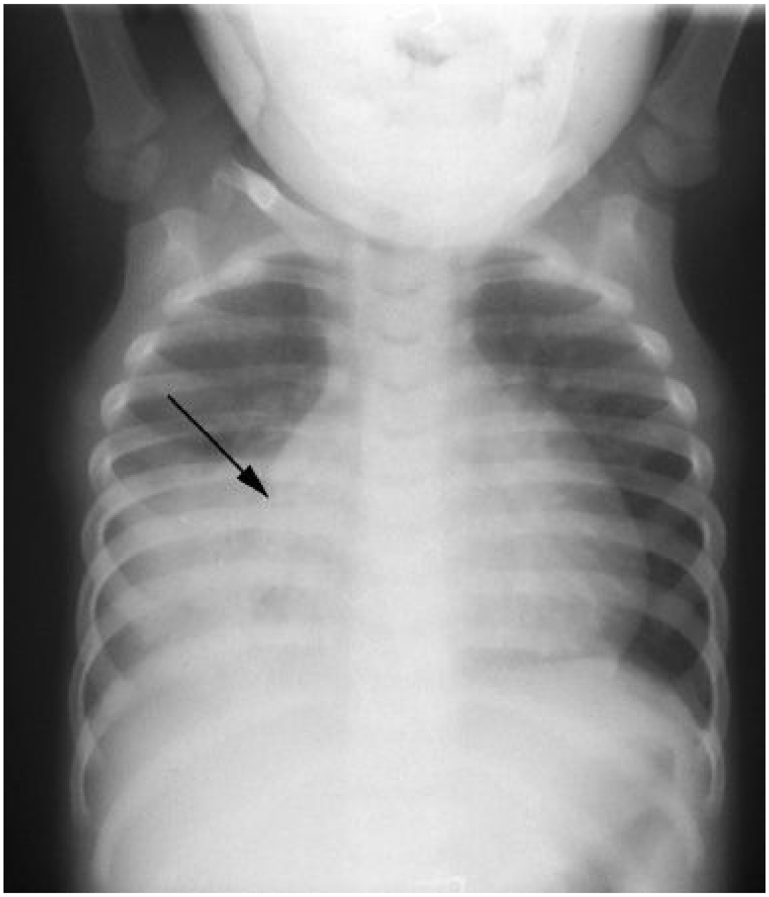

FIGURE 50-3 Right middle lobe infiltrate in an infant with bacterial pneumonia. Note the obliteration of the right heart border (arrow) characteristic of a right middle lobe process. (*Used with permission from Camille Sabella, MD*.)

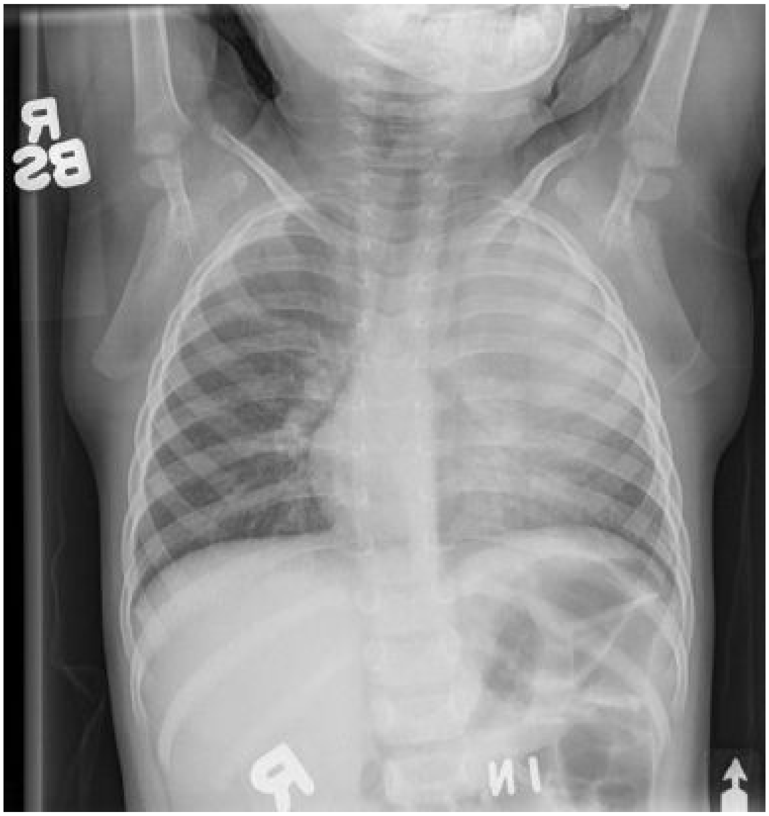

FIGURE 50-4 Left upper lobe consolidation on PA chest x-ray in a 1-year-old infant. (*Used with permission from Camille Sabella, MD*.)

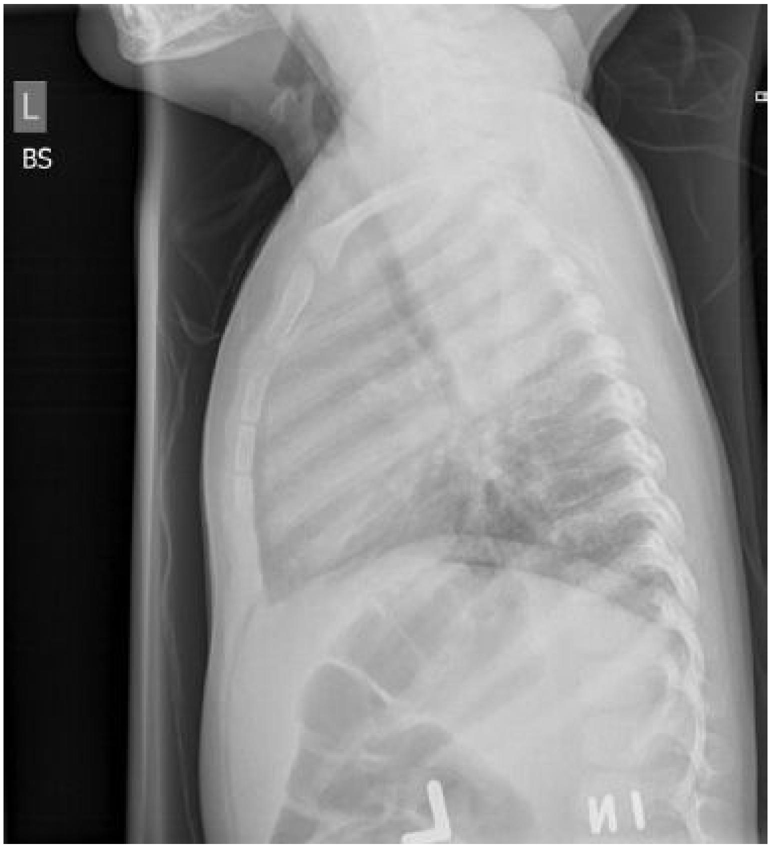

FIGURE 50-5 Left upper lobe consolidation on lateral chest x-ray in the same infant as previous Figure 50-4. (*Used with permission from Camille Sabella, MD*.)

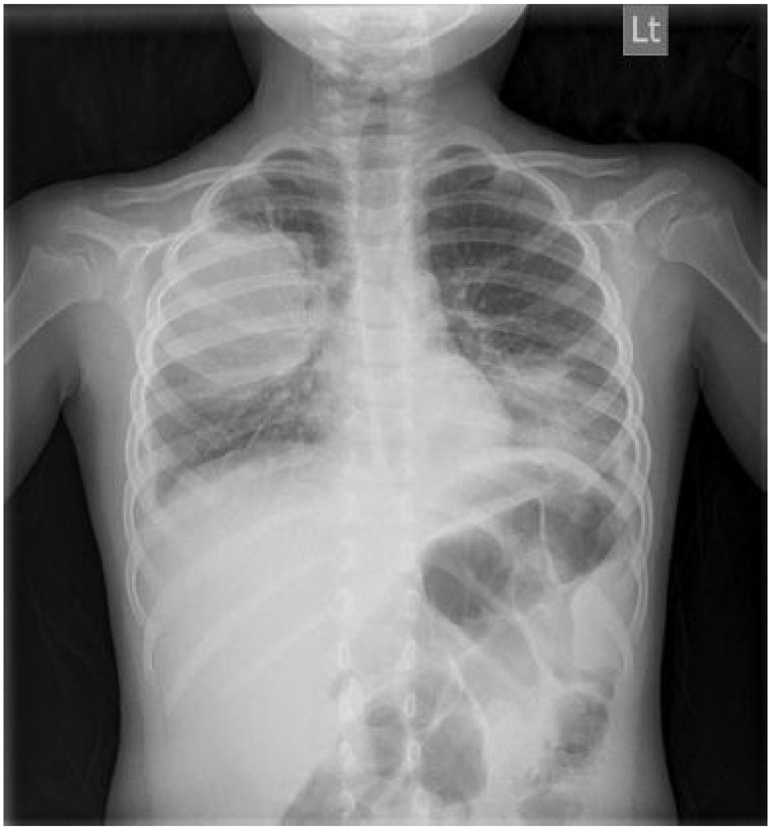

FIGURE 50-6 Round pneumonia involving the right upper lobe on a PA chest x-ray in a 4-year-old girl. This infection was presumed to be due to *S pneumoniae* and she responded well to appropriate antibiotics. (*Used with permission from Camille Sabella, MD*.)

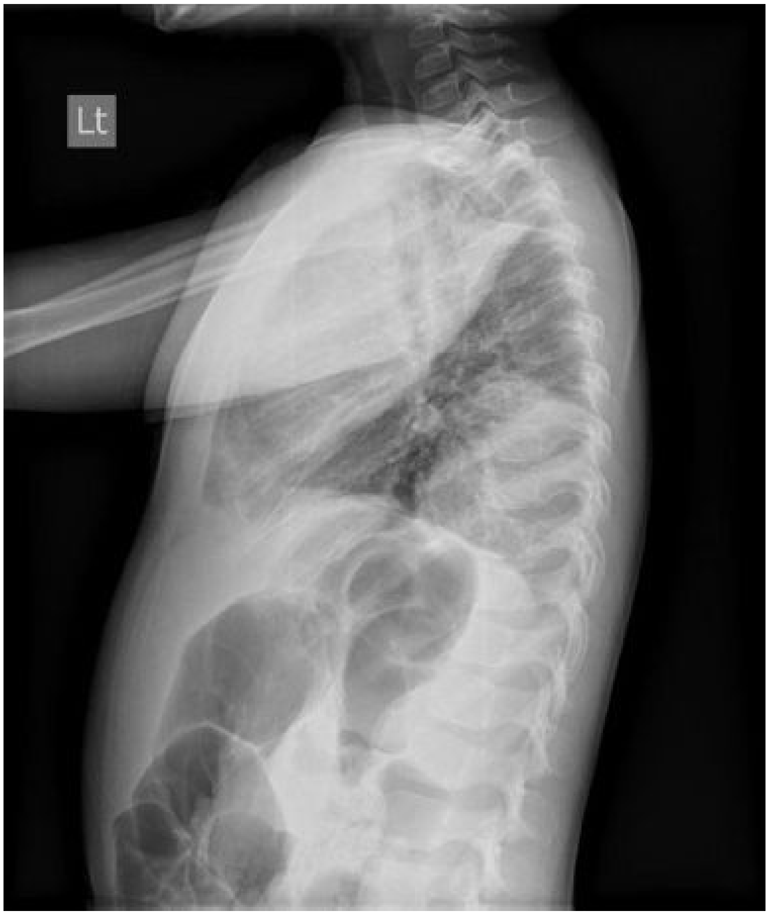

FIGURE 50-7 Pneumonia involving the right upper lobe on lateral chest x-ray in the same girl as previous Figure 50-6. (*Used with permission from Camille Sabella, MD*.)

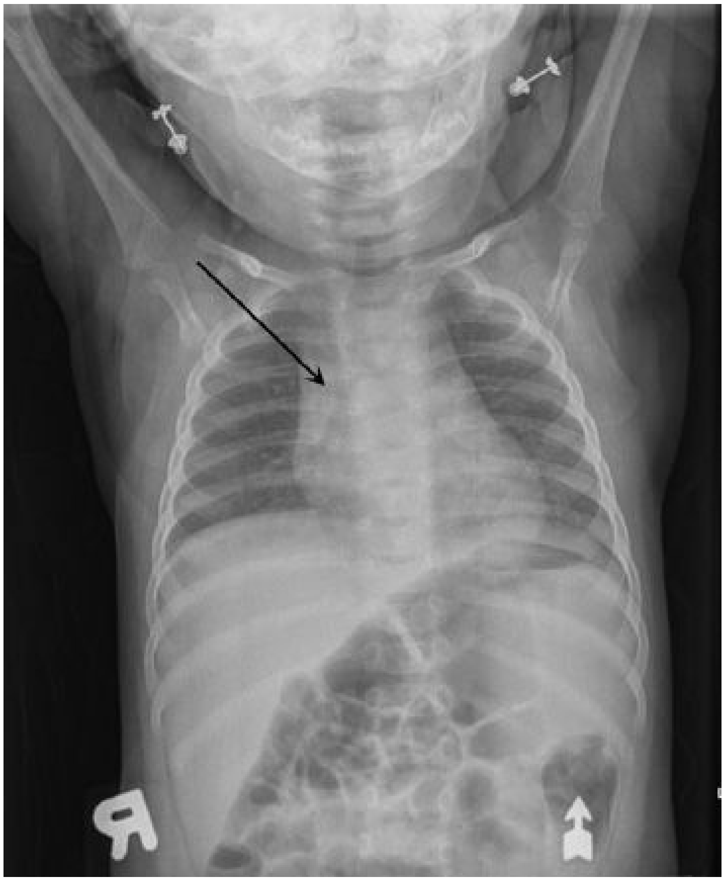

FIGURE 50-8 Thymic shadow (arrow) on a chest x-ray of a young infant, which can be mistaken for pneumonia. (*Used with permission from Camille Sabella, MD.*)

- Bronchopneumonia—Patchy involvement of one or several lobes that may be extensive, usually in the dependent lower and posterior lungs. Although bilateral patchy infiltrate with hilar lymphadenopathy are commonly associated with atypical pneumonia, lobar consolidation is not uncommon (**Figures 50-9** to **50-11**).

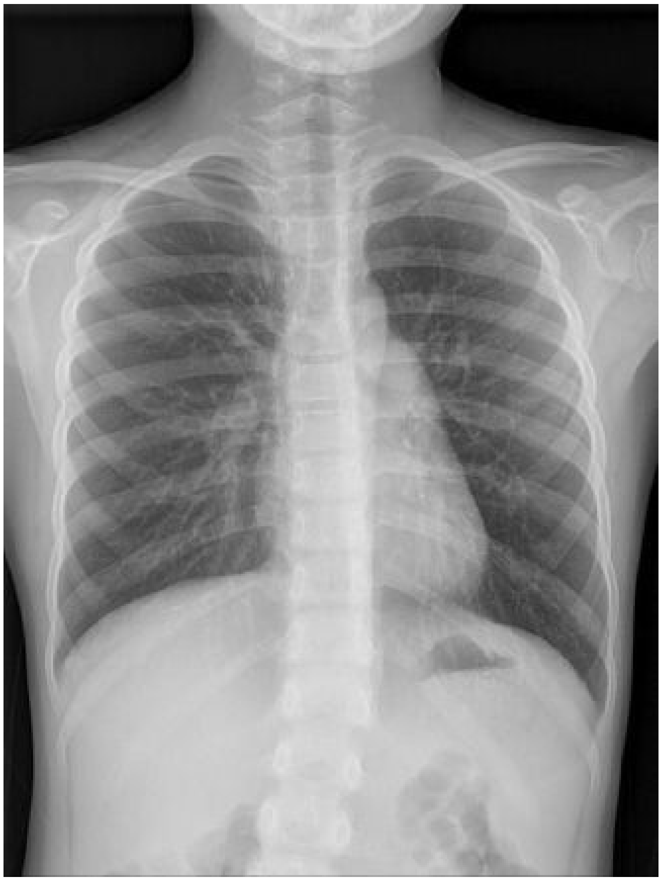

FIGURE 50-9 Bilateral diffuse infiltrates in a 9-year-old child with -*Mycoplasma* pneumonia. (*Used with permission from Camille Sabella, MD*.)

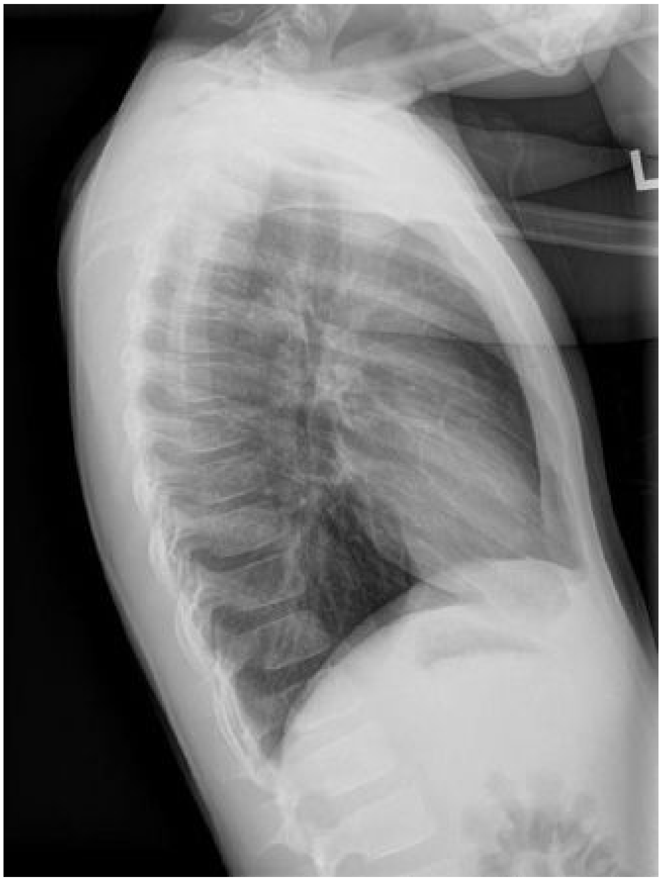

FIGURE 50-10 Bilateral diffuse infiltrates on lateral CXR in a 9-year-old with *Mycoplasma* pneumonia. Same child as in Figure 50-9. (*Used with permission from Camille Sabella, MD*.)

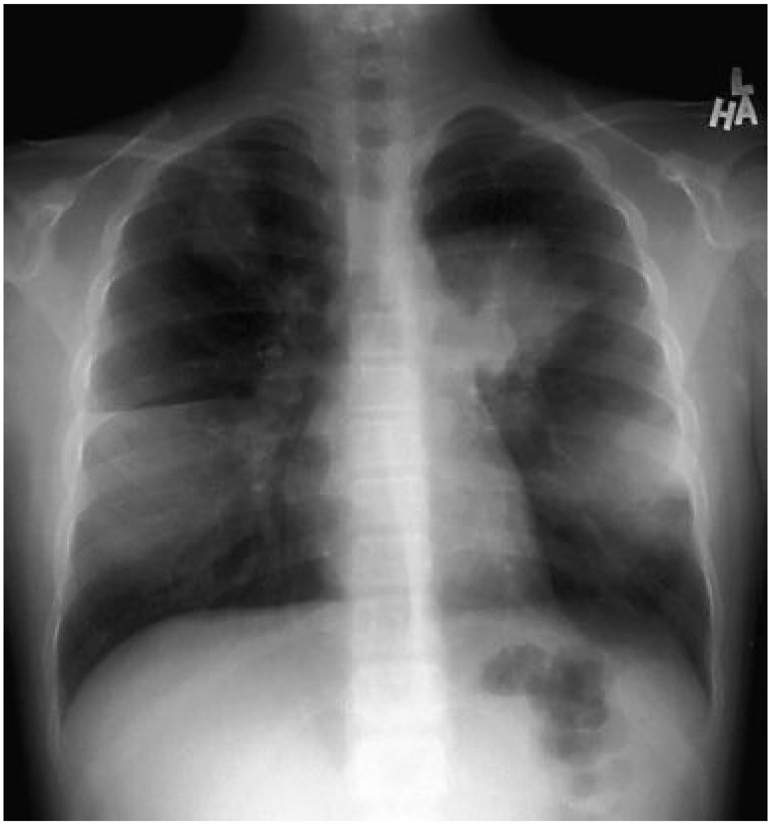

FIGURE 50-11 Multilobar infiltrate in a school-aged child with *Mycoplasma* pneumonia. Although the classic radiographic finding of *Mycoplasma* is a bibasilar diffuse infiltrate, a lobar and multilobar pattern can be seen. (U *sed with permission from Camille Sabella*, *MD*.)

- Interstitial pneumonia—Inflammatory process involves the interstitium and is usually patchy and diffuse (**Figure 50-12**). Viral pneumonia in children often appears radiographically as parihilar peribronchial infiltration in a diffuse reticular pattern; the heart's borders may appear shaggy due to adjacent peribronchial inflammation.[23] *Pneumocystis* pneumonia can be represented by any type of radiographic pattern, but a diffuse interstitial pattern has classically been described (**Figure 50-13**).

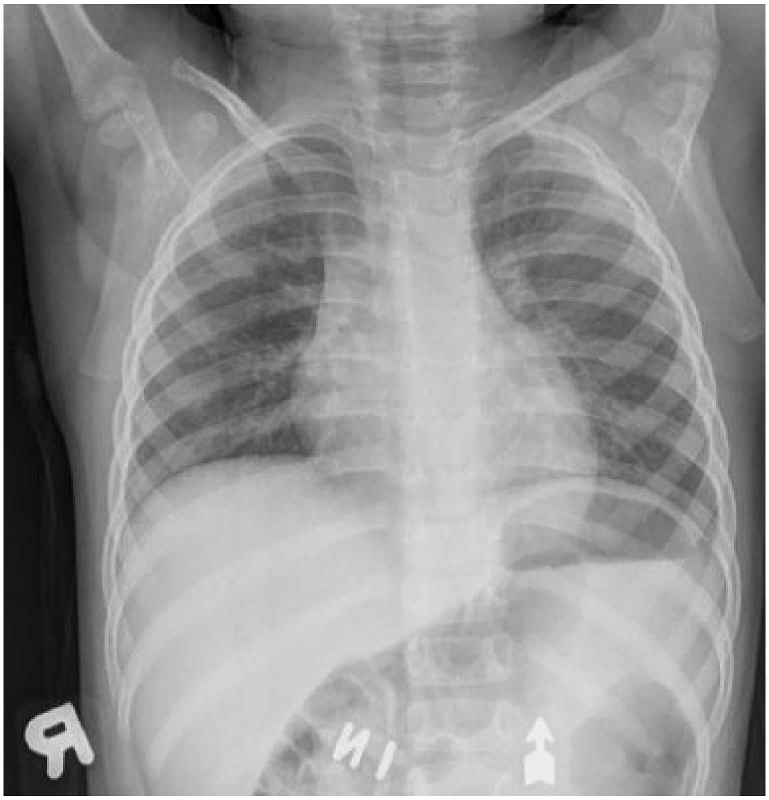

FIGURE 50-12 Central peribronchial thickening and pathy infiltrates in an infant with viral pneumonia. (*Used with permission from Camille Sabella, MD*.)

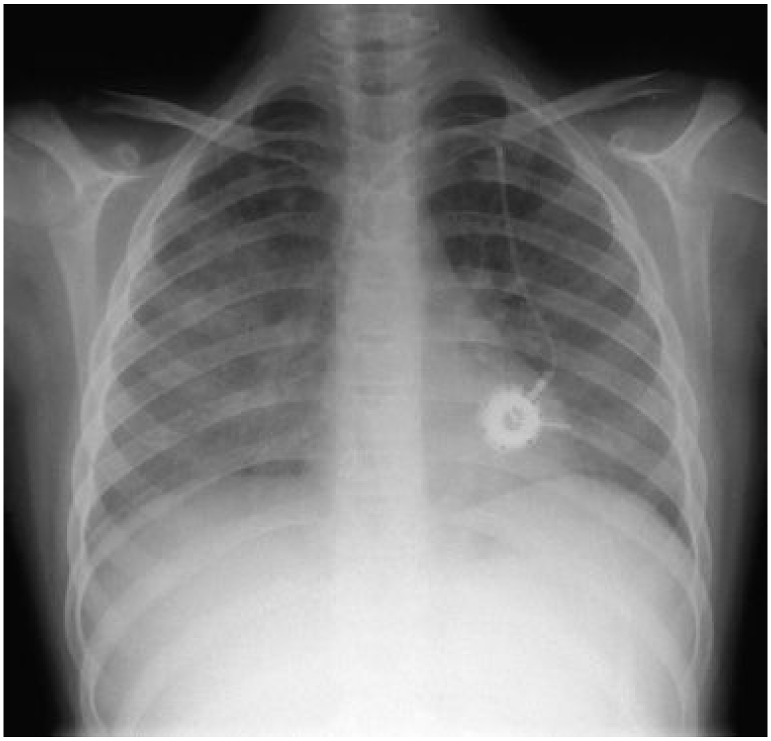

FIGURE 50-13 Diffuse interstitial pattern in child with *Pnemocystis jiroveci* pneumonia. This child's predisposition for this infection is acute leukemia. Note the presence of a central venous catheter to treat his underlying leukemia. (*Used with permission from Camille Sabella, MD*.)

  - Miliary pneumonia—Numerous discrete lesions from hematogenous spread (see Chapter 186, Tuberculosis).
- Parapneumonic effusions and empyema, as well as necrotizing pneumonia, can often be appreciated on CXR (**Figure 50-14**).

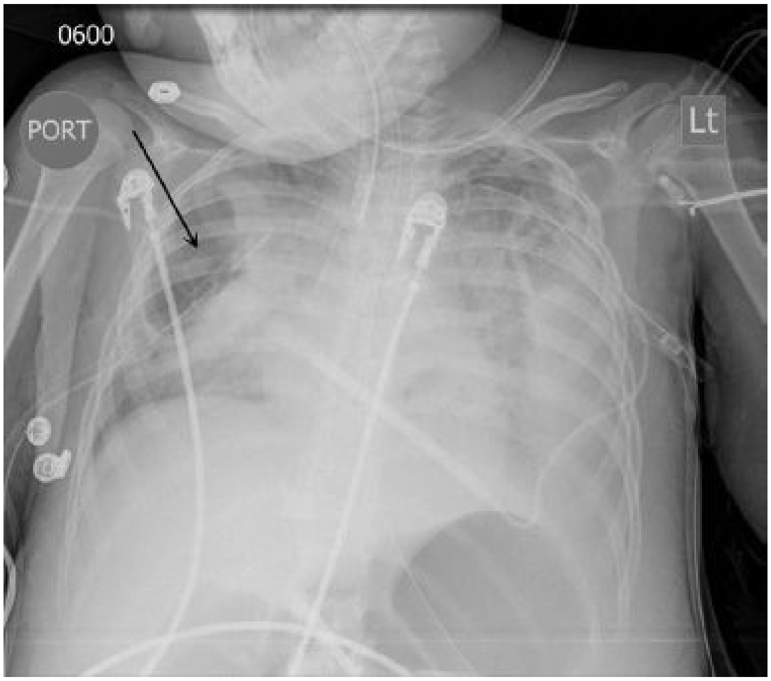

FIGURE 50-14 Necrotizing pneumonia (arrow) in the right upper lobe and large pleural effusion on the left side caused by *S pneumoniae* in a 4-year-old girl. (*Used with permission from Camille Sabella, MD*.)

- Ultrasound may be useful for evaluation of pleural effusion.[24]
- Computed tomography (CT) may be useful in the evaluation of complications of pneumonia, such as parapneumonic effusions, empyema, and necrotizing pneumonia (**Figures 50-15** and **50-16**).

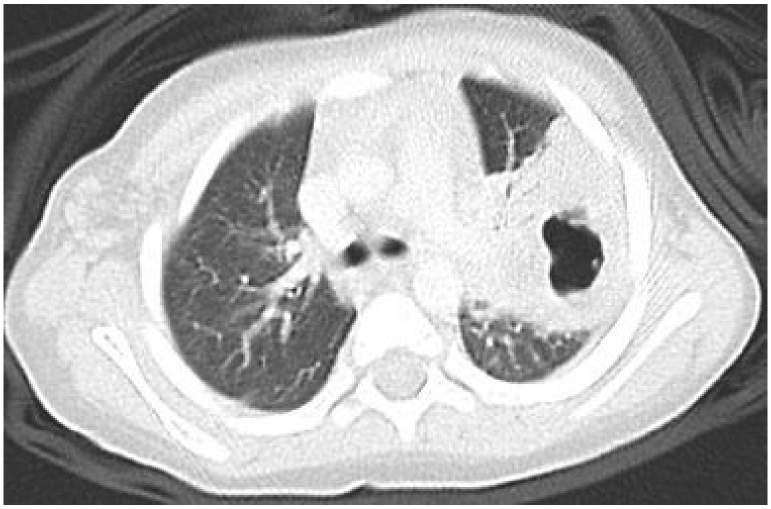

FIGURE 50-15 CT scan of the chest showing left lobar consolidation and cavitation from necrotizing pneumonia in a previously healthy 15-month-old child. (*Used with permission from Camille Sabella, MD*.)

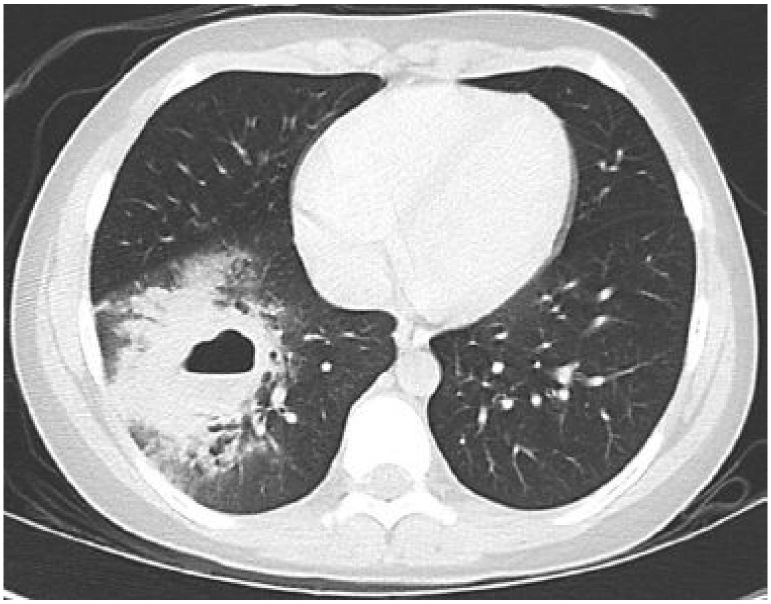

FIGURE 50-16 CT scan of the chest showing right lobar consolidation and cavitation from necrotizing pneumonia caused by *S pneumoniae* in a previously healthy 9-year-old child. (*Used with permission from Camille Sabella, MD*.)

DIFFERENTIAL DIAGNOSIS

- Upper respiratory illnesses, including bronchitis, can cause cough, fever, chills, and sputum production with a negative CXR.
- Asthma can cause cough, wheezing, dyspnea, and hypoxia; CXR is negative unless mucous plugging causes collapse of airways (see Chapter 49, Asthma and Pulmonary Function Testing).

MANAGEMENT

Initial determination of hypoxia and clinical severity of illness is used to identify children with CAP who may be candidates for inpatient treatment (see the following section “Hospitalize”). Children should be admitted to an Intensive Care Unit (ICU) if they require invasive ventilation SOR Ⓐ or have a pulse oximetry measurement of <92 percent on inspired oxygen of >0.50. Children should be admitted to either an ICU or a unit with continuous cardiorespiratory monitoring capabilities for any of the following:[19]

- Requirement for noninvasive positive pressure ventilation. SOR Ⓐ
- Impending respiratory failure. SOR Ⓑ
- Sustained tachycardia, inadequate blood pressure, or need for pharmacologic support of blood pressure or perfusion. SOR Ⓑ
- Altered mental status. SOR Ⓒ

There is no existing pediatric severity of illness score for CAP in children but items in the adult CAP severity score can be considered, including need for assisted ventilation (invasive or non-invasive positive pressure), shock, respiratory distress, multilobar infiltrates or effusion, comorbid conditions, and unexplained metabolic acidosis. In the PERCH study focused on hospitalized children aged 1 to 59 months with pneumonia, children defined with severe pneumonia had lower chest wall indrawing and those with very severe pneumonia had symptoms and signs including central cyanosis, difficulty breastfeeding/drinking, vomiting everything, convulsions, lethargy, unconsciousness, or head nodding.[25] The Pediatric Infectious Diseases Society (PIDS) and the Infectious Diseases Society of America (IDSA) guideline, however, recommends that a severity score alone should not be used as the sole criteria for ICU admission but should be used in the context of other clinical, laboratory, and radiologic findings.[19]

NONPHARMACOLOGIC

- Based on three clinical trials, chest physiotherapy (PT) did not improve outcomes for children with CAP.[26] In one RCT (N = 72 children aged 1 to 12 years), there were no differences in respiratory rate, decrease in severity score or days of hospitalization for children randomized to standardized chest PT versus the group randomized to non-mandatory request to breathe deeply, expectorate sputum, and maintain a lateral body position once a day.[27]

- Drainage procedures for children with pneumonia complicated by parapneumonic effusion include chest tube without fibrinolysis, chest tube with fibrinolysis, video-assisted thoracoscopic surgery (VATS), and thoracotomy. In one multihospital case series (N = 3500), there was no difference in length of stay (median 10 days) by type of procedure and outcomes were similar in patients undergoing initial chest tube placement with or without fibrinolysis.[28] Children undergoing VATS in this study received fewer additional drainage procedures.

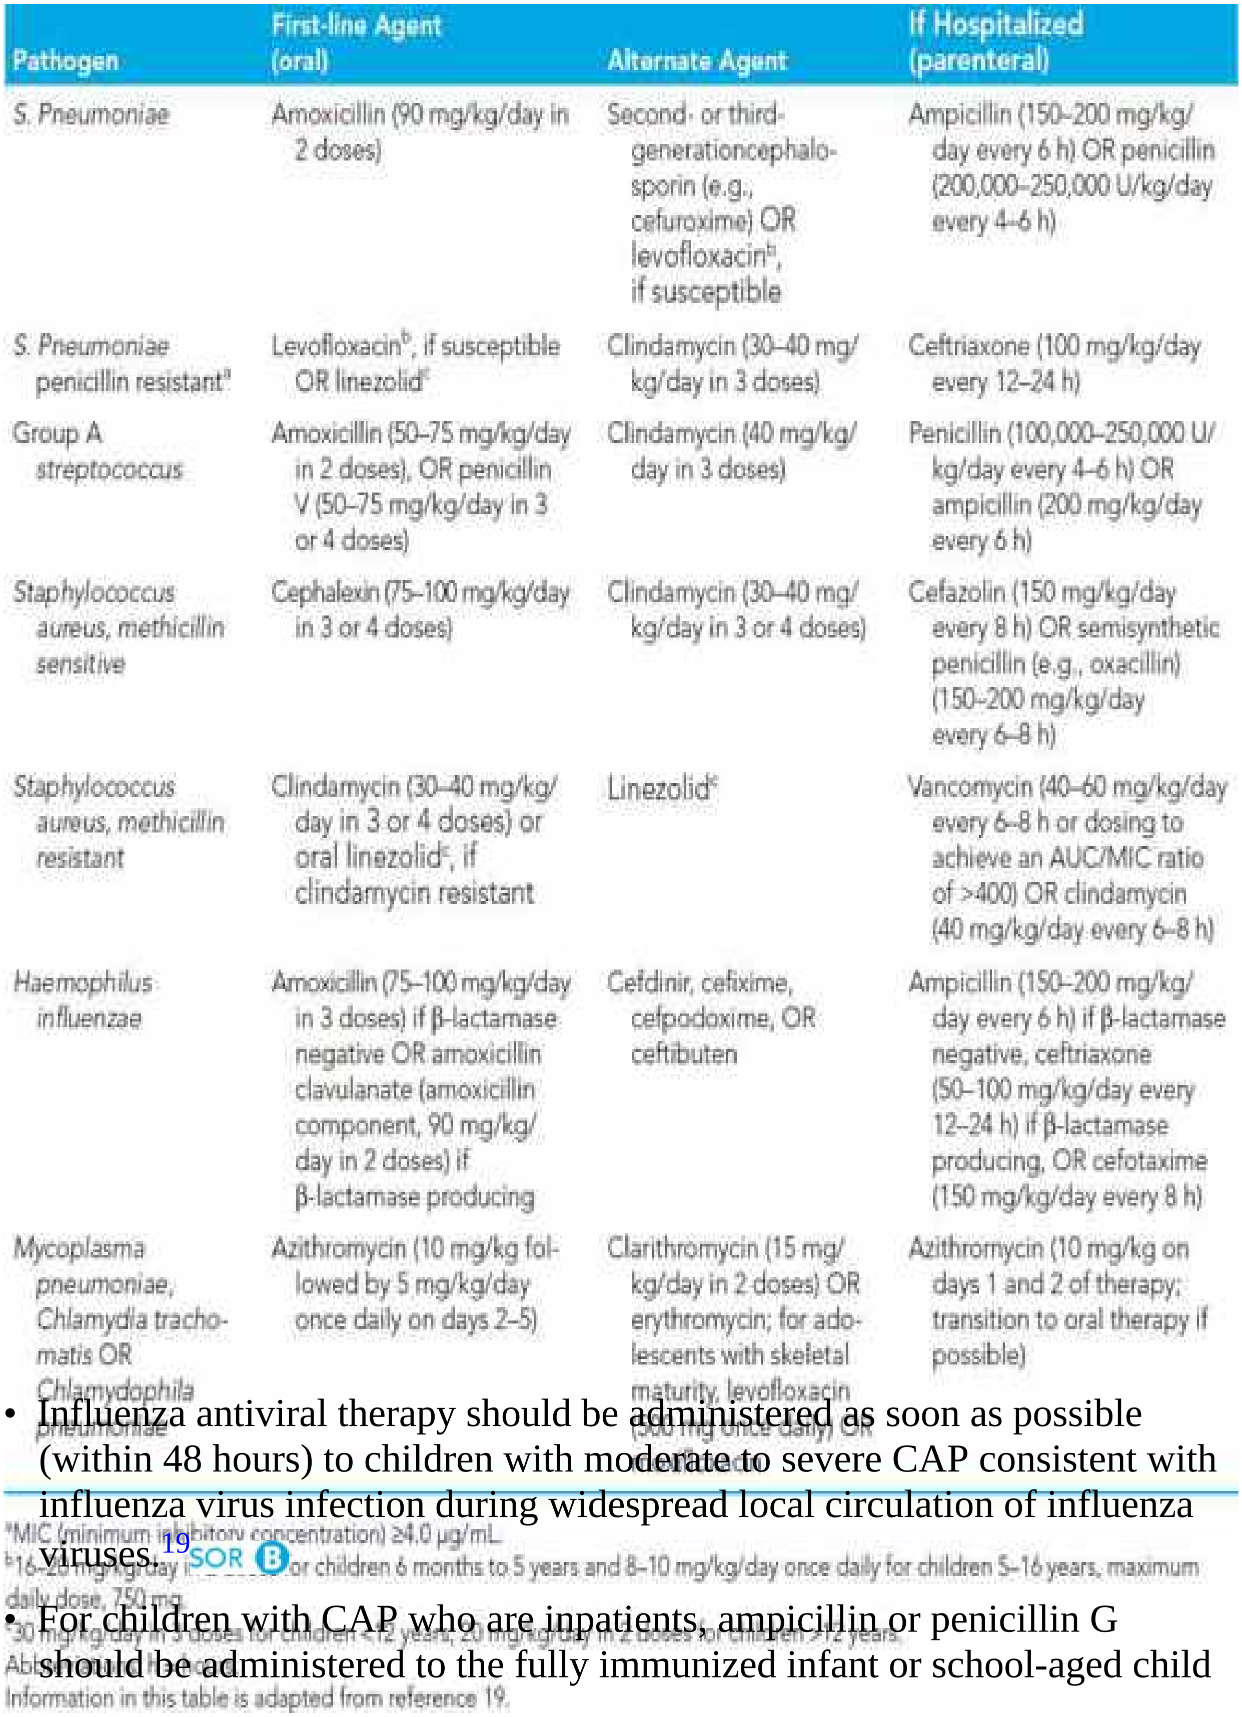
MEDICATIONS

Antimicrobial therapy is not routinely required for preschool-aged children with CAP because of the high proportion with viral disease.[19] SOR Ⓐ When antibiotics are prescribed, treatment courses of 10 days are recommended.[19] Recommended and alternate treatments for CAP based on a known bacterial pathogen are summarized in **Table 50-1**.

- Amoxicillin should be used as first-line therapy for previously healthy, appropriately immunized infants and preschool children with mild to moderate CAP suspected to be of bacterial origin.[19] SOR Ⓑ A Cochrane review supported use of amoxicillin (or co-trimoxazole) as first-line therapy with amoxicillin clavulanate and cefpodoxime considered as alternative second-line drugs; limited data were available on other antibiotics.[29]
- Amoxicillin is also recommended for previously healthy, appropriately immunized school-aged children and adolescents with mild to moderate CAP with consideration of atypical pathogens.[19] SOR Ⓑ If atypical pathogens are suspected clinically, macrolide antibiotics should be prescribed and diagnostic testing performed (**Table 50-1**). Authors of a Cochrane review were unable to determine whether macrolides were superior to other agents for pneumonia due to Mycoplasma as most trials found no differences in clinical response with the exception of a single

trial where macrolides were associated with higher clinical resolution (100% vs. 77% for those not treated with azithromycin).[30]

TABLE 50-1 Antimicrobial Therapy for Pediatric Community-Acquired Pneumonia



Pathogen	First-line Agent (oral)	Alternate Agent	If Hospitalized (parenteral)
S. Pneumoniae	Amoxicillin (90 mg/kg/day in 2 doses)	Second- or third-generationcephalosporin (e.g., cefuroxime) OR levofloxacin[b], if susceptible	Ampicillin (150–200 mg/kg/day every 6 h) OR penicillin (200,000–250,000 U/kg/day every 4–6 h)
S. Pneumoniae penicillin resistant[a]	Levofloxacin[b], if susceptible OR linezolid[c]	Clindamycin (30–40 mg/kg/day in 3 doses)	Ceftriaxone (100 mg/kg/day every 12–24 h)
Group A *streptococcus*	Amoxicillin (50–75 mg/kg/day in 2 doses), OR penicillin V (50–75 mg/kg/day in 3 or 4 doses)	Clindamycin (40 mg/kg/day in 3 doses)	Penicillin (100,000–250,000 U/kg/day every 4–6 h) OR ampicillin (200 mg/kg/day every 6 h)
Staphylococcus aureus, methicillin sensitive	Cephalexin (75–100 mg/kg/day in 3 or 4 doses)	Clindamycin (30–40 mg/kg/day in 3 or 4 doses)	Cefazolin (150 mg/kg/day every 8 h) OR semisynthetic penicillin (e.g., oxacillin) (150–200 mg/kg/day every 6–8 h)
Staphylococcus aureus, methicillin resistant	Clindamycin (30–40 mg/kg/day in 3 or 4 doses) or oral linezolid[c], if clindamycin resistant	Linezolid[c]	Vancomycin (40–60 mg/kg/day every 6–8 h or dosing to achieve an AUC/MIC ratio of >400) OR clindamycin (40 mg/kg/day every 6–8 h)
Haemophilus influenzae	Amoxicillin (75–100 mg/kg/day in 3 doses) if β-lactamase negative OR amoxicillin clavulanate (amoxicillin component, 90 mg/kg/day in 2 doses) if β-lactamase producing	Cefdinir, cefixime, cefpodoxime, OR ceftibuten	Ampicillin (150–200 mg/kg/day every 6 h) if β-lactamase negative, ceftriaxone (50–100 mg/kg/day every 12–24 h) if β-lactamase producing, OR cefotaxime (150 mg/kg/day every 8 h)
Mycoplasma pneumoniae, Chlamydia trachomatis OR Chlamydophila pneumoniae	Azithromycin (10 mg/kg followed by 5 mg/kg/day once daily on days 2–5)	Clarithromycin (15 mg/kg/day in 2 doses) OR erythromycin; for adolescents with skeletal maturity, levofloxacin (500 mg once daily) OR [illegible]	Azithromycin (10 mg/kg on days 1 and 2 of therapy; transition to oral therapy if possible)

[a] MIC (minimum inhibitory concentration) ≥4.0 μg/mL.

[b] 16–20 mg/kg/day [illegible] for children 6 months to 5 years and 8–10 mg/kg/day once daily for children 5–16 years, maximum daily dose, 750 mg.

[c] 30 mg/kg/day in 3 doses for children <12 years, 20 mg/kg/day in 2 doses for children >12 years.

Abbreviations: [illegible]

Information in this table is adapted from reference 19.

- Influenza antiviral therapy should be administered as soon as possible (within 48 hours) to children with moderate to severe CAP consistent with influenza virus infection during widespread local circulation of influenza viruses.[19] SOR B
- For children with CAP who are inpatients, ampicillin or penicillin G should be administered to the fully immunized infant or school-aged child

when local epidemiologic data document lack of substantial high-level penicillin resistance for invasive *S. pneumoniae*.[19] Empiric therapy with a third-generation parenteral cephalosporin (ceftriaxone or cefotaxime) should be prescribed for hospitalized infants and children who are not fully immunized, in regions where local epidemiology of invasive pneumococcal strains documents high-level penicillin resistance, or for infants and children with life threatening infection.[19] SOR B

- For children who are inpatients, empiric combination therapy with a macrolide (oral or parenteral) in addition to a b-lactam antibiotic should be prescribed when *M. pneumoniae* and *C. pneumoniae* are significant considerations; diagnostic testing should be performed.[19] SOR B
- Vancomycin or clindamycin (based on local susceptibility data) should be provided in addition to b-lactam therapy for hospitalized children if clinical, laboratory, or imaging characteristics are consistent with infection caused by *S. aureus*.[19] SOR C
- Among children hospitalized with CAP, adjunctive steroids appear to reduce hospital stay but only in children on concomitant b-agonist therapy (i.e., likely only children with acute wheezing benefit).[31] SOR B For others, steroid use increased length of stay and readmission.
- It is not known whether cough medications (mucolytics or cough suppressants) provide relief in reducing cough severity for patients with pneumonia.[32] SOR C

COMPLEMETARY AND ALTERNATIVE THERAPY

- Zinc adjuvant therapy might be useful for children with severe pneumonia. In one large RCT (N = 610 children in Nepal), zinc (10 mg in 2- to 11-month-olds and 20 mg in older children) was not significantly better than placebo in reducing recovery time or response to treatment[33] while in another RCT (N = 352 children in Uganda), zinc at similar dosing reduced the case fatality rate (4% versus 11.9%), especially among children with human immunodeficiency virus.[34]

HOSPITALIZATION[19]

- Children and infants who have moderate to severe CAP, as defined by several factors including respiratory distress and hypoxemia (sustained saturation of peripheral oxygen [SpO2] <90% at sea level), should be hospitalized for management (skilled pediatric nursing care). SOR Ⓐ
- Infants less than 3 to 6 months of age with suspected bacterial CAP. SOR Ⓒ
- Children and infants with suspected or documented CAP caused by a high virulence pathogen (e.g., community-acquired MRSA). SOR Ⓒ
- Children and infants for whom there is concern about careful observation at home or who are unable to comply with therapy or follow-up. SOR Ⓒ

PREVENTION

- Vaccination—Children should be immunized with vaccines for bacterial pathogens including *S. pneumoniae*, *Haemophilus influenzae* type b, and pertussis to prevent CAP.[19] SOR Ⓐ The use of pneumococcal conjugate vaccine is associated with an overall decreased incidence of invasive disease among children <age 5 years (from approximately 99 cases per 100,000 population (1998–1999) to 21 cases per 100,000 population (2008).[35]
- All infants ≥6 months of age, children, adolescents, persons ≥50 years of age, others at risk for influenza complications, and health care workers should be immunized annually with vaccines for influenza virus to prevent CAP.[12,19] SOR Ⓐ Vaccination status should be assessed at the time of hospital admission for all patients and appropriate vaccines offered at discharge.[12] SOR Ⓒ
- Smoking cessation assistance should be offered to adolescents and children who smoke. Parents who smoke around their children should be counseled about the adverse health consequences that this poses for their children.

- To prevent spread of respiratory pathogens, respiratory hygiene measures should be practiced.[12] These include the coughing into the elbow and use of hand hygiene and masks or tissues for patients with cough, particularly in outpatient settings and EDs.

PROGNOSIS

- Patients on adequate therapy for CAP should demonstrate clinical (and laboratory) signs of improvement within 48 to 72 hours.[19]
- Complications of CAP include pulmonary (e.g., pleural effusion, empyema or abscess, pneumothorax, bronchopleural fistula), metastatic (e.g., meningitis or brain abscess, peri- or endocarditis, osteomyelitis, septic arthritis), and systemic (e.g., sepsis, hemolytic uremic syndrome).[12]
- Most US children with CAP recover. In a case series from Sweden (N = 277), 4 percent of children hospitalized with CAP died; the most important factor independently associated with death was an initial low serum albumin concentration.[36] Elevated interleukin-6 was also associated with mortality.
- In a systematic review of 13 papers on long term sequelae from childhood pneumonia, the risk of at least one major sequelae (restrictive lung disease, obstructive lung disease, bronchiectasis) was 5.5 percent (95% CI, 2.8–8.3%) in non-hospitalized children and 13.6 percent (95% CI, 6.2–21.1%) in hospitalized children.[37] Adenovirus pneumonia was associated with the highest risk of sequelae.

FOLLOW-UP

- Assess need and provide pneumococcal and influenza vaccination at hospital discharge and/or follow-up.
- Monitor improvement and treat comorbid illness (which may worsen).

- Repeat blood cultures to document resolution of bacteremia in children with bacteremia caused by S. aureus, regardless of clinical status.[19] SOR C Otherwise, repeat blood cultures in children with clear clinical improvement are not needed.[19] SOR C
- Acute phase reactants can be useful in conjunction with clinical findings to assess response to treatment for children who are hospitalized with CAP of have pneumonia-associated complications.[19] SOR C
- Repeat CXRs (inpatient or outpatient) are not routinely required if recovery from an episode of CAP is uneventful.[19] SOR B Follow-up chest radiographs should be obtained in patients with complicated pneumonia with worsening respiratory distress or clinical instability, or in those with persistent fever that is not responding to therapy over 48 to 72 hours or with clinical deterioration.[19] SOR C
- Repeated CXR at 4 to 6 weeks after the diagnosis of CAP should be obtained in patients with recurrent pneumonia involving the same lobe and in patients with lobar collapse at initial CXR with suspicion of an anatomic anomaly, chest mass, or foreign body aspiration.[19] SOR B

PATIENT EDUCATION

- Improvement is expected in healthy outpatients in 48 to 72 hours with return to school in approximately 4 to 5 days and complete improvement within 2 weeks.

51 CYSTIC FIBROSIS

Di Sun, BS, MPH
Elumalai Appachi, MD, MRCP

PATIENT STORY

A 9-month-old girl presents to her pediatrician for persistent cough, failure to gain weight and a bulging mass from her rectum. Her mother reports that the girl has had two episodes of “pneumonia” requiring hospitalization at the age of 3 and 5 months. Since that time, she has not gained much weight and is noted to be at the 10th percentile for weight and length. On examination, the patient has course breath sounds and wheezes throughout the lung fields, and has rectal prolapse (**Figure 51-1**). The pediatrician suspects cystic fibrosis and orders a sweat chloride test, which is 120 mEq/L. This confirms the suspected diagnosis, as a result greater than 60 mEq/L is diagnostic for cystic fibrosis. The family is referred to a comprehensive cystic fibrosis center.

INTRODUCTION

- Cystic fibrosis (CF) is an autosomal recessive disorder caused by a mutation in the CF transmembrane conductance regular gene that alters the composition of mucus secreted in the lungs, pancreas, sweat glands, digestive tract, and vas deferens. This leads to obstructive lung disease and pancreatic insufficiency leading to malabsorption and malnutrition in affected children.

SYNONYMS

CF, fibrocystic disease of pancreas, mucoviscidosis.

EPIDEMIOLOGY

- Incidence of CF is 1 in 3200 newborns in the US.[1]
- CF is the most common fatal inherited disorder among Caucasians.
- Current median life expectancy of patients diagnosed with CF in the US is between 30 to 40 years.[2]
- CF is most common among Caucasians; 4 to 5 percent of Caucasians in North America are heterozygous for CF.[1,3]
- CF incidence among Hispanics ranges from 1:9200 to 1:13500 individuals.[4]

- CF has an incidence of 1:15,000 in African Americans and 1:31,000 in Asian Americans.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- CF is caused by a mutation in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene on chromosome 7.
- The *CFTR* gene is a 250 kb, 27 exon gene encoding an ATP binding cassette transporter found on the apical surface of mucosal epithelial cells. This protein is responsible for regulating chloride entrance into mucosal cells.[5]
- Mutations in CFTR are divided into several classes:[3,5]
    - Class 1 mutations—Premature transcription termination signal leading to a defective protein.
    - Class 2 mutations—Protein misfolding leading to premature degradation of CFTR and absence of CFTR expression at the apical surface of mucosal epithelial cells.
    - Class 3 mutations—Defective regulation of CFTR at the apical surface despite intact ability to traffic CFTR to the cell surface.
    - Class 4 mutations—Defective CFTR channel conductance of chloride.
    - Class 5 mutations—Decreased synthesis of functional CFTR due to splicing abnormalities.
    - Class 6 mutations—Increased turnover of CFTR at the apical surface.
- Class 1, 2, and 3 mutations are associated with more severe disease, while class 4 and 5 mutations tend to demonstrate pancreatic insufficiency and milder pulmonary disease.[3]
- The most common mutation in CF is ΔF508, a class 2 mutation that is present in 70 percent of CF patients.[1]
- The pathophysiology of CF lies in the importance of CFTR in regulating the chloride conductance across the apical membrane of mucosal cells, which impacts sodium and water transport. The end result is a thick,

viscous mucus that leads to inflammation, obstruction, and finally fibrosis of organs expressing CFTR in its mucosal cells.[6]

- Pulmonary manifestations of CF are due to increased viscosity of the airway surface liquid, which leads to impaired ciliary beating and thus decreased mucociliary clearance.[5]
- In addition to alteration of the airway surface liquid, pulmonary disease in CF is also characterized by an impaired immune response to pathogens because of decreased opsonization, decreased pH, and inactivation of antimicrobial peptides.[5,7]
- CFTR protein is also hypothesized to serve as a binding site for *Pseudomonas aeruginosa* which leads to phagocytosis and clearance via desquamation.[5]
- Another important manifestation of CF is pancreatic insufficiency, which results from thickened secretions from epithelial mucosal cells in the pancreas and leads to destruction of pancreatic β cells. Although insulin secretion is decreased, there is still some endogenous production, preventing the development of ketosis. In addition, the inflammation in the pancreas also reduces α cell mass, which leads to decreased glucagon. Insulin resistance is present in some patients with more severe disease, possibly due to increased inflammation. As patients develop diabetes, slight peripheral insulin resistance also develops.[6]

RISK FACTORS

- Family history of CF or carrier state.
- Caucasian.

DIAGNOSIS

CLINICAL FEATURES

- Pulmonary symptoms are the most common presenting manifestations of CF. Thick airway mucus and impaired clearance of pathogens leads to colonization of the airways and inflammation. This culminates in obstructive lung disease, specifically bronchiectasis, and leads to clinical findings such as diminished breath sounds, tachypnea, and increased chest diameter.[1]
- Common pathogens colonizing the airways early in life include *Staphylococcus aureus* and *Haemophilus influenzae*.
- Eventually, almost all patients acquire and become permanently colonized with *P aeruginosa*.
- Patients with more severe disease may also be colonized with *Burkholderia cepacia*, which is associated with a poor prognosis.
- Pulmonary complications, although uncommon, can become life threatening and include massive hemoptysis, spontaneous pneumothorax, and pulmonary hypertension.
- Digital clubbing is apparent even with only mildly reduced lung function (**Figure 51-2**).

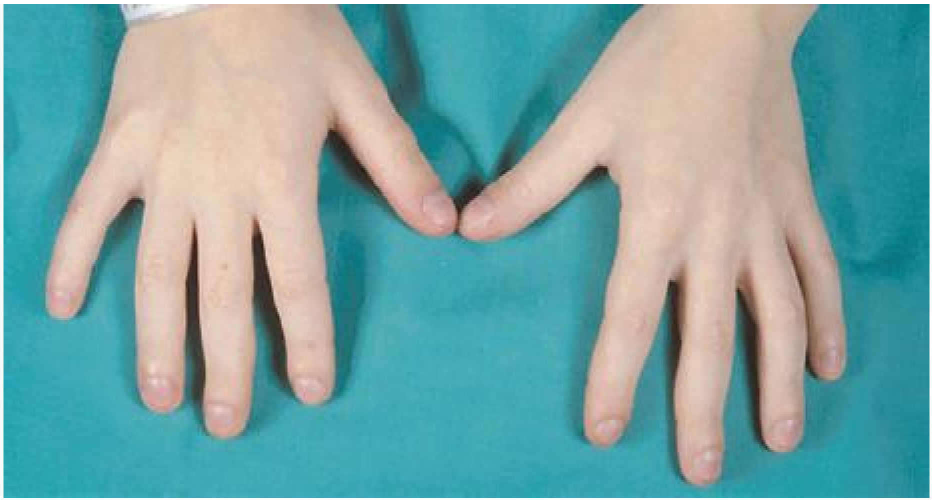

FIGURE 51-2 Digital clubbing in a boy with cystic fibrosis. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

- Pancreatic disease in children with CF is characterized by obstruction of pancreatic ducts, which can lead to pancreatitis and eventual loss of pancreatic exocrine function. Consequently, children are unable to digest fat and protein, leading to greasy, foul-smelling stool, abdominal distention, and cramping. This can also lead to malnutrition and failure to thrive. Loss of pancreatic endocrine function can also lead to diminished insulin secretion and thus diabetes.[6]
- Twenty to thirty percent of newborns with CF present with meconium ileus due to obstruction from thick intestinal secretions. Older infants and children can develop distal intestinal obstruction syndrome (DIOS) when stool becomes firm and accumulates at the ileocecal valve.
- Rectal prolapse occurs in about 20 percent of infants and children and usually occurs early in life (**Figure 51-1**). This is caused by bowel obstruction, malnutrition, and loss of anal sling musculature.
- Hepatobiliary disease occurs from thickened biliary secretions which can lead to acalculous cholecystitis. Liver disease occurs in about a third of children who have CF and a small percentage of them will develop cirrhosis and eventual liver failure.
- Pansinusitis is present in almost all children, while nasal polyposis occurs in about 25 percent children with CF. Children less than 12 years of age who have nasal polyposis should be screened for CF.
- Infertility is common in males due to absence of the vas deferens. Women with CF may also have decreased fertility due to thickened mucus obstructing the cervix.

LABORATORY TESTING

- Newborn screening is increasingly used in the US to identify newborns with CF. Newborns are identified by testing for immunoreactive trypsinogen (IRT), an inactive pancreatic enzyme that is elevated in the serum of infants with CF. Infants who are positive on this initial screen will then undergo either a DNA mutation analysis (IRT/DNA) or a second IRT (IRT/IRT), depending on state policy.[8]

- Infants who have a positive newborn screen (2 positive IRT screens or a positive IRT screen and DNA mutation analysis) should be referred to a CF center and undergo sweat chloride testing or definitive genetic testing to confirm the diagnosis.
- Sweat chloride testing remains the gold standard for diagnosis and involves using quantitative pilocarpine iontoelectrophoresis. Pilocarpine is applied to stimulate sweat glands. Sweat is collected and analyzed for chloride content.
    - A chloride concentration greater than 60 mEq/L is diagnostic for CF, whereas a concentrations less than 40 mEq/L is normal. A concentration between 40–60 mEq/L (30–60 mEq/L in infants less than 2 months) is considered indeterminate.
    - Infants and children with indeterminate tests should undergo genotype analysis.
- DNA testing for known CF mutations can also be used to diagnose CF. This requires identifying two known CF-causing mutations in the *CFTR* gene. Current DNA tests identify >90 percent *CFTR* mutations. Thus, a diagnosis of CF cannot be totally excluded using genetic testing. Uncharacterized *CFTR* mutations are more common in non-Caucasian CF patients. Thus, DNA testing may be more likely to miss a mutation in these patients.[1]
- In general, genetic testing for CF should be reserved for patients in whom sweat testing is logistically difficult or has yielded indeterminate results.
- The function of the CFTR protein in respiratory epithelium can also be assessed directly in vivo by measuring the bioelectric voltage difference across nasal epithelium (the “nasal potential difference”), which is available in a few specialized CF centers.[9] This test can be used for children who have clinical symptoms of CF but who have normal sweat chloride and genetic testing.

IMAGING

- Chest x-ray may be normal early in the course of the disease.

- Persistent obstruction and inflammation leads to bronchiectasis that is visible on routine chest x-ray as the disease process progresses (**Figures 51-3** to **51-5**).

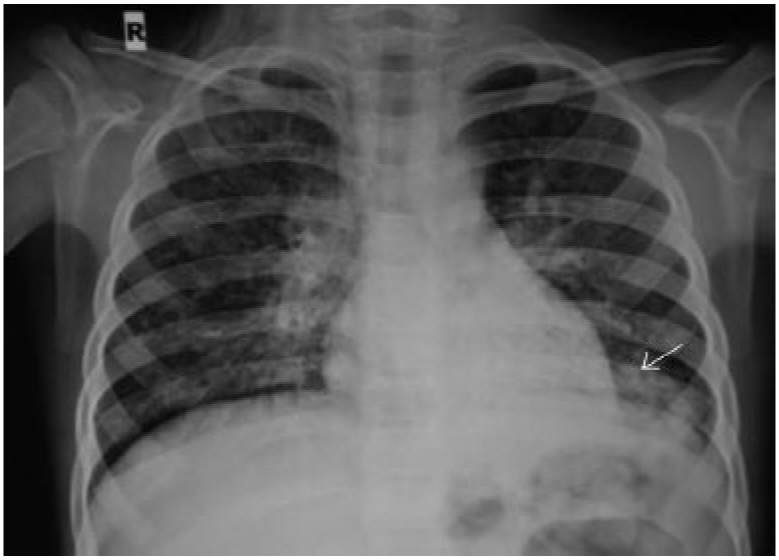

FIGURE 51-3 Marked peribronchial thickening, chronic left lower lobe collapse/consolidation (arrow), bronchiectatic changes, and mucus plugging of bronchioles on chest x-ray in a 6-year-old girl with a homozygous delta F508 mutation of cystic fibrosis. (*Used with permission from Samiya Razvi, MD.*)

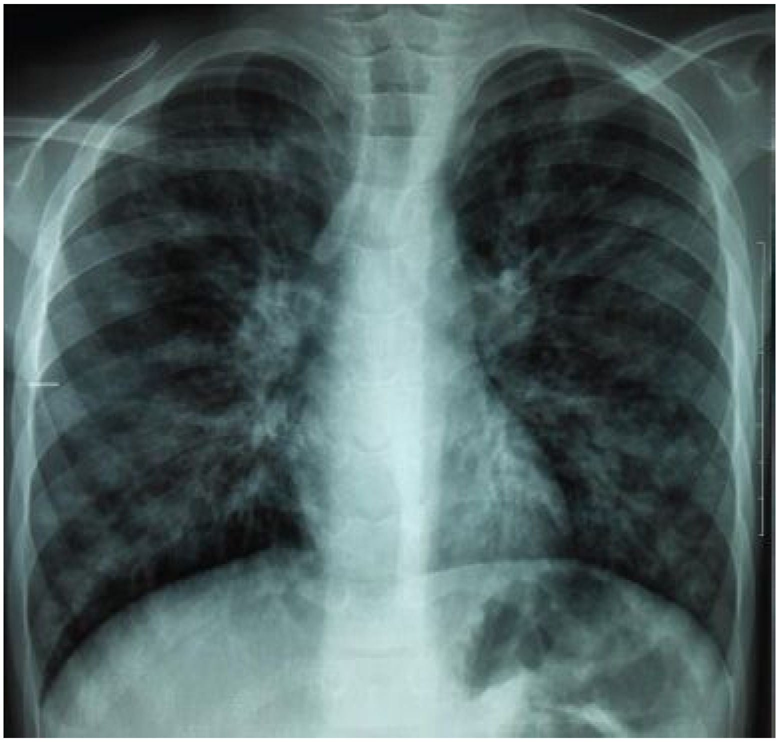

FIGURE 51-4 Bilateral patchy opacities, marked peribronchial thickening extending into the lung peripheries, and hyperinflation indicating airway obstruction and air trapping on chest x-ray in a 10-year-old boy with cystic fibrosis, homozygous delta F508. (*Used with permission from Samiya Razvi, MD.*)

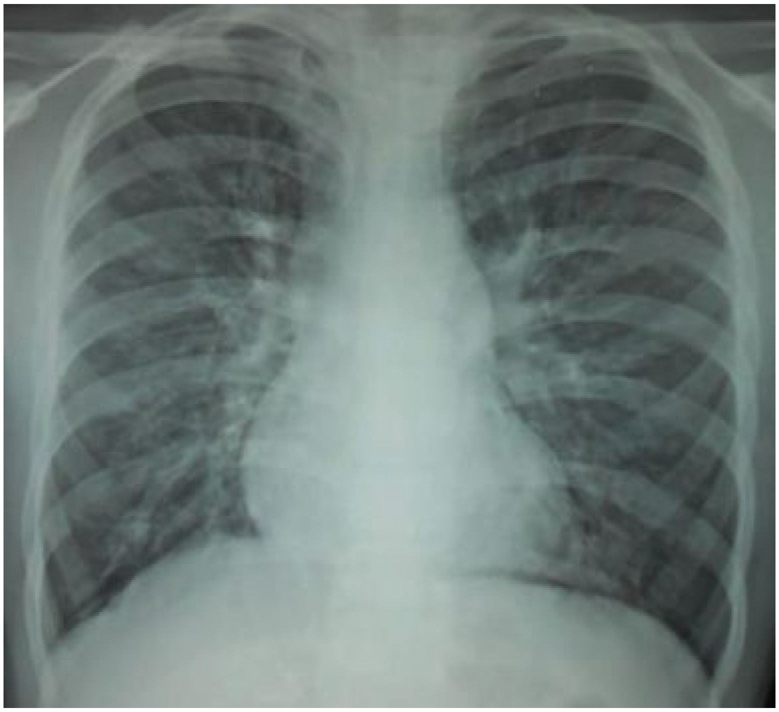

FIGURE 51-5 Increased bronchovascular markings, peribronchial thickening and cystic changes of bronchiectasis on chest x-ray in a 13-year-old boy with cystic fibrosis. (*Used with permission from Samiya Razvi, MD.*)

- Chest-x-ray is important in identifying complications such as pneumothorax and pulmonary hemorrhage (**Figure 51-6**).

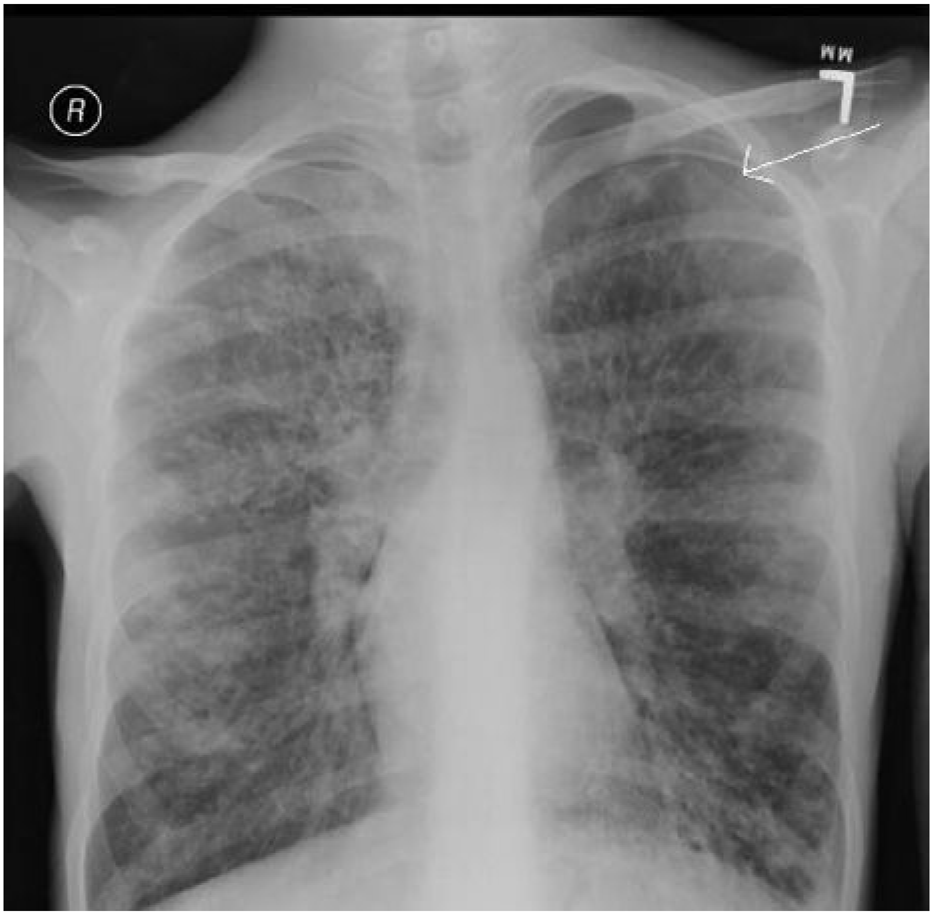

FIGURE 51-6 Increased interstitial markings, peribronchial thickening, bronchiectasis in the left lower lobe and an acute small left apical pneumothorax with visible left lung margin (arrow) on chest x-ray in a 20-year old patient with cystic fibrosis. (*Used with permission from Samiya Razvi, MD.*)

- CT scan can further define the extent of bronchiectasis and other complications of CF (**Figures 51-7** to **51-9**).

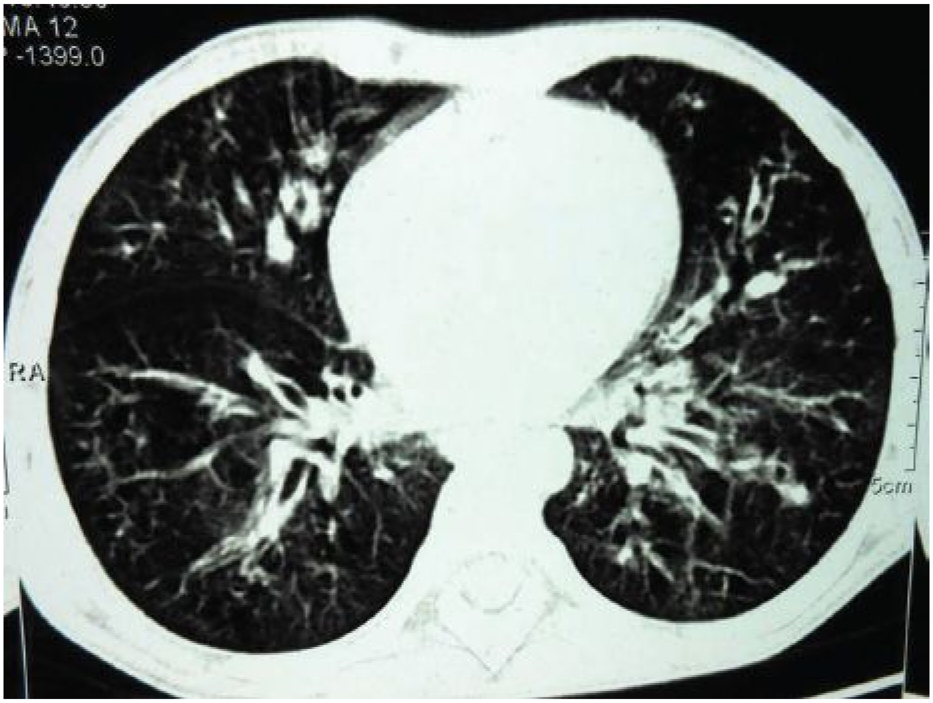

FIGURE 51-7 Peribronchial thickening, increased interstitial markings, and cylindrical bronchiectasis on axial CT scan of the same boy as in **Figure 51-4**. (*Used with permission from Samiya Razvi, MD.*)

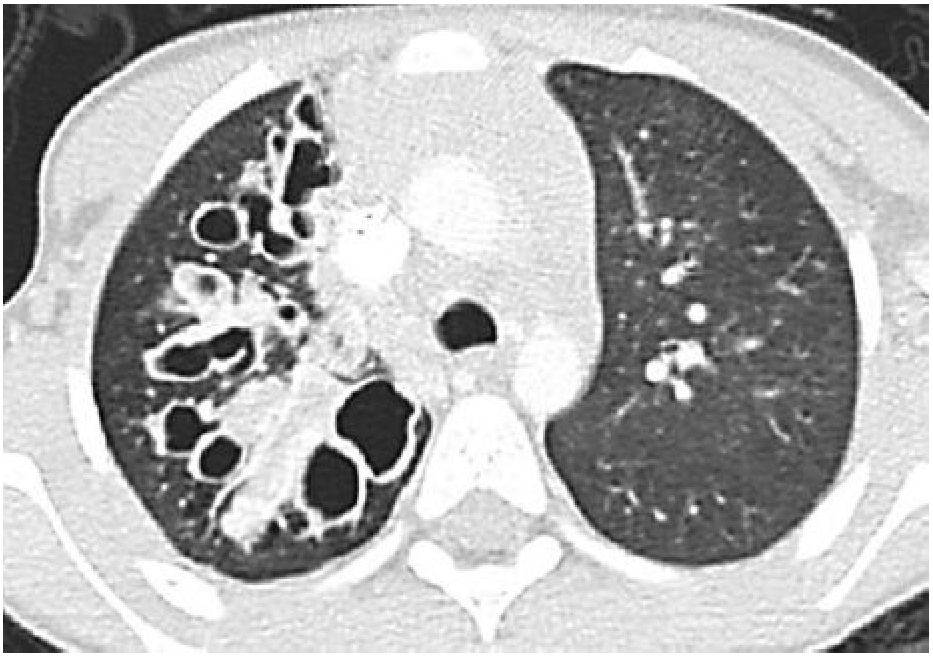

FIGURE 51-8 Saccular bronchiectasis of the right upper lobe with cavitary changes and peribronchial thickening on axial chest CT scan in a 7-year-old

boy with cystic fibrosis. This boy had a history of chronic productive cough, hemoptysis during pulmonary exacerbations, and sputum cultures positive for multidrug resistant *Pseudomonas aeruginosa*. (*Used with permission from Samiya Razvi, MD.*)

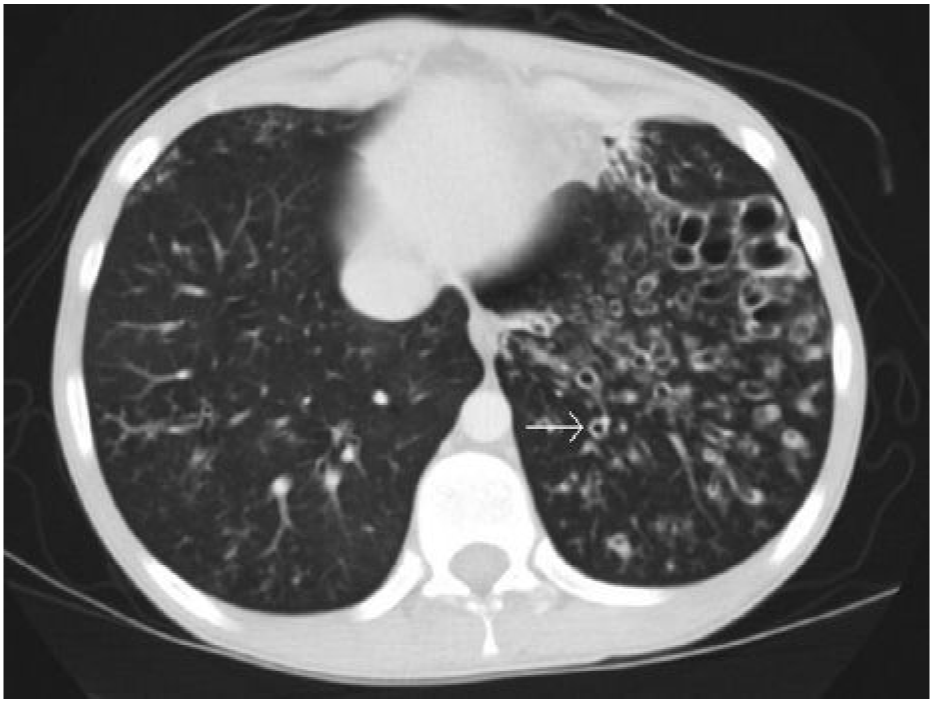

FIGURE 51-9 Saccular bronchiectasis of the left lower lobe, peribronchial thickening and signet ring sign (arrow) demonstrating dilatation and enlarged diameter of bronchiole compared to the accompanying pulmonary blood vessel on axial chest CT scan in a 17-year-old girl with cystic fibrosis. (*Used with permission from Samiya Razvi, MD.*)

- Testicular ultrasonography can be used to determine the presence of the vas deferens.
- Abdominal x-rays and contrast studies can be used to identify bowel obstruction.
- Right upper quadrant ultrasound is useful in diagnosing biliary disease.

DIFFERENTIAL DIAGNOSIS

- CF is easily recognized in any infant or child who has the classic triad of chronic pulmonary disease, steatorrhea, and growth failure.
- Recurrent pneumonia due to other causes, such as aspiration pneumonia due to dysphagia or gastroesophageal reflux, anatomic abnormalities such as bronchogenic cysts, congenital airway malformations, immunodeficiencies, sickle cell disease, asthma, right middle lobe syndrome, and foreign body aspiration should always be considered.[10]
- The lack of other features of CF, such as growth failure and gastrointestinal manifestations, help to differentiate these entities from CF. However, a sweat chloride test should be part of the work up of a child with recurrent pneumonia to definitively exclude CF.

MANAGEMENT

- Management of CF should focus on slowing the course of the disease. This requires educating family members, particularly families of infants identified through the newborn screen. Infants identified at birth may often not have clinical manifestations, but it is imperative to educate families that early intervention can result in better outcomes.
- After diagnosis, all patients should be referred to an accredited CF care center with coordination of care between all health care providers, especially the primary care physician.
- The goal of care is to maintain normal growth and delay the development of pulmonary disease.
- Delaying onset of pulmonary disease:
  - Ensure that the patient is in a smoke-free environment.
  - Airway clearance.
    - These regimens take considerable time with adults reporting spending a mean of 108 min/day on all CF therapies.[11] This makes adherence an issue for many CF patients.
    - For infants <2 years of age, the recommended method of mucociliary clearance is percussion followed by postural drainage.

    - In older children, there are many mechanical devices for airway clearance including: positive expiratory pressure masks, Flutter, Acapella, and high-frequency chest wall oscillation (Vest). No trials have demonstrated the superiority of one device over another; treatment should be individualized to the patient.
    - Children >6 years of age should also receive inhaled daily Dornase Alfa (recombinant Human DNase) and twice daily 7 percent hypertonic saline after bronchodilator pretreatment.[12,13] SOR Ⓐ
    - Azithromycin given three times a week is recommended for children >6 years of age colonized with *P aeruginosa*, based on trials showing increased pulmonary function and increased length of time between infectious exacerbations.[14,15] SOR Ⓐ The precise mechanism of action of azithromycin in this setting in not known, although an anti-inflammatory effect is postulated. The long-term benefit of such treatment is not clear.
  - Pulmonary function tests (PFTs) should be performed to monitor progression of lung disease.
  - Aerobic exercise should also be encouraged.

- Prevention of infection.
  - Patients should receive:
    - Influenza vaccine annually if >6 months of age.
    - Palivizumab for infants <2 years of age to prevent severe respiratory syncytial virus infections.
  - Upon diagnosis in infants <2 years of age, all patients should undergo oropharyngeal cultures every 3 months.
  - A variety of antimicrobial prophylactic antimicrobial agents are used in different CF centers. Treatment is individualized taking into consideration potential benefits and risks.
  - Infants <2 years of age who are colonized with *P aeruginosa* should receive primary treatment aimed at eradicating the pathogen.[11,16] SOR Ⓒ
  - Patients chronically infected with *P aeruginosa* should receive inhaled antibiotic treatment. Although prior recommendations were to receive inhaled tobramycin every other month, recently centers have switched to continuous inhaled tobramycin treatment or alternating inhaled tobramycin with colistin.[12] SOR Ⓒ

  - In clinic and in the hospital, CF patients should not come into contact with each other to prevent spread of colonizing agents among patients.
- Maintaining normal growth.
  - CF children should be maintained at the 50th percentile in weight-for-length by 2 years of age. This is associated with improved pulmonary function in later life. Although breast milk is recommended, infants who are formula-fed have similar weights to breast milk-fed babies. Standard infant formula can be used as there are no benefits from hydrolyzed formula.[17]
  - Infants and children failing to gain adequate weight can be supplemented with fortified human milk, formulas with higher calories, or complementary foods. Enteral supplements may be necessary to improve weight gain.[17]
  - CF patients often have more behavioral issues regarding food. Early intervention with parents consistently praising children for trying new foods or eating independently, ignoring behavior when children refuse to eat, and limiting meal times to 15 minutes while increasing the frequency of snacks can help with this issue.[17]
  - Pancreatic insufficiency (PI) is present in 60 percent of patients with CF at birth even if patients are asymptomatic. The fecal elastase assay, which is low in patients with PI, can be used in infants >2 weeks of age to check for PI. Patients with symptoms of PI or who have diagnosed PI should be started on nongeneric pancreatic enzyme replacement therapy (PERT).[17]
    - If patients have 2 CFTR mutations associated with PI, nongeneric PERT should also be started even if they are asymptomatic.
    - Asymptomatic patients with at least one copy of a pancreatic sufficient genotype should not be started on PERT.
  - All patients should be started on age-appropriate doses of fat soluble vitamins (A, D, E, K). Vitamin levels should be measured every two months the first year and annually afterward.
  - In infants <2 years of age who fail to grow despite adequate intake and PERT, a trial of zinc supplementation can be initiated.[17]
  - Other supplementations for infants under age 2 years include salt (1/8 tsp daily and increased to 1/4 tsp daily at 6 months of age) and fluoride

    0.25 mg/dl if the water supply contains <0.3 ppm fluoride.[17]
  - Patients who develop CF-related diabetes should be managed by an endocrinologist.[12]

- Acute exacerbation of pulmonary disease:
  - Frequent comprehensive clinical evaluation of patients, including microbiological examination of respiratory tract flora by a laboratory that is experienced in detecting pathogens of cystic fibrosis, is critical for the management of patients with CF.
  - Clinical symptoms of acute pulmonary exacerbation include increased cough, increased sputum production, dyspnea, chest pain, hemoptysis, loss of appetite, weight loss, and decline in PFTs.
  - In general, patients who are having a pulmonary exacerbation should be admitted to the hospital for intravenous and inhaled antibiotic administration.
  - Antimicrobial agents are chosen based on the colonizing strains and their susceptibilities.
  - During this acute exacerbation, airway clearance regimens may be intensified. Patients may also require additional support including supplemental oxygen and bronchodilators.

SURGERY

- Lung transplantation has been successful for a limited number of patients with cystic fibrosis and end-stage pulmonary disease. A recent study, however, questioned the benefit of lung transplantation for children with CF.[18]

- Surgery may be indicated for sinus disease and polyposis.

REFERRAL

- All patients diagnosed with CF should be referred to a certified CF center. Care should be coordinated between the CF center, the patient’s PCP, and any other specialties (e.g., endocrine).

PREVENTION AND SCREENING

- Newborn CF screening is increasingly utilized in the US.
- Children with any clinical manifestations of CF such as recurrent pulmonary infections, nasal polyposis, failure to thrive, or pancreatic dysfunction should be tested for CF using the sweat chloride test.

PROGNOSIS

- Currently, the life expectancy for CF is 30 to 40 years, a dramatic improvement from a life expectancy of 25 years in 1985.[1,2]
- Most children with CF can participate in normal childhood activities with 90 percent of CF patients completing high school.[1]

FOLLOW-UP

- A comprehensive clinical evaluation including PFT testing and microbiologic cultures of respiratory flora should be carried out on a regular basis at a CF center.
- Patients should continue to follow-up with their primary care physicians. All routine vaccinations should be given at age appropriate times.

PATIENT EDUCATION

- CF requires a coordinated effort from the family to manage the time-consuming airway clearance therapies. Families should be provided with education on the importance of adhering to these regimens.

- As children transition to adolescents and adults, they must also learn to take charge of their own therapies. This often requires additional training and support from the provider.

52 CONGENITAL PULMONARY MALFORMATIONS

Samiya Razvi, DCH, MD
Ellen Park, MD

Congenital pulmonary malformations are relatively rare entities that can cause a wide variety of pulmonary findings in infants and children. In this chapter, we review the clinical and radiographic features of the most important malformations, including:

1. Congenital absence of the pulmonary vein
2. Tracheal bronchus
3. Bronchial cyst
4. Congenital lobar emphysema
5. Congenital cystic adenomatoid malformation
6. Pulmonary sequestration
7. Pulmonary agenesis

CONGENITAL ABSENCE OF THE PULMONARY VEIN

PATIENT STORY

A 5 year-old-girl is hospitalized for respiratory distress and hypoxemia. This is her third episode of right-sided pneumonia. She is thinly built; both height and weight are at the 25th percentile for age. Chest auscultation reveals fine alveolar crackles over the entire right lung without wheeze; the left lung is clear. Heart sounds are normal without a murmur. Her chest x-ray shows haziness of the entire right lung, with patchy opacity in the right lower zone; the left lung is normal. She is treated with parenteral antibiotics and improves. Blood and sputum cultures are negative. She is evaluated further for recurrent pneumonia. Serum immunoglobulin profile is normal. Sweat chloride is within normal limits. Chest CT scan with contrast shows Swiss cheese appearance of the entire right lung with cystic lucencies and septal thickening; the left lung is normal (**Figure 52-1**). Further cardiac evaluation with Echocardiography shows no intra-cardiac defect. Cardiac catheterization and pulmonary angiography reveal normal pulmonary artery anatomy, with isolated absence of the right main pulmonary vein. She is followed closely and her subsequent respiratory illnesses are treated early with antibiotics and bronchodilators. She remains asymptomatic with exercise tolerance and growth appropriate for age.

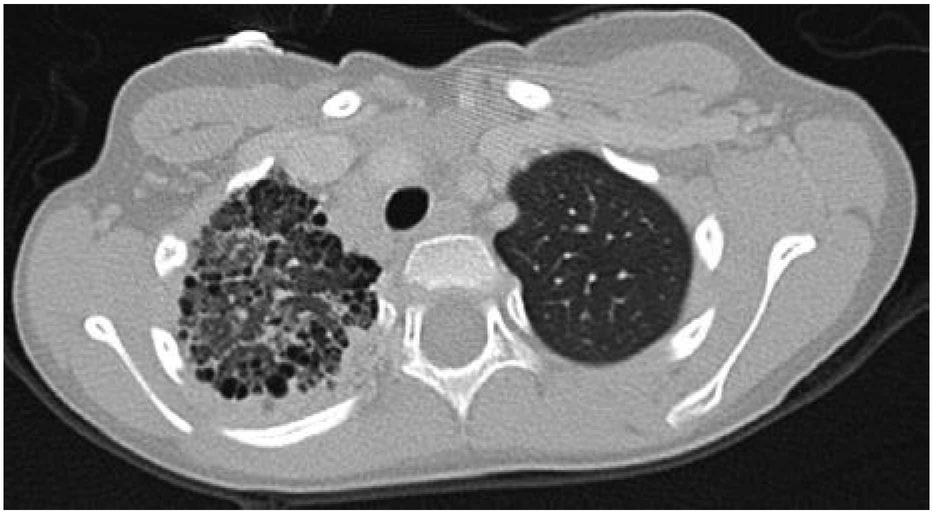

FIGURE 52-1 Congenital absence of the right pulmonary vein: Axial cut of chest CT scan with contrast showing classical findings of ground glass changes, interlobular and interstitial septal thickening of the right lung as compared to the normal left lung. (*Used with permission from Samiya Razvi, DCH, MD and Ellen Park, MD.*)

INTRODUCTION

Unilateral absence of the pulmonary vein is a rare congenital abnormality thought to be due to atresia of the pulmonary vein during development in the prenatal period. This results in abnormal venous drainage of the affected lung and significant ventilation perfusion mismatch.

SYNONYM

Congenital unilateral pulmonary vein agenesis.

EPIDEMIOLOGY

- Congenital absence of the pulmonary vein is a rare congenital anomaly, found in about 0.5 percent of autopsies performed in children.
- May occur as an isolated lesion or associated with other congenital cardiac defects in about 30 to 50 percent of cases.
- Mortality rate approaches 50 percent if untreated.

ETIOLOGY AND PATHOPHYSIOLOGY

- Rare developmental abnormality, in which there is absence of the right or left pulmonary vein or both.
- Thought to result from failure of incorporation of the pulmonary vein into the left atrium.
- There is a spectrum of disease: lesser degrees of venous atresia result in pulmonary vein stenosis with narrowing, venous obstruction and anatomic variations in the pulmonary vessels that drain the affected lung to complete absence of the affected pulmonary vein.

- Pulmonary venous obstruction from the intrauterine period affects normal development and architecture of the lung, leading to engorgement of bronchial veins, chronic pulmonary edema, lymphatic dilatation, inter-alveolar septal thickening, patchy interstitial fibrosis, cystic changes, and development of collateral vessels.
- Inadequate gas exchange occurs at the alveolar level of the entire affected lung, resulting in large dead space ineffective ventilation and significant ventilation perfusion mismatch.

DIAGNOSIS

The diagnosis is often elusive and difficult to make; it requires a high index of suspicion when a patient presents with the clinical history of recurrent pneumonia together with asymmetry of lung aeration with reticular interstitial infiltrates on imaging. This should prompt further investigation with CT scan and pulmonary angiography.

CLINICAL FEATURES

- Presentation is often in infancy or early childhood (usually less than 5 years age).
- Typical symptoms include recurrent unilateral respiratory infections/pneumonia and exercise intolerance with dyspnea on exertion.[1]
- Occasionally, hemoptysis may be a presenting symptom.
- As the pulmonary circulation is suboptimal, infections can spread rapidly within the lung parenchyma with suppuration; repeated infections lead to bronchiectasis and chronic lung disease.
- Rarely, mildly symptomatic cases without associated cardiac defects or pulmonary hypertension can remain undetected and present later in adulthood.[2]
- Mortality approaches 50 percent if untreated.

- Complete atresia of the common pulmonary vein has been reported in the neonatal period presenting with severe respiratory distress, refractory hypoxemia, acidosis, pulmonary hypertension, and death, with diagnosis made at autopsy.

IMAGING

Chest x-ray—Shows haziness of the entire affected lung with reticular opacities and septal prominence. The affected lung is reduced in volume with ipsilateral mediastinal shift at baseline. Opacification of the affected lung or lobar involvement with consolidation or suppuration may occur when symptomatic with lower respiratory infection.

Chest CT scan

- Shows asymmetry with small hemithorax due to reduced lung volume, and ground-glass haziness with interlobular septal thickening throughout the affected lung (**Figure 52-1**).
- Interstitial fibrosis can occur secondary to pulmonary venous infarction and chronic pulmonary edema.
- There may be an ipsilateral small pulmonary artery with aberrant systemic arterial supply to the affected lung.
- The bronchial anatomy and patency are normal.[3]
- Of note, multidetector CT noninvasively demonstrates the anatomy and may obviate the need for invasive angiography.[4]

Magnetic resonance imaging—Confirms hypoplasia of affected lung, with diffuse interstitial thickening, pulmonary edema, and engorgement of pulmonary lymphatics.

Ventilation perfusion scan—Shows marked reduction in ventilation and perfusion to the affected side without air trapping.

Bronchoscopy—Shows normal tracheal and bronchial anatomy.

Cardiac catheterization—Pulmonary angiography is used for definitive diagnosis with characteristic findings: markedly increased pulmonary capillary wedge pressures, small ipsilateral pulmonary artery, and absence of the pulmonary vein on venous phase imaging.[5]

HISTOPATHOLOGY

The pulmonary parenchyma shows patchy interstitial fibrosis, pulmonary arteries show medical muscular hypertrophy. The pulmonary veins show medial muscular hypertrophy with intimal fibrosis and luminal narrowing without inflammatory change.

DIFFERENTIAL DIAGNOSIS

- Pulmonary lymphangiectasia—Usually distinguished by the radiographic appearance of the lymphatic malformation.

MANAGEMENT

NONPHARMACOLOGIC

- Attention to nutritional intake for optimal somatic and lung growth and development and recovery from infection.
- Chest physiotherapy for airway clearance with respiratory illnesses.
- Inhaled bronchodilators if there is associated bronchospasm or wheeze.
- Immunization—In addition to routine childhood immunizations, annual influenza vaccine after age 6 months, 23-valent pneumococcal vaccine for children aged >2 years every 5 years.

MEDICATIONS

- Early appropriate antibiotic therapy for lower respiratory infections; antibiotics tailored to known bacterial pathogens according to age.
- Aggressive approach in treating respiratory infections is essential to avoid suppurative complications; parenteral antibiotics when dictated by clinical presentation and radiological findings on chest x-ray.

SURGERY

- Anastomosis of the atretic pulmonary vein to the left atrium is a theoretical consideration but may not be possible due to complex and abnormal vascular anatomy.
- Pneumonectomy is recommended if there are recurrent or chronic suppurative complications or if the affected lung becomes a nidus of infection.[6] Pneumonectomy effectively eliminates the dead space and left to right shunt that may have developed.

REFERRAL

- Pediatric Cardiology—For (1) echocardiography to screen for associated congenital heart defects and (2) Cardiac catheterization and pulmonary angiography, measurement of pulmonary capillary wedge pressures for definitive diagnosis.
- Pediatric Pulmonology—To effectively manage recurrent respiratory infections, chest physiotherapy for airway clearance and to monitor pulmonary function longitudinally.

PREVENTION AND SCREENING

Maintain high index of suspicion and screen children with history of recurrent unilateral pneumonia with or without hemoptysis in early infancy or childhood with chest CT with contrast.

PROGNOSIS

- Prognosis following pneumonectomy is excellent with good functionality.
- Post-pneumonectomy, there is potential for scoliosis to develop in the growing child. Plombage (in which the empty hemithorax is filled with an inert material, e.g., sterile Lucite balls) is an option to maintain thoracic volume and prevent/minimize scoliosis.
- Mortality approaches 50 percent if left untreated.

FOLLOW-UP

- Optimize nutrition for lung growth and development.
- Annual cardiac screening with ECHO to monitor for pulmonary hypertension and right heart strain secondary to repeated lung infections.

TRACHEAL BRONCHUS

PATIENT STORY

A 17-year-old boy with Type 1 neurofibromatosis, seizure disorder, developmental delay, and dysphagia presents in winter with high-grade fever, cough, and respiratory distress. On examination he appears toxic and is tachycardic and tachypneic with intercostal and subcostal retractions. He requires oxygen via facemask at 5 liters/minute to maintain pulse oximetry saturations above 92 percent. Chest auscultation reveals scattered crackles and expiratory rhonchi over both lung fields. Rapid viral screen for influenza (H1N1) virus is positive. Chest x-ray shows right upper lobe consolidation and bibasilar patchy infiltrates. Laboratory investigations show an elevated white count and blood culture is negative. He is treated with broad spectrum parenteral antibiotics, oral oseltamivir, inhaled bronchodilators, and aggressive chest physiotherapy for airway clearance. He improves with weaning in his oxygen requirement to room air. Serial chest x-rays show right upper lobe collapse, which persists despite clinical improvement, even a month after discharge home. Further imaging with chest CT with contrast is done, which shows a tracheal bronchus supplying the right upper lobe, with a mucus plug obstructing the aberrant tracheal bronchus lumen (**Figure 52-2**). As he is asymptomatic and clinically stable, he is continued on chest physiotherapy with manual clapping and inhaled bronchodilators. A follow-up chest x-ray 2 months later shows resolution of the right upper lobe atelectasis with well aerated lung fields bilaterally.

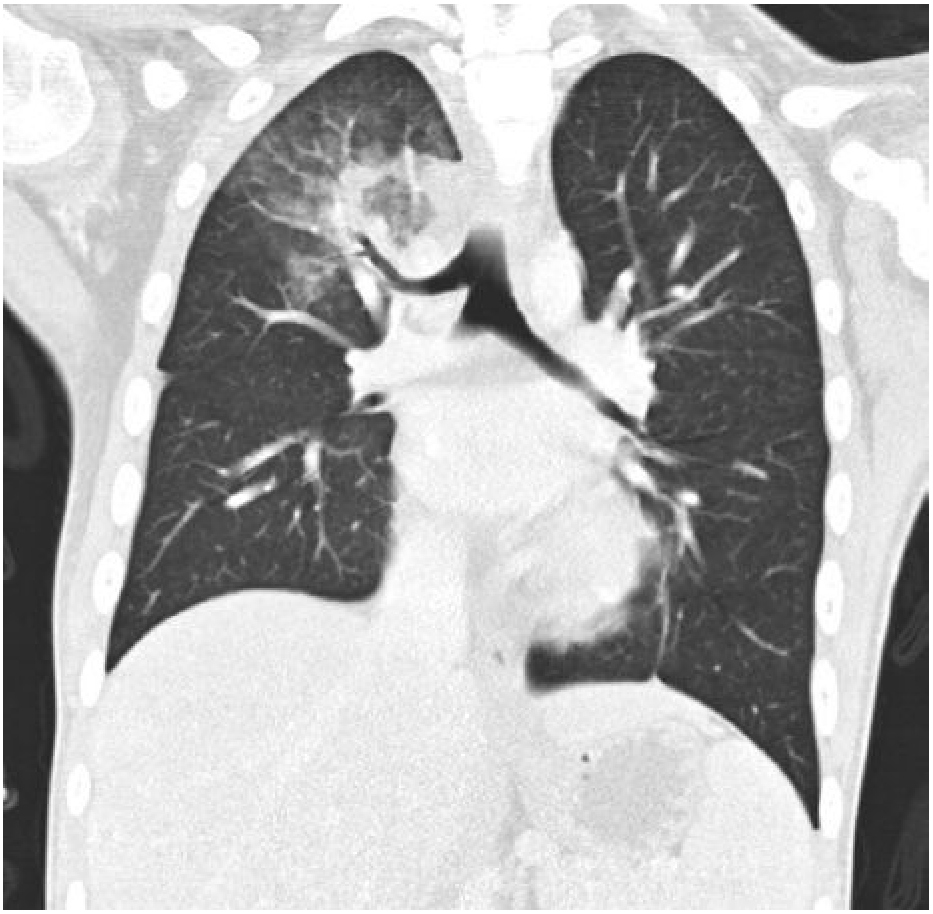

FIGURE 52-2 Aberrant right tracheal bronchus arising from the trachea proximal to its bifurcation, and supplying the right upper lobe, on coronal view chest CT scan. The carina, both right and left mainstem bronchi and their bronchial divisions are normal. (*Used with permission from S. Pinar Karakas, MD.*)

INTRODUCTION

Tracheal bronchus describes a variety of bronchial anomalies, which arise from the main trachea proximal to the carina. An aberrant tracheal bronchus to the right upper lobe of the lung arises directly from the trachea itself proximal to the carina, unlike its typical origin after tracheal bifurcation, from the right main bronchus.

SYNONYMS

Bronchus suis, Pig bronchus.

EPIDEMIOLOGY

- An aberrant tracheal bronchus is often detected incidentally on CT imaging of the chest or bronchoscopy, and occurs in about 2 percent of the population.
- The right tracheal bronchus may be displaced in its origin to arise from the mainstem of the trachea proximal to the carina (a “pig bronchus” with all three segmental branches from it with no connection of the right upper lobe to the right main bronchus) or it may consist of only the right upper lobe apical bronchus with anterior and posterior segmental upper lobe branches arising from the right main bronchus.
- A prevalence of 0.1 to 2 percent for right tracheal bronchus and 0.3 to 1 percent for left tracheal bronchus have been reported in bronchoscopic and imaging studies.[7]
- Very rarely, bilateral tracheal bronchi may occur directed to both upper lobes of the lung.
- Tracheal bronchus has been found in association with other congenital anomalies including trachea-esophageal fistula, tracheal stenosis, VATER syndrome (vertebral anomalies, anal atresia, trachea-esophageal fistula, esophageal atresia, renal defects), and Trisomy 21.

ETIOLOGY AND PATHOPHYSIOLOGY

- Embryogenic hypotheses for this congenital bronchial abnormality are the reduction, selection and theories of bronchial bud development (that the final anatomy is the result of shrinkage, suppression of portions of the original distribution and movement/migration from the initial location to arise from new origins) resulting in local disturbances in morphogenesis.[7]

- Altered drainage of the affected right upper lobe can result in localized pulmonary problems: partly due to the more horizontal direction of the tracheal bronchus, which impairs airway clearance as compared to the more vertical and gravitationally assisted normal configuration of the right upper lobe bronchus.
- This may result in localized or persistent atelectasis of the right upper lobe and recurrent infections with potential for suppurative changes and development of bronchiectasis.
- Both the pulmonary and bronchial vascular supply to the affected lobe of the lung are normal.

DIAGNOSIS

Tracheal bronchus is now diagnosed with increased frequency as a result of advances in and availability of chest CT imaging. Bronchoscopic examination of the airways is definitive, clearly demonstrating the tracheal origin of the aberrant bronchus.

CLINICAL FEATURES

- Often asymptomatic; may be detected incidentally on imaging or bronchoscopic examination.
- May cause recurrent infection, atelectasis, or consolidation of the right upper lobe due to mucus plugging and/or retained airway secretions.[8]
- Persistent cough may be a symptom. Occasionally hemoptysis may occur.
- Bronchiectatic changes may occur with repeated infections.
- If unrecognized, it may be the cause of persistent right upper lobe atelectasis/collapse in intubated patients due to occlusion of the orifice of

the aberrant tracheal bronchus by the endotracheal tube.[9] Occasionally, inadvertent intubation of the aberrant bronchus may occur resulting in impaired ventilation.

IMAGING

- Chest x-ray—Right upper lobe atelectasis/collapse with lobar opacification that may be recurrent or persistent in nature.
- Chest CT scan—Shows the origin of the aberrant tracheal bronchus proximal to the carina; the rest of the bronchial anatomy is normal with normal lung parenchyma.[10] CT virtual bronchoscopy is a non-invasive alternative for diagnosis.
- Bronchoscopy—Definitive diagnosis rests on bronchoscopic examination of the airway, and visualization of the origin of the aberrant bronchus from the tracheal lumen proximal to the carina.[11]

DIFFERENTIAL DIAGNOSIS

- Supernumerary tracheal bronchus—This occurs in addition to the normally originating right upper lobe bronchus arising from the right main bronchus.
- Accessory bronchus—Will be seen on radiographic imaging.

MANAGEMENT

- Although asymptomatic and often incidentally detected, if present it can impact the care of children undergoing anesthesia and intubation and post-operative recovery. This airway anomaly must be kept in mind when chronic right upper lobe atelectasis/collapse is noted.[9]

- Management is based on the severity and frequency of associated symptoms.
- Surgical resection of the anomalous bronchus and lobe is indicated if recurrent suppurative infections occur.
- In asymptomatic or infrequently symptomatic patients, conservative and expectant management with antibiotics, chest physiotherapy and airway clearance are preferred.

NONPHARMACOLOGIC

- Care must be taken when intubation is being performed especially in children with conditions known to be associated with tracheal bronchus, including Down syndrome, foregut malformations, and tracheal stenosis.
- Chest physiotherapy regimen for airway clearance.

MEDICATIONS

- Inhaled bronchodilators may be used to aid mucociliary clearance and augment chest physiotherapy maneuvers.

SURGERY

- Right upper lobectomy is indicated if there is recurrent suppurative lung disease secondary to bronchial obstruction and impaired drainage of secretion.

REFERRAL

Physiotherapist—To teach parent/caregiver chest physiotherapy for airway clearance, instruct patient in use of airway clearance devices using positive end-expiratory pressure, that is, Acapella or Flutter device.

PREVENTION AND SCREENING

Tracheal bronchus should be screened for in children presenting with recurrent right upper lobe pneumonia or collapse, particularly if there are other associated congenital malformations of the heart, vertebrae, and gastrointestinal tract.

PROGNOSIS

Risk of recurrent respiratory infections due to obstruction of tracheal bronchus. Prognosis is good following surgical intervention with lobectomy.

PROVIDER RESOURCES

- Congenital malformations of the Trachea—**www.emedicine.medscape.com/article/837827**.

BRONCHOGENIC CYST

PATIENT STORY

A healthy, athletic 16-year-old-girl presented with acute right lower abdominal pain and vomiting for one day. She was evaluated with an abdominal CT scan with contrast which ruled out acute appendicitis. Incidentally, the lower thoracic cuts of the CT scan showed a low density mass inferior to the left mainstem bronchus (**Figure 52-3**). There were no lung parenchymal abnormalities, no adenopathy or effusion noted. She reported no symptoms, her lungs were clear on auscultation and spirometry revealed normal lung function and capacities. A chest MRI was done which showed a 40 × 30 × 37 mm mass with increased signal intensity located between the left inferior pulmonary vein and the descending thoracic aorta without contrast enhancement following administration of gadolinium (**Figure 52-4**). This cystic infrahilar mass appeared most compatible with a bronchogenic cyst. Elective surgical resection of the cyst was done successfully via thoracotomy; histopathology showed ciliated respiratory epithelium with goblet cells without metaplasia. She recovered uneventfully, was asymptomatic and returned to sport with normal exercise tolerance.

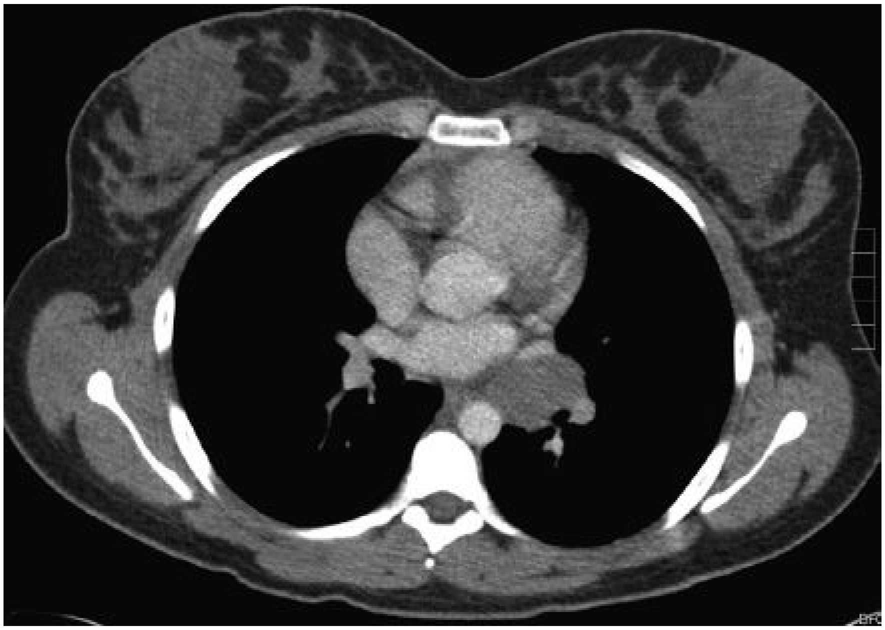

FIGURE 52-3 Cystic homogenous infratracheal lesion on chest CT without contrast, axial cut. (*Used with permission from Samiya Razvi, DCH, MD and Ellen Park, MD.*)

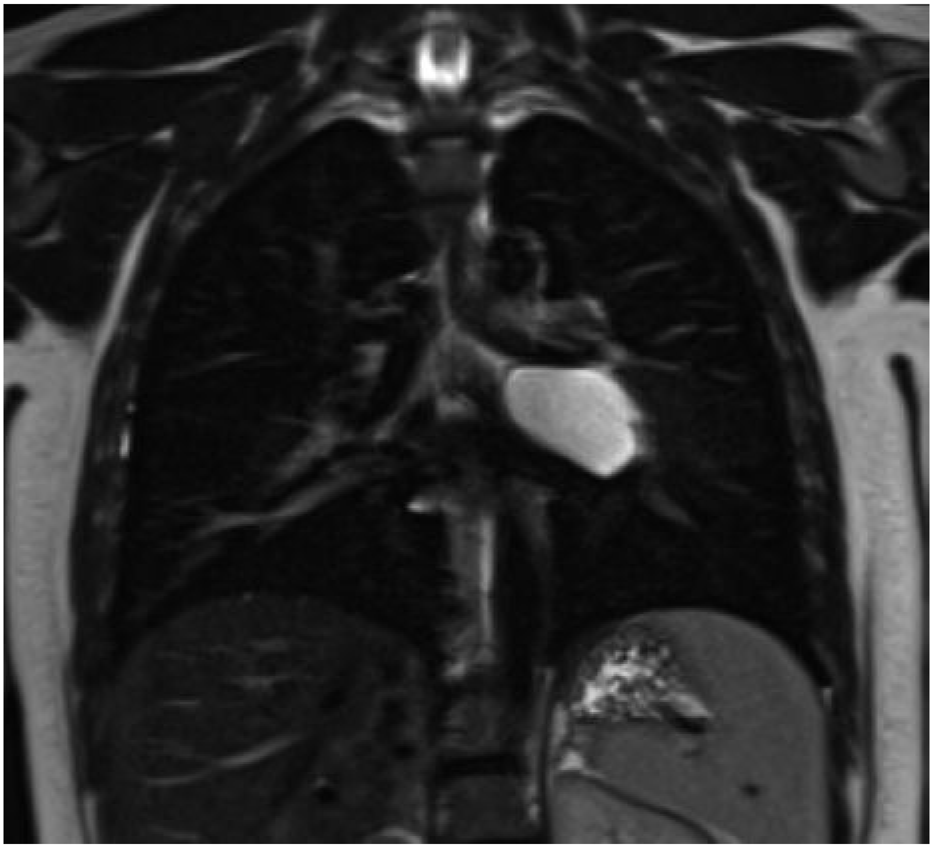

FIGURE 52-4 MRI chest with gadolinium demonstrating uniform fluid density cystic lesion inferior to left mainstem bronchus. (*Used with permission from Samiya Razvi, DCH, MD and Ellen Park, MD.*)

INTRODUCTION

- Bronchogenic cysts result from abnormal branching or budding of the ventral diverticulum of the foregut during embryologic development of the tracheobronchial tree.[12]
- Most often unilocular and lined with pseudo-stratified columnar respiratory epithelium, with a fibrovascular connective tissue wall of hyaline cartilage, smooth muscle and mucus glands.
- Do not usually communicate with the bronchial tree and therefore not typically air filled. They contain fluid (water), with variable amounts of proteinaceous material.

SYNONYMS

- Foregut duplication cyst.

EPIDEMIOLOGY

- Bronchogenic cysts comprise approximately 6 percent to 15 percent of primary mediastinal masses. Most often detected incidentally upon routine chest radiography.
- Tend to be detected more commonly in the right chest and more often in males.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Bronchogenic cysts are characteristically oval or round in shape and occur in various locations depending on the stage of embryogenesis in which their formation occurs.
- Most commonly located in the mediastinum (paratracheal, pericarinal), intrapulmonary, and extrathoracic (para-esophageal and even subdiaphragmatic).
- Often asymptomatic, but have the potential to enlarge and compress adjacent structures in the mediastinum.
- Infection and rupture of the cyst can result in mediastinitis.

DIAGNOSIS

Usually suspected from its appearance on chest radiograph as a well marginated opacity of fluid attenuation. Definitive diagnosis can only be made by surgical excision and histopathological confirmation of the cyst lining as pseudo-stratified ciliated epithelium and wall containing cartilage, smooth muscle, or mucus glands.

CLINICAL FEATURES

- Usually benign congenital masses, which are asymptomatic; most commonly mediastinal in location.
- Clinical presentation varies from asymptomatic with incidental detection on imaging, to symptomatic large masses causing compression of adjacent structures.[13]
- Complete bronchial obstruction due to compression can lead to atelectasis of the lung; or air trapping if partial bronchial obstruction.
- Potential for infection of the cyst, resulting in fever, cough, dyspnea, and chest pain. Occasionally life-threatening hemoptysis or mediastinitis may occur.[13] Repeated cyst infection and inflammation can result in pericystic adhesions, ulceration of the cyst wall, and fistulous connection with the bronchial tree.
- Rarely, metaplasia may occur in the cyst lining, with malignant degeneration, and potential for development of bronchioalveolar carcinoma.

DISTRIBUTION

- Bronchogenic cysts can be broadly classified as mediastinal and intrapulmonary.
- Most common location is middle mediastinum (2/3)—Typically these cysts do not communicate with the tracheobronchial tree, and can be hilar, paratracheal, or subcarinal in location.
- Intrapulmonary or parenchymal (1/3)—Typically perihilar with a predilection for the lower lobes of the lung, and cyst lumen may

communicate with the tracheobronchial tree.

IMAGING

- Prenatal diagnosis—With ultrasound imaging confirmed by fetal MRI at birth and then by Chest CT scan at age 1 month.
- Chest x-ray—Plain films reveal homogenous mass lesions, occasionally an air fluid level or peripheral calcification in the wall are noted.
- Chest CT scan with contrast—Selected thin slices delineate the cyst in relation to adjacent structures which aids preoperative planning. On CT imaging, the cyst is usually round or oval in shape with well circumscribed smooth or lobulated margins. The cyst typically has homogenous fluid density/consistency and hypoattenuation without contrast enhancement.[14]
- Magnetic resonance imaging with gadolinium—Differentiates these cysts from solid mediastinal masses. Simple bronchogenic cysts are fluid filled and characterized by very low intensity signals on T1 weighted images, in combination with markedly high signal intensity on T2 weighted images depending on the proteinaceous content.[14] There is usually no enhancement with contrast.

DIFFERENTIAL DIAGNOSIS[15]

- Esophageal duplication cyst, pericardial cyst.
- Thymic mass or cyst.
- Neurenteric cyst.
- Cystic teratoma.
- Cystic hygroma, lymphangioma.
- Infected bulla of lung, lung abscess, or fungal ball.

- Enlarged lymph node.
- These can be differentiated by the radiographic appearance, but ultimately definite diagnosis is made by histopathologic confirmation.

MANAGEMENT

Although the clinical course is uncertain, surgical excision is recommended even in asymptomatic patients to prevent complications including compression, infection, hemorrhage and malignant degeneration. The optimal timing for surgical resection is debated, as cysts tend to grow with age (likely due to mucus secretion), increasing the need for open thoracotomy as compared minimally invasive procedures (video assisted thoracoscopic surgery).[16]

With prenatal detection on ultrasonography, early thoracoscopic resection between the ages of 6 to 12 months is reported to better conserve lung parenchyma with lower risk of inflammatory/infectious complications.

SURGERY

- Complete surgical excision is recommended for mediastinal bronchogenic cysts and if required, lobectomy for intrapulmonary bronchogenic cysts.
- If excision is incomplete due to adhesion to surrounding tissues, partial excision with de-epithelization must be done in order to prevent recurrence at a later date.
- Surgical approach varies from open thoracotomy to video assisted thoracic surgery (VATS) with favorable outcomes for both with regard to duration of surgery and overall complications.[17]

REFERRAL

Pediatric cardiothoracic surgery.

PROGNOSIS

- If left untreated, the risk of morbidity (infections, inflammation, rupture, compression of adjacent structures) is estimated to be about 20 percent, and untreated cysts would need to be followed with periodic CT imaging, resulting in cumulative radiation dose exposure.
- Surgical excision is well tolerated; extended surgical dissection is required in complicated cysts, which have been infected resulting in adhesions to surrounding tissues.

CONGENITAL LOBAR EMPHYSEMA

PATIENT STORY

A 10 month-old-male infant presents with history of recurrent wheezing episodes with intercurrent viral infections. Each episode begins with upper respiratory symptoms, cough, low grade fever, and rapidly escalates to severe respiratory distress and hypoxemia necessitating hospitalization. Review of his serial chest x-rays show persistent localized hyperlucency of the right upper lobe of the lung (**Figure 52-5**). Chest CT scan is done and reveals isolated hyperinflation of the right upper lobe with emphysematous appearance, reduced vascularity, and herniation across the mediastinum with contralateral mediastinal shift (**Figure 52-6**). There is ipsilateral compression and atelectasis of the right lower lobe of the lung. The tracheobronchial anatomy is normal. Surgical consultation is obtained and an elective right upper lobectomy is performed. Histopathological examination of the resected lobe of the lung shows overinflation of alveoli with emphysematous changes, and destruction and paucity of interalveolar septae (**Figure 52-7**). He recovers well postoperatively without complication. Over the next several months, he continues to have mild residual airway hyperreactivity and wheezing with respiratory illnesses; however this responds satisfactorily to inhaled bronchodilator treatments and does not progress to severe respiratory distress and decompensation as before. He continues to do well at follow-up with good growth and development with well aerated lung fields on follow-up chest x-ray.

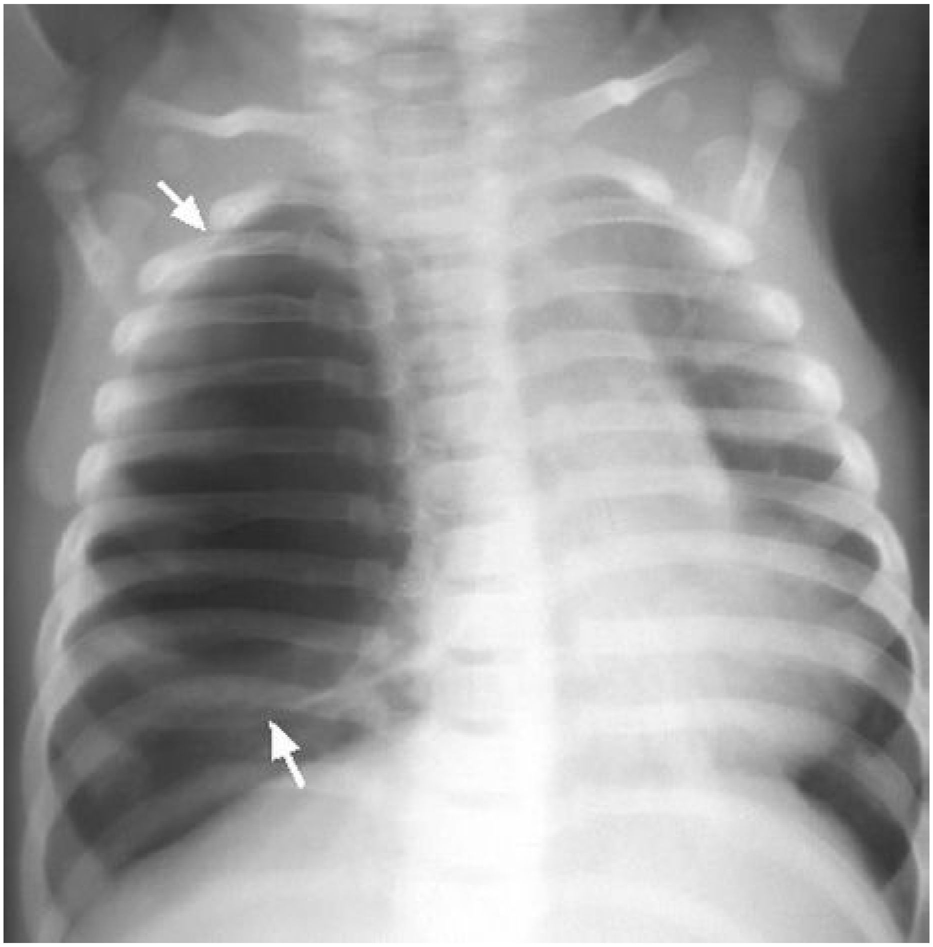

FIGURE 52-5 Plain chest x-ray demonstrating asymmetry in lung aeration (arrows), emphysematous right upper lobe, with herniation across the midline and compression of right lower lobe. (*Used with permission from Nitin Mehta, MD.*)

INTRODUCTION

Congenital lobar emphysema is a rare congenital abnormality caused by localized hyperinflation of a histologically normal single lobe of the lung with herniation of the emphysematous lobe and mediastinal shift to the contralateral side and compressive atelectasis of the ipsilateral adjacent lung lobes.[18] There may be varying degrees of respiratory distress, and occasionally this condition may be mistaken for pneumothorax. This entity was first reported in 1932.

SYNONYMS

Infantile lobar emphysema.

EPIDEMIOLOGY

- Typically, symptoms occur in infancy, with tachypnea, retractions, wheeze, and respiratory distress with in infants less than 6 months age.
- Approximately twice as common in males as compared to females.[18]
- Fourteen to forty percent of cases are noted to be associated with congenital anomalies, most often congenital heart disease.
- Rarely, this may be discovered as an incidental finding in an asymptomatic older child or adult.

ETIOLOGY AND PATHOPHYSIOLOGY

- Pathogenetic factors implicated as causes for congenital lobar emphysema include developmental anomalies of the bronchus supplying the affected lobe.
- Cartilaginous dysplasia, bronchomalacia, or deficiency of the bronchial cartilaginous rings cause the bronchus to collapse during expiration resulting in ball valve effect and air trapping causing emphysematous changes of the affected lobe.[19]
- In some cases, there is intraluminal bronchial obstruction due to bronchial mucosal proliferation or extrinsic bronchial compression from aberrant vessels.

DIAGNOSIS

Congenital lobar emphysema is diagnosed based on clinical and radiologic findings with histological confirmation in patients who have undergone surgical removal of the affected lung lobe.

CLINICAL FEATURES

- Typically presentation occurs in the newborn period or infancy.
- Neonatal presentation can occur with respiratory distress, which may be severe; about half the cases are reported to be symptomatic in the first few weeks of life.
- Intercurrent respiratory illnesses precipitate onset of respiratory failure/distress in infancy.
- On auscultation, breath sounds are decreased over the affected lobe.
- Respiratory symptoms range from asymptomatic tachypnea, recurrent episodes of wheezing to severe respiratory decompensation and respiratory failure.
- Emphysematous changes in the affected lobe result in tachypnea at baseline due to increase in dead space ventilation, progressive distension

and hyperinflation of the affected lobe with respiratory distress.

- Rarely, may remain asymptomatic until detected in adulthood.[20]

DISTRIBUTION

- The left upper lobe is more often affected than the right upper lobe; next in frequency is the right middle lobe and involvement of the lower lobes is rare.

LABORATORY TESTING

- Arterial blood gas analysis shows hypoxemia when symptomatic and hypercarbia due to increased dead space ventilation.

IMAGING

- Improved resolution in prenatal ultrasound techniques can detect unilateral hypoechoic lesion in the lung.[21]
- Chest x-ray—Hyperlucency of the affected lobe with herniation across the midline to opposite side, mediastinal shift, and compressive atelectasis of adjacent ipsilateral lung lobes. There may be a widening of the rib spaces as well as flattening of the hemi-diaphragm on the affected side.
- Chest CT scan—Provides definitive diagnosis, by delineating normal bronchial anatomy with stretched attenuated vessels in the affected emphysematous lobe and herniation across the mediastinum to the opposite side.[22]
- Bronchoscopy—Can rule out bronchial luminal obstruction, bronchial structural anomalies, bronchial stenosis, or an obstructing mucus plug.
- Ventilation perfusion scan with technetium 99m—Shows reduced ventilation and perfusion in the affected lobe. This technique also

establishes whether the lobe affected by CLE is nonfunctional, and whether the compressed lung is functioning normally.

HISTOPATHOLOGY

Shows emphysematous change, overinflation of alveoli with destruction, and paucity of interalveolar septae (**Figure 52-7**).

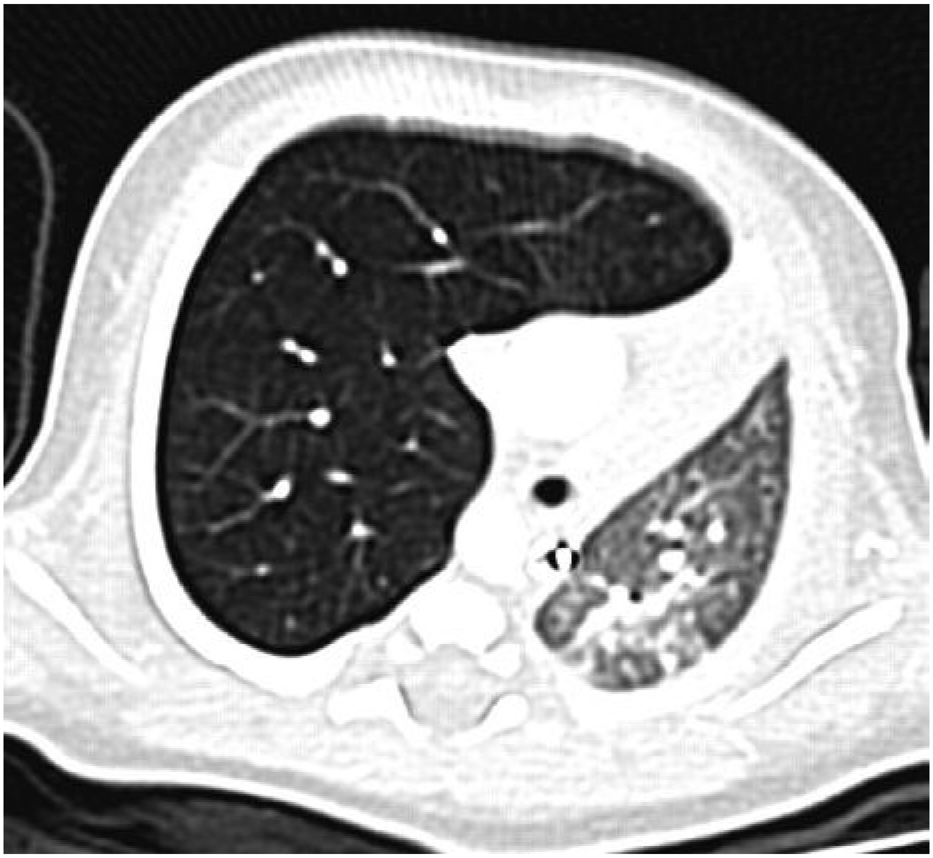

FIGURE 52-6 Chest CT scan showing emphysematous, hyperlucent right upper lobe with herniation across the midline. The bronchial anatomy and vascular supply to the lung is normal. (*Used with permission from Nitin Mehta, MD.*)

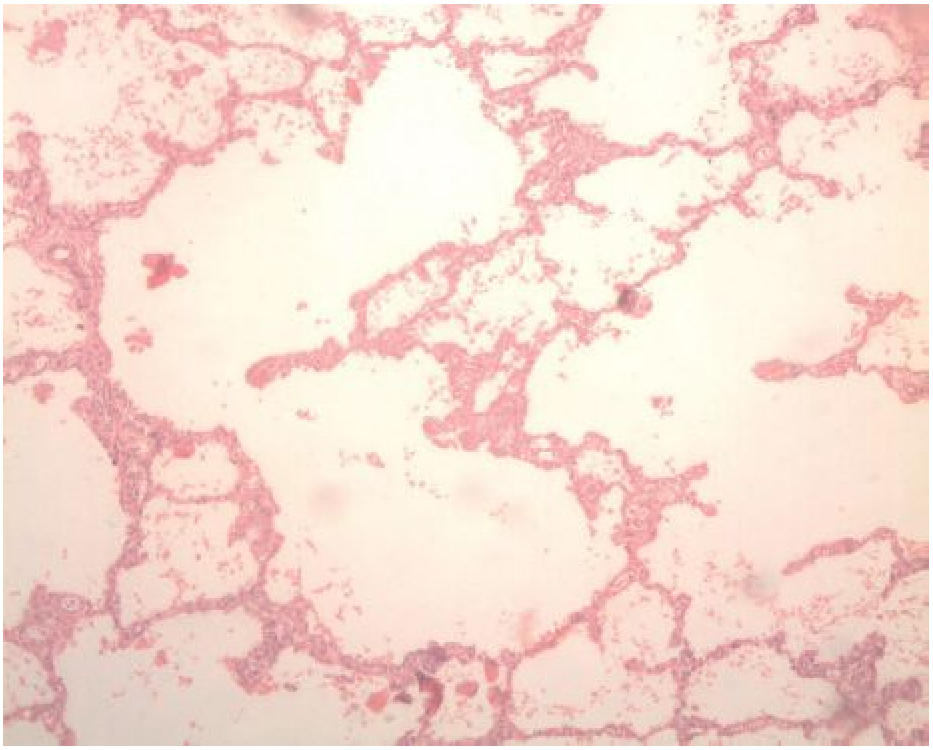

FIGURE 52-7 Histopathologic section with diagnostic findings of emphysematous change, overinflation of alveoli with destruction and paucity of interalveolar septae. (*Used with permission from the Department of Pathology, Christian Medical College Hospital, Vellore, India*.)

DIFFERENTIAL DIAGNOSIS

- Tension pneumothorax in grossly distended lobe; differentiated by presence of lung markings in CLE.

MANAGEMENT

Treatment is based on the acuity of presentation and severity of respiratory distress. Traditionally, surgical resection of the affected lobe is recommended, either electively in the mildly symptomatic infant or urgently when there is life-threatening respiratory decompensation and failure.[23]

Some patients with mild symptoms have been treated conservatively without surgical intervention and are reported to have done well. However the long-term impact of conservative treatment is yet undetermined and needs further evaluation.

SURGERY

- Lobectomy is recommended early in order to prevent potentially life-threatening respiratory distress.
- During anesthesia these patients may tolerate positive pressure ventilation poorly with risk for air trapping, further distension of the affected lobe with cardiorespiratory compromise for which they must be carefully monitored.[23]
- Rapid thoracotomy may be necessary and the surgeon present at anesthetic induction; the abnormal lobe herniates through the thoracotomy while the remaining lung is atelectatic.
- Following lobectomy, the remaining lobe of the ipsilateral lung expands to fill the hemithorax.

REFERRAL

Pediatric cardiothoracic surgery. Pediatric pulmonology to follow lung function and development longitudinally.

PROGNOSIS

- Lobectomy is safe and effective therapy, and tolerated well.[24]
- Growth and expansion of the remaining lung tissue occurs in children up to the age of 6 to 8 years, resulting in near normal lung volume and

function.

FOLLOW-UP

- Postoperative chest x-rays are near normal with good potential for lung growth and development in young children.[24]
- Serial pulmonary function testing to assess lung capacities and to screen for small airway obstruction/airway hyperreactivity can be done in older children.

CONGENITAL CYSTIC ADENOMATOID MALFORMATION (CCAM)

PATIENT STORY

A 35-year-old-woman, with history of 4 previous spontaneous abortions (all occurring in the first trimester of pregnancy) is followed closely at the obstetric high risk clinic. Prenatal ultrasound screening of the fetus, detects a cystic lesion of the right lung at 20 weeks gestation, which occupies about 40 percent of the right hemithorax. There are no associated congenital abnormalities and fetal growth and developmental parameters are normal. On serial ultrasound imaging, the cystic lesion of the right lung is noted to be progressively smaller with fetal growth, and is reduced in size to about 10 percent of the right lung towards term. The infant is born normally at 40 weeks gestation, a male with birth weight 3.5kg, and Apgar scores 9 and 10, and 1 and 5 minutes respectively. There are no respiratory symptoms or distress. The neonate is asymptomatic, feeding and sucking well, with comfortable respirations and normal oxygenation on pulse oximetry. Physical examination is normal and his lungs are clear on auscultation. Chest x-ray taken on the first day of life shows normal well aerated lung fields bilaterally without any masses or opacity noted.

The infant is followed closely and remains well without any respiratory symptoms. He has mild gastroesophageal reflux in the first 3 months but normal weight gain. Chest x-rays are repeated at regular intervals at age 1, 3, and 6 months and are normal. A chest CT scan with contrast is planned and done electively at age 12 months, given the history of the prenatally detected cystic right lung lesion. The chest CT scan shows a cystic lesion of the right lower lobe, with hyperlucent loculation, normal bronchial anatomy and normal blood supply (**Figure 52-8**).

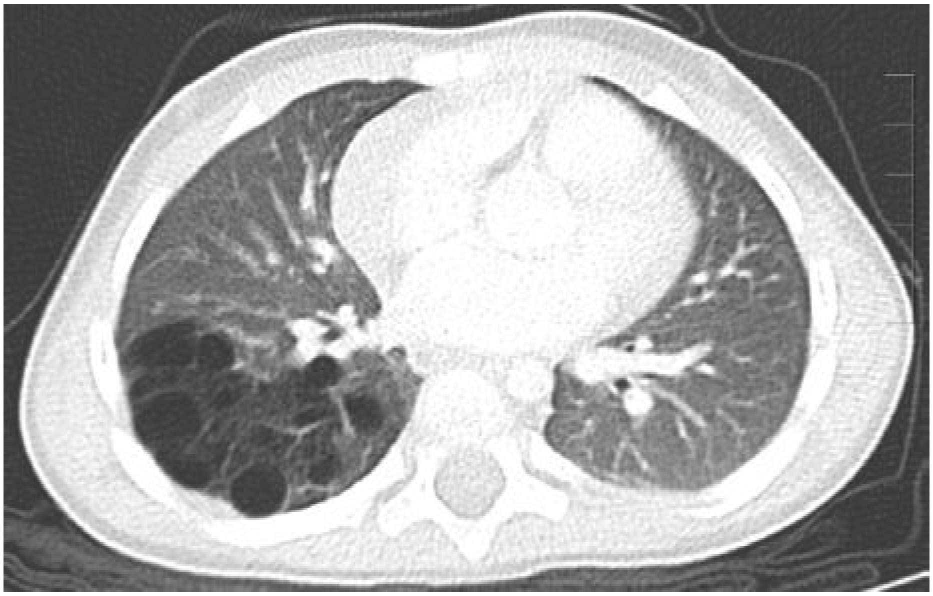

FIGURE 52-8 CT axial view showing cystic lucencies in the right lower lobe of the lung diagnostic of congenital cystic adenomatoid malformation (CCAM). (*Used with permission from Samiya Razvi, DCH, MD and Ellen Park, MD.*)

Diagnosis of a congenital cystic adenomatoid malformation (CCAM) is made, and elective right lower lobectomy is performed via thoracotomy. He tolerates the surgery well, without complications. On long-term follow-up, he has normal growth and development, is active with good exercise tolerance, and no respiratory symptoms.

INTRODUCTION

CCAM is a rare developmental abnormality of lung, first described by Chin and Tang in 1949. This malformation is considered to be a benign hamartomatous or dysplastic lung tumor. CCAM occurs as a result of cessation of bronchial maturation, and characteristic overgrowth of mesenchymal elements, which produce the adenomatoid appearance with reduction in the number of alveoli.[25]

SYNONYMS

Congenital pulmonary airway malformation (CPAM).

EPIDEMIOLOGY

- Incidence is reportedly between 1:11,000 and 1:35,000 live births.
- Slightly more predominant in males than females.

ETIOLOGY AND PATHOPHYSIOLOGY

- Overgrowth, hyperplasia, and hamartoma formation have been proposed as etiology. Failure in the interaction between mesenchyma and epithelial elements during lung development and maturation may result in the discordance in vascularity and proliferation of lung tissue.
- Traditionally, one classification based on the size of the cysts and histopathology by Stocker et al.[26] is as follows:
    - Type I—Macrocystic adenomatoid malformation usually affecting a single lobe, with cysts usually greater than 2 cm in diameter. Cyst walls have a lining of respiratory epithelium and communicate with the proximal airways and distal lung parenchyma.
    - Type II—Microcystic adenomatoid malformation resulting from obstruction of the airways during development resulting in multiple small cysts less than 1 cm in diameter.
    - Type III—Solid airless mass consisting of mostly bronchiolar elements with respiratory epithelial lining, and some alveolar elements.

DIAGNOSIS

A significant proportion are detected on antenatal ultrasound screening as cystic or solid fetal lung lesions. If detected postnatally on chest x-ray, chest CT scan imaging is definitive. CCAMs should be suspected in cases of unilateral recurrent pneumonia, or when there is persistent localized opacification noted on serial chest x-rays.

CLINICAL FEATURES

- Prenatal ultrasound detects hypoechoic lung lesions in the fetus, which are then confirmed postnatally by chest CT scan in those who are liveborn.[27]
- Majority (80%) present in the neonatal period with respiratory distress, especially if large cystic lesions. Significant cardiorespiratory compromise can occur due to associated pulmonary hypoplasia, which can be severe, as a result of mass effect of the lesion during intrauterine development.[27]
- Smaller cystic or solid CCAMS may be asymptomatic and go undetected in early infancy, and may present later in childhood or even adulthood as unilateral recurrent pneumonia, lung abscess, persistent localized chest opacity on chest x-ray or rarely with malignant transformation.[27]

DISTRIBUTION

- Usually unilateral involving only one lobe of the lung; rarely bilateral lesions have been reported.
- Left sided lesions are more common than right.
- Coexistence of a pulmonary sequestration occurs in up to half the patients in some reports.

IMAGING[28]

- High resolution ultrasound can detect CCAMs on prenatal screening, as hypoechoic or cystic fetal lung lesions, depending on the relative amounts of cystic and solid tissue. Fetal MRI provides additional detail on structure of the lesion and reliably distinguishes CCAM from congenital diaphragmatic hernia. Color Doppler ultrasound is used to identify the absence of a systemic feeding vessel, which differentiates this from pulmonary sequestration.
- Chest x-ray findings vary and may show no abnormality, a large air filled cystic lesion, cystic lesions interspersed with parenchymal opacity or a solid appearing lung mass (**Figures 52-9** and **52-10**).

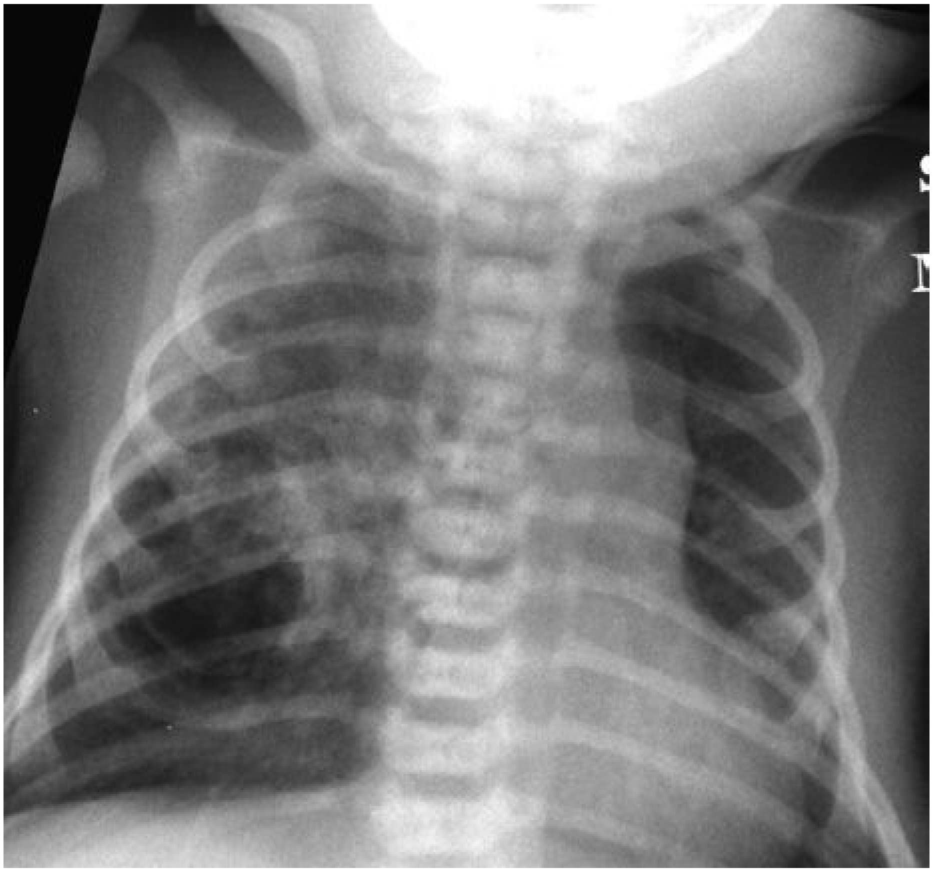

FIGURE 52-9 Chest radiograph in a newborn with congenital cystic adenomatoid malformation (CCAM) shows large cystic areas in the right lower lobe with some mass effect and depression of the hemidiaphragm. (*Used with permission from S. Murthy Chennapragada, MD.*)

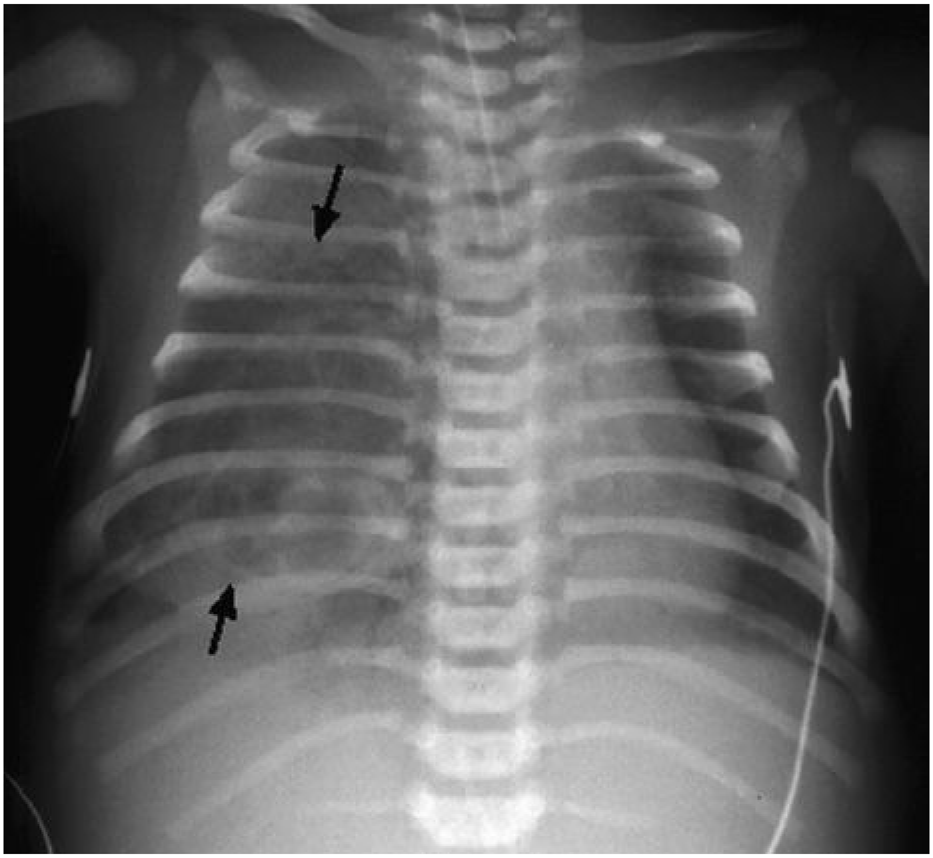

FIGURE 52-10 Plain CXR of a newborn showing cystic lesions with soap bubble appearance in right lung (arrows), with poorly defined margins. This is another example of congenital cystic adenomatoid malformation. (*Used with permission from Nitin Mehta, MD.*)

- Chest CT scan with contrast is the imaging modality of choice in the postnatal evaluation of infants suspected to have a congenital lung lesion (**Figures 52-11** and **52-12**).

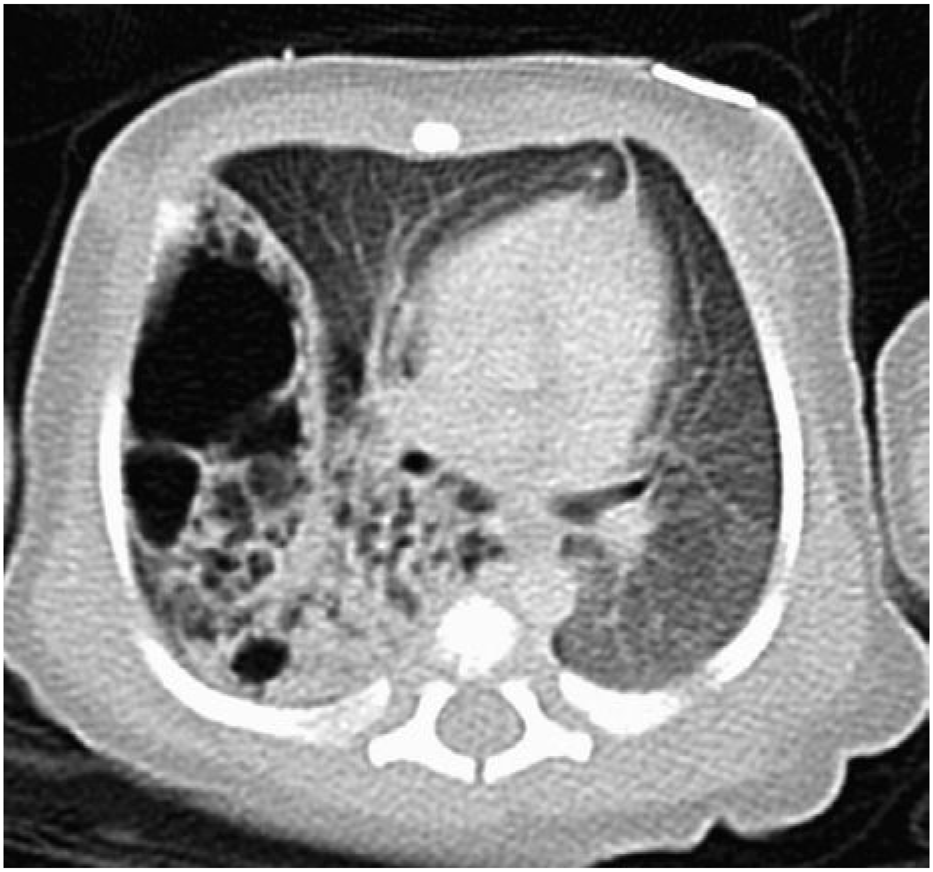

FIGURE 52-11 Congenital pulmonary airway malformation Type 1. Chest CT showing multiple cysts of varying sizes replacing the right lower lobe. The dominant ones measure >2 cm and are surrounded by multiple smaller cysts. (*Used with permission from S. Murthy Chennapragada, MD.*)

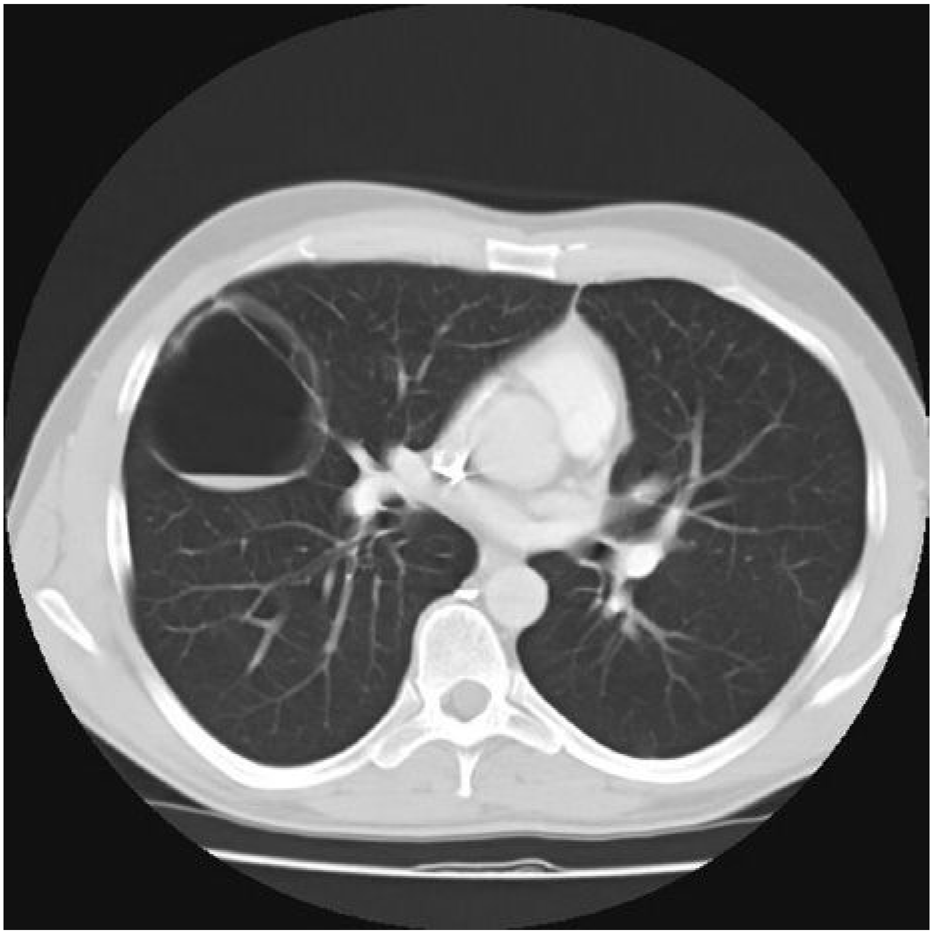

FIGURE 52-12 Axial cut chest CT showing single large cystic lesion with well-defined wall in right lung consistent with congenital cystic adenomatoid malformation. (*Used with permission from Nitin Mehta, MD.*)

DIFFERENTIAL DIAGNOSIS

- These entities can usually be distinguished by the classic appearance of CCAM on Chest CT:
  - Pulmonary sequestration.
  - Congenital diaphragmatic hernia.
  - Teratoma.
  - Bronchogenic or enteric duplication cyst.
  - Congenital lobar emphysema.

MANAGEMENT

- Congenitally diagnosed lung masses have been reported to decrease in size toward term on serial ultrasonography and “disappear”; controversy exists whether postnatal imaging should be done for such infants. Several authors have shown that significant abnormalities do remain in such cases, and CT imaging is essential to delineate the presence, location, and size of the lung lesion.[29]
- Surgical resection is now the standard of care, even if asymptomatic, given the risk of complications which include sudden respiratory compromise, pneumothorax, infection, compression of adjacent structures, rupture, and malignant degeneration.

SURGERY

- Lobectomy is the procedure of choice and well tolerated; occasionally emergency resection may be needed. Video-assisted thoracoscopic surgery is minimally invasive, safe, and effective. The optimal timing for elective surgery is not well delineated, and is often recommended in the latter half of infancy to reduce anesthetic and surgical risks.[29]
- Debate exists whether segmental resection of the lung can be done as a parenchymal sparing technique to conserve normal pulmonary remnants for subsequent growth and development. However, it has been described that the preoperative CT is not predictive of extension of the malformation to the rest of the lobe. Segmental resection (subtotal lobectomy or segmentectomy) would therefore risk leaving remnants of the CCAM and may also be associated with greater incidence of postoperative complications such as air leak and infections requiring repeat surgery and lobectomy.[30]

REFERRAL

Pediatric Cardiology to evaluate for associated cardiac anomalies or intracardiac defects.

PREVENTION AND SCREENING

Prenatal high resolution ultrasound screening and serial evaluation; fetal MRI when indicated.

PROGNOSIS

- Perinatal mortality varies greatly depending on the size of the lesion from 9 to 49 percent, with complications resulting from severe respiratory distress in symptomatic neonates.
- Lobectomy overall provides good symptom relief and excellent long-term outcomes. Infants and children tolerate lobectomy well with continued lung growth resulting in near normal lung volumes and gas exchange capacity.
- Type I CCAMs have the best prognosis, whereas Type III lesions have worse outcomes.
- Poor prognosis is associated with bilateral lesions, presence of associated pulmonary hypoplasia and cardiac anomalies.

FOLLOW-UP

- Residual mild respiratory symptoms including airway hyperreactivity and wheeze may be present on long-term follow-up in some patients.
- Serial pulmonary function testing may be done in older patients to monitor lung function.

PULMONARY SEQUESTRATION

PATIENT STORY

A 13-year-old-African American girl presents with history of intermittent colicky, abdominal pain for several weeks with acid reflux symptoms. She also has exercise induced asthma, which is well controlled with inhalers. She has a history of pneumonia once at the age of 5 years; her previous Cx-rays are unavailable. Cx-ray shows cystic lesion in the right lower lobe with well-defined wall, central lucency, and an air fluid level (**Figure 52-13**). She is evaluated with an upper GI series for the abdominal pain, which detects intestinal malrotation without acute obstruction. CT scan of the abdomen is done and shows polysplenia. Chest CT shows a dense contrast enhancing opacity of the right lower lobe, with mixed solid and cystic characteristics supplied by an aberrant artery from the descending thoracic aorta (**Figure 52-14**). There are no other anomalous vessels. She first undergoes surgical correction of the intestinal malrotation with relief of her abdominal symptoms. Elective surgical resection of the right lower lobe lesion with interruption and ligation of the anomalous supplying artery is done successfully at a later date, with an uneventful postoperative course. Histopathological examination of the resected lung lobe shows features characteristic of intrapulmonary sequestration (**Figure 52-15**). On follow-up, she is asymptomatic with normal chest x-ray and normal lung function as assessed by spirometry.

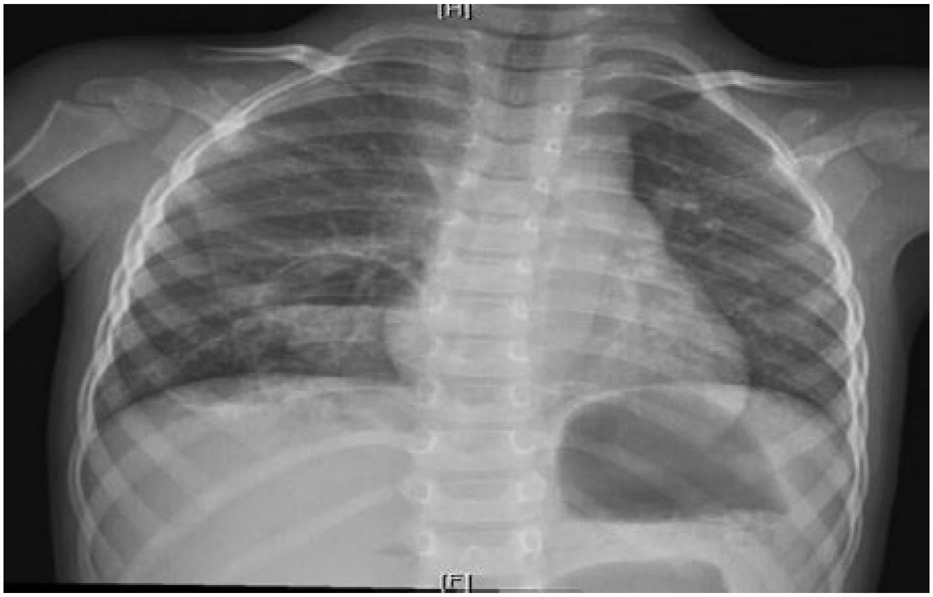

FIGURE 52-13 Plain CXR showing cystic lesion in the right lower lobe, with well circumscribed wall and central lucency with air fluid level. (*Used with permission from Sneha Varki, MD.*)

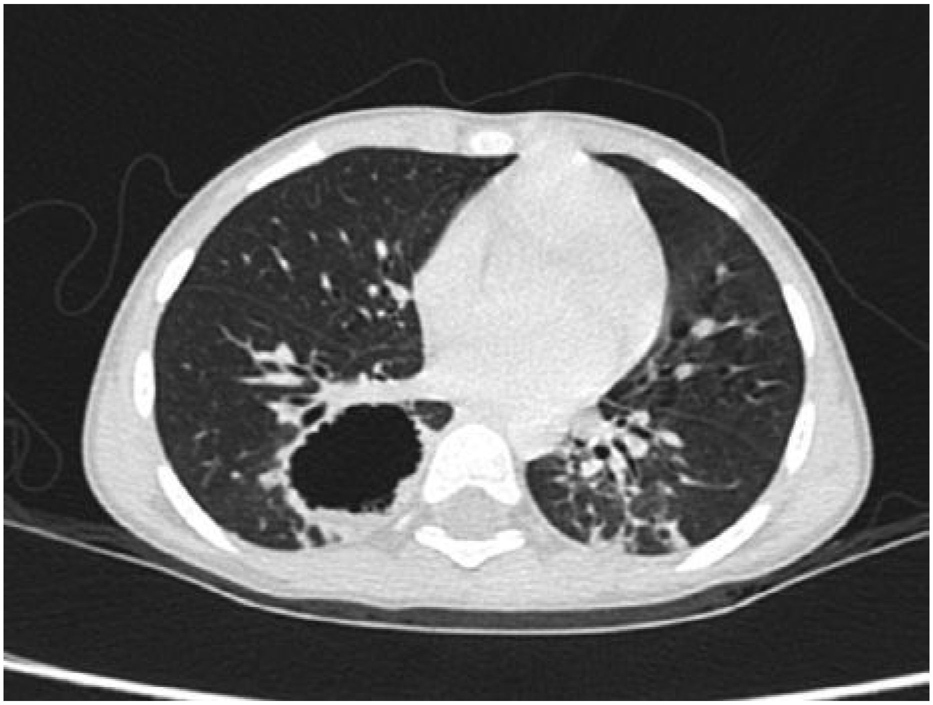

FIGURE 52-14 CT scan axial cut of the same lesion in Figure 52-13 showing cystic nature of intralobar sequestration contained within the right lower lobe of the lung. (*Used with permission from Sneha Varki, MD.*)

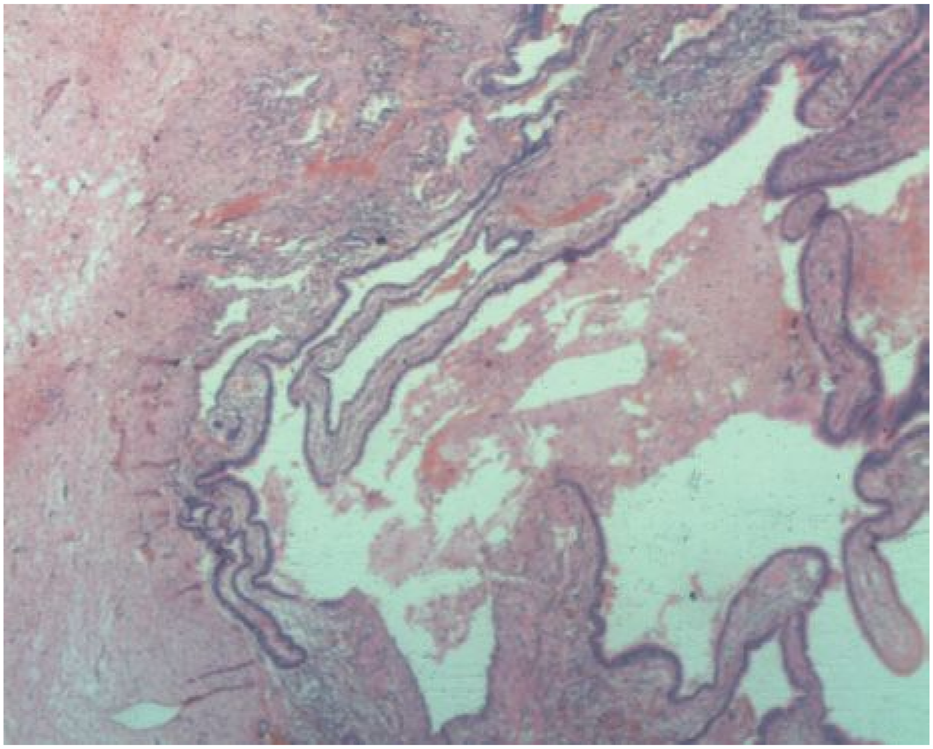

FIGURE 52-15 Histopathological section of intrapulmonary sequestered lobe- demonstrating well circumscribed lesion, dilated bronchi with moderate mononuclear cell infiltrate in the bronchial wall, dilated alveoli, a few of which contain foamy histiocytes as well as hemosiderophages within the lumen. The blood vessels have thick muscular walls and there is moderate interstitial fibrosis. (*Used with permission from the Department of Pathology, Christian Medical College Hospital, Vellore, India*.)

INTRODUCTION

Pulmonary sequestration occurs as a localized abnormality of the lung parenchyma that is nonfunctioning, lacks communication with the tracheobronchial tree, and has aberrant arterial blood supply directly from the aorta. Sequestration can be either intralobar sequestration (ILS) or extralobar sequestration (ELS) depending on whether the affected lung tissue is within the normal lung lobe or outside.[31]

SYNONYMS

Bronchopulmonary sequestration.

EPIDEMIOLOGY[31]

- Second most common congenital pulmonary malformation, with the frequency of intralobar (ILS) to extralobar sequestration (ELS) being about 3:1.
- Anomalies of the chest wall, spine, diaphragm, intestinal tract, and heart associated more often with ELS (65%) and fewer with ILS (11%). Most common anomalies associated with ELS include congenital diaphragmatic hernia and CCAM.

ETIOLOGY AND PATHOPHYSIOLOGY

- Pulmonary sequestration occurs due to abnormalities in development during branching and proliferation of the bronchial structures, with separation of the affected lobe and loss of communication with the tracheobronchial tree.[32]
- Intralobar sequestration (ILS) is contained with the lung and the affected lobe does not have its own pleura.
- Extralobar sequestration (ELS) has its own covering with visceral pleura and thus is anatomically separate from adjacent lung tissue.
- Both ILS and ELS have systemic arterial blood supply arising from the aorta. The venous drainage of ELS is usually into the systemic veins, whereas the ILS drains into the pulmonary veins.

- Large sequestration lesions may compress residual lung tissue during development, increasing the risk of pulmonary hypoplasia.
- Connections to the gastrointestinal tract (stomach, esophagus) may be present and increase the risk of infection.

DIAGNOSIS

CLINICAL FEATURES

- ILS usually are symptomatic early in infancy, whereas ELS usually have a silent clinical course and may be asymptomatic (10%) until incidentally detected in the older child or adult.[33]
- May present as recurrent pneumonia localized to the affected lobe and persistent opacity on chest x-ray prompting further imaging with CT.
- High output cardiac failure may occur due to left to right shunting in the affected lobe with increased pulmonary blood flow via the aberrant systemic arterial blood supply.
- Congenital anomalies such as diaphragmatic hernia, CCAM, foregut duplication cysts, pectus excavatum, and congenital heart defects are reported in about 60 percent of ELS cases.[34]
- Serious complications include infection with formation of lung abscess, massive hemoptysis due to erosion of the systemic artery supplying the sequestered lobe, and malignant degeneration.

DISTRIBUTION

- ILS occurs equally in both genders, whereas ELS has a slight male predominance (3:1).
- Occurs more commonly in the left lung (55% of ILS and 65% of ELS).

- Most common location for ILS is the posterior basal segment of the left lower lobe and for EPS is below the left lower lobe.

IMAGING

- Demonstration of a systemic arterial blood supply is essential for diagnosis of pulmonary sequestration, either by Doppler ultrasound, CT, or MRI angiography.[35]
- Chest x-ray—Nonspecific and may show a homogenous opacity in the lower lobes of the lung; areas of cavitation may occur with infection and communication with the tracheobronchial tree.
- Ultrasound—Both ILS and ELS appear as solid, well-circumscribed, and echogenic masses on ultrasound. Color Doppler can demonstrate the aberrant systemic feeding artery to the sequestered lobe.
- Angiography—Traditionally considered the gold standard for diagnosis by depiction of the arterial and venous anatomy. However, it is invasive, with radiation exposure and need for sedation in young children and has been replaced by noninvasive multidetector CT or MR angiography.
- **Chest CT scan with contrast**—Now the diagnostic modality of choice. CT noninvasively confirms the diagnosis, delineates the anatomical location of the sequestered lobe, its lack of communication with the bronchial system, and clear demonstration of the aberrant systemic arterial supply to the affected lobe (**Figure 52-16**).

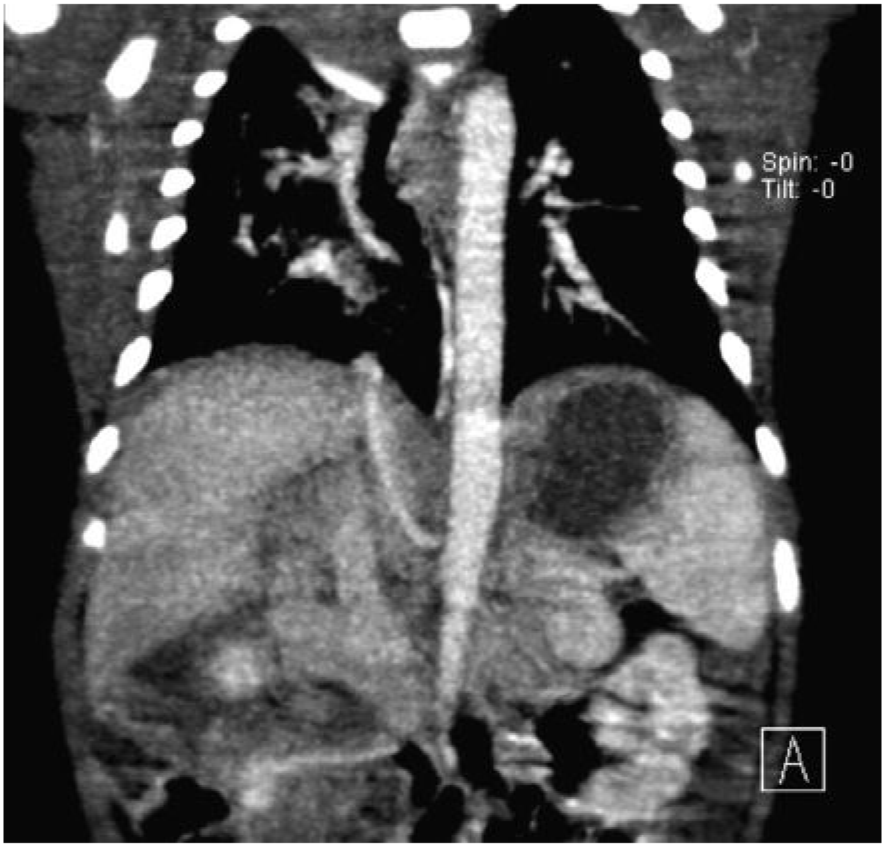

FIGURE 52-16 Coronal Chest CT scan post contrast images in the arterial phase demonstrate an aberrant artery arising from the abdominal aorta and supplying the sequestered lung in the right lower lobe; the venous drainage is into the pulmonary veins: intralobar sequestration. (*Used with permission from S. Murthy Chennapragada, MD.*)

HISTOPATHOLOGY

Microscopy shows dilated bronchioles, alveoli, and air spaces lined with respiratory epithelium. There may be changes of chronic infection or inflammation and fibrosis.

DIFFERENTIAL DIAGNOSIS

- CCAM—See previous section.

- Teratoma—Usually detected by radiographic manifestations.

MANAGEMENT

SURGERY

- Definitive treatment for both ILS and ELS is surgical resection of the mass, even if asymptomatic, to prevent complications.
- Preoperatively, it is imperative to delineate the anomalous blood vessels to the sequestered lobe to minimize the risk of hemorrhage during surgery.
- Lobectomy is indicated since the anomalous vasculature may be difficult to delineate intra-operatively, making resection challenging for the surgeon and the risk for significant and massive bleeding given the systemic arterial supply.
- As recurrent infection results in inflammatory changes and adhesions, which may obliterate intersegmental planes, early elective resection is recommended.
- Arterial embolization of the sequestered lobe with subsequent reduction in size on CT imaging has been reported, but does not exclude the presence of residual dysplastic tissue with risk for malignant degeneration.
- Traditionally, thoracotomy is used as it provides adequate exposure for lobectomy. Minimally invasive techniques are an alternative approach in minimizing surgical trauma, morbidity, and postoperative pain.[36]

PREVENTION AND SCREENING

Serial prenatal ultrasound imaging for monitoring fetal lung lesions is recommended at 1- to 3-week intervals until stability of the lesion has been established, and then typically monthly thereafter. Fetal MRI imaging is useful to delineate vascular anatomy and other associated congenital anomalies.

PROGNOSIS

Overall, the outcome is good with resolution of symptoms and complications including heart failure due to left to right shunting. As the lung tissue in the sequestered lobe is nonfunctional, the functional consequences are insignificant after postoperative recovery. With the increasing use of minithoracotomies and minimally invasive techniques, the long-term sequelae on thoracic wall growth and development are reduced.

PROVIDER RESOURCES

PULMONARY AGENESIS

PATIENT STORY

A term male infant is born by elective Caesarean section, to a third gravida mother with gestational diabetes mellitus and history of two previous Caesarean sections. The infant is pink, vigorous at birth with good cry and tone; Apgar scores are 8 and 9 at 1 and 5 minutes, respectively. His birth weight is 3000 grams. At 24 hours age, he is noted to have mild respiratory distress with a respiratory rate of 50/min and subcostal retractions. His pulse oximetry saturations are 96 percent on room air. He is afebrile, sucking and feeding well. On auscultation of the chest, breath sounds appear diminished over the right chest. Heart sounds are normal and there is no murmur. A chest x-ray is ordered and shows opacification of the right hemithorax, with shift of the mediastinum to the right. The left lung is hyperinflated and extends across the midline to the right upper chest. The cardiac silhouette is normal. An echocardiogram is done and shows no intracardiac defect, the great vessels are normal. A chest CT scan is done and shows absence of the right lung and right main bronchus (**Figures 52-17** and **52-18**). The left lung bronchial anatomy and lung parenchyma are normal. Virtual bronchoscopy using reconstructive images confirms the findings of normal trachea, and absent right main bronchus, normal left bronchial anatomy. He is diagnosed to have complete agenesis of the right lung. There are no other congenital abnormalities; renal ultrasound is normal. He is followed closely after discharge from hospital. He continues to have mild tachypnea with retractions at rest, but is otherwise well and gaining weight.

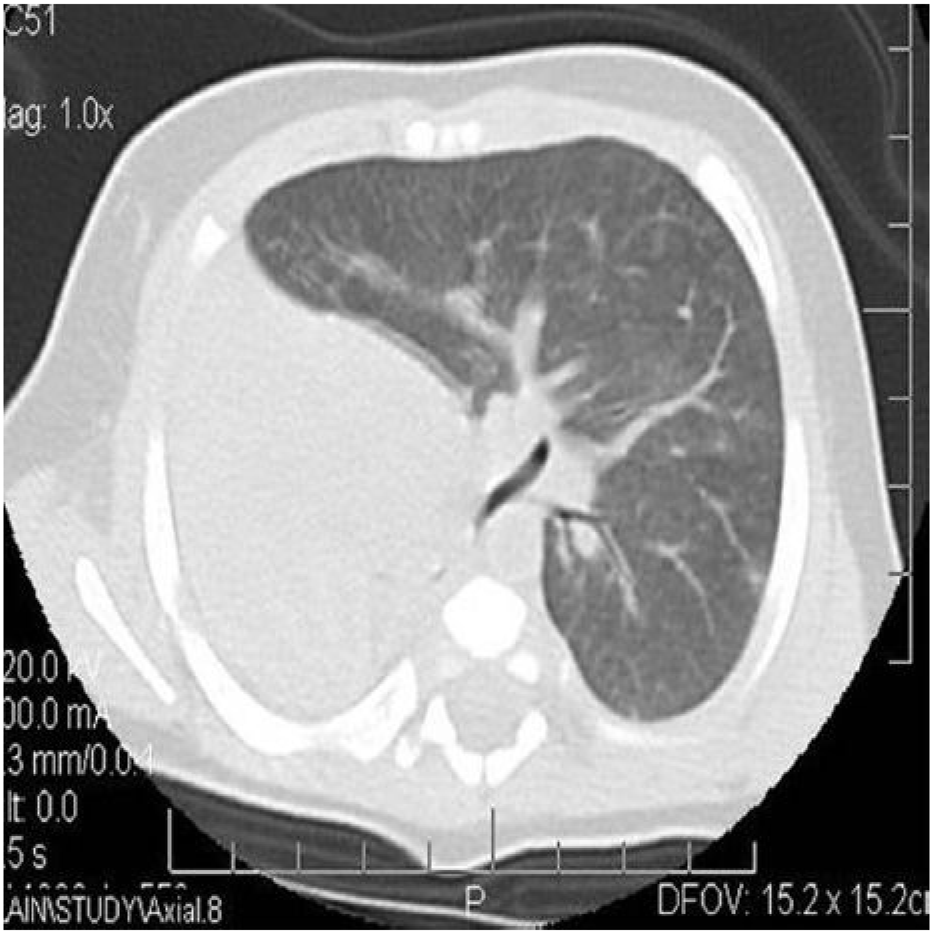

FIGURE 52-17 Axial cut of chest CT of right pulmonary agenesis with classical findings of no definable lung tissue, pulmonary artery or main bronchus on the affected side. There is ipsilateral shift of the heart and mediastinum. (*Used with permission from Nadeem Ahmed, MD, DNB.*)

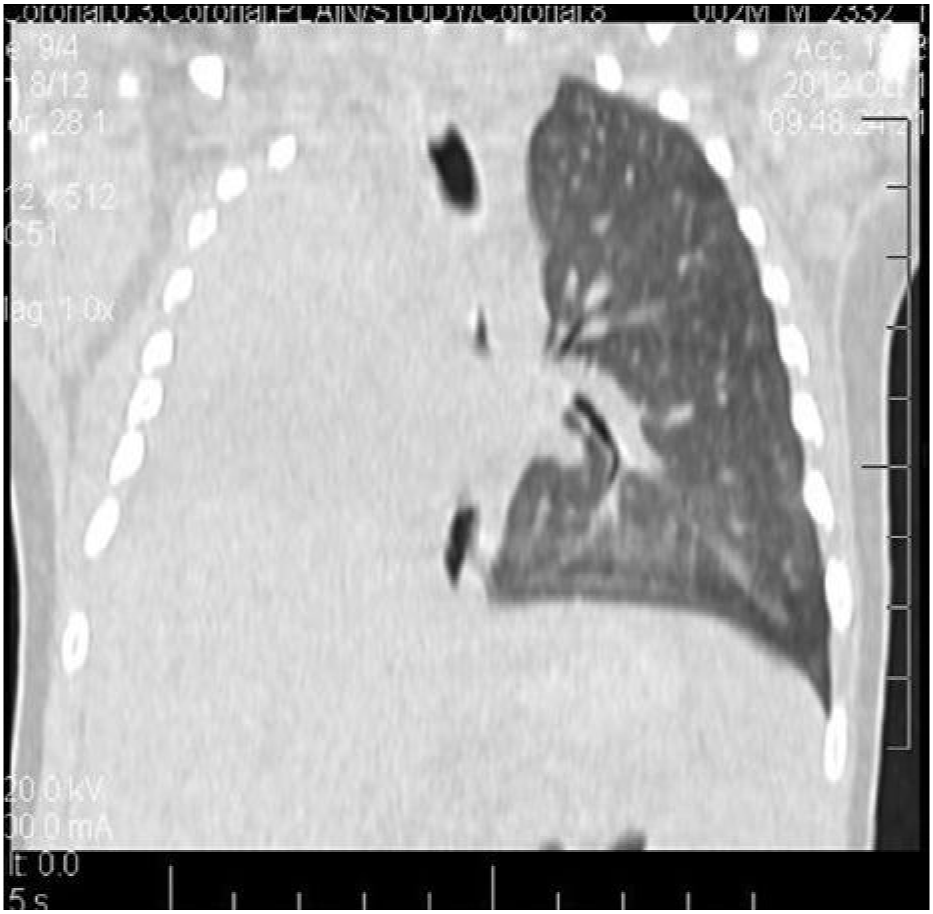

FIGURE 52-18 Chest CT scan coronal view showing complete absence of right lung, including right main bronchus and right pulmonary artery with opacification of the affected hemithorax. (*Used with permission from Nadeem Ahmed, MD.*)

INTRODUCTION

Pulmonary agenesis (PA) is a rare developmental defect in which there is unilateral or bilateral complete absence of the lung, its bronchus and vascular supply. Schneider and Schwalbe classified the anomaly into 3 categories: (1) agenesis: complete absence of a lung, bronchus and pulmonary vasculature (2) aplasia: there is a blind-ending rudimentary bronchus coming off the trachea without lung tissue or pulmonary vasculature (3) hypoplasia: there is a rudimentary bronchus and hypoplastic lung, airways, alveoli and pulmonary vessels are decreased in size and number.[37]

EPIDEMIOLOGY

- Rare congenital anomaly estimated to occur in approximately 1 per 15,000 pregnancies and frequently associated with other abnormalities. The true incidence may be higher as 50 percent of cases are stillborn and more than 20 percent die at birth or during their first few months.[37]

ETIOLOGY AND PATHOPHYSIOLOGY

- Occurs as a result of complete failure of development of one of the lung buds. It has been hypothesized that abnormal blood flow in the dorsal aortic arch during the 4th week of gestation (embryonic phase) causes pulmonary agenesis.
- There is mediastinal shift with compensatory hyperexpansion of the contralateral normal lung.
- Tracheal compression can be caused by the displaced aorta; there may also be intrinsic tracheobronchial anomalies including tracheal stenosis and tracheomalacia.
- Cardiac failure or pulmonary hypertension can occur in survivors; due to associated congenital heart disease and/or pulmonary vascular anomalies.
- Esophageal anomalies such as tracheoesophageal fistula and gastroesophageal reflux can occur; pulmonary agenesis can be a part of

VACTERL sequence.[38]

DIAGNOSIS

CLINICAL FEATURES

- Variable clinical presentation; may be asymptomatic and incidentally detected.[39]
- Symptoms range from mild dyspnea on exertion, recurrent respiratory infections to severe distress with respiratory failure requiring mechanical ventilatory support in the neonatal period.
- Associated anomalies involving cardiovascular, GI, skeletal, and urogenital systems are present in about half the cases.
- Agenesis of the right lung is associated with a higher frequency of anomalies than agenesis of the left lung.
- Tracheal compression can be caused by a deviated aorta, dilated pulmonary artery, or cardiac chamber or vascular ring. Tracheal stenosis and tracheomalacia can occur.

DISTRIBUTION

- Slight preponderance in females.
- Right and left lungs are absent with equal frequency.

IMAGING

- Ultrasound—Prenatal diagnosis is characterized by unilateral hyperechogenicity of the affected lung.[40]
- Chest x-ray—Shows complete opacification or white-out of the affected hemithorax suggestive of collapse consolidation. There is asymmetry in

the lung volumes and configuration with overexpansion of the contralateral normal lung often causing mediastinal shift. The definitive diagnosis is made via pulmonary angiography, which shows the pulmonary artery to the affected side to be absent.

- Chest CT scan with contrast—Provides precise anatomical delineation with no definable lung tissue, pulmonary artery, or main bronchus on the affected side with ipsilateral shift of the heart and mediastinum. Vascular compression of the major airways can also be detected.
- MRI—Accurately defines the airway and vascular anatomic abnormalities and has replaced conventional angiocardiography in patient management and surgical planning.
- Bronchoscopy—Reveals a blind-ending main bronchus on the affected side.

MANAGEMENT

Asymptomatic patients do not require surgical intervention especially in the absence of associated anomalies. Respiratory infections should be treated early and aggressively as there is low respiratory reserve. Pulmonary hypertension can occur due to reduction in the pulmonary vascular bed, and if associated with left to right intracardiac shunts can progress to irreversible vascular disease.

SURGERY

- Surgery may also be indicated to relieve significant bronchial obstruction (aortopexy, division of vascular rings, and resection of stenotic and malacic bronchus) or for stabilization of the mediastinum (relocation of diaphragm and insertion of prosthesis).
- Associated cardiac and esophageal anomalies will require surgical correction.[37]

REFERRAL

Pediatric Cardiology to rule out associated congenital heart disease.

PROGNOSIS

- Survival has improved with advancements in neonatal and surgical management; survival into adulthood is reported.
- Right-sided agenesis has poor outcome attributed to greater shift of heart and mediastinum with consequent distortion of the vascular structures and airway, and a higher incidence of associated cardiac and vascular anomalies.[37]

FOLLOW-UP

- Patients should be closely monitored for growth retardation and scoliosis; major airway compression may lead to symptoms of stridor.
- Serial pulmonary function tests can help assess and monitor lung capacities, lung volumes and airway flow rates in older children and adults.

PROVIDER RESOURCES

- Congenital lung malformations— **www.emedicine.medscape.com/article/905596-overview**.

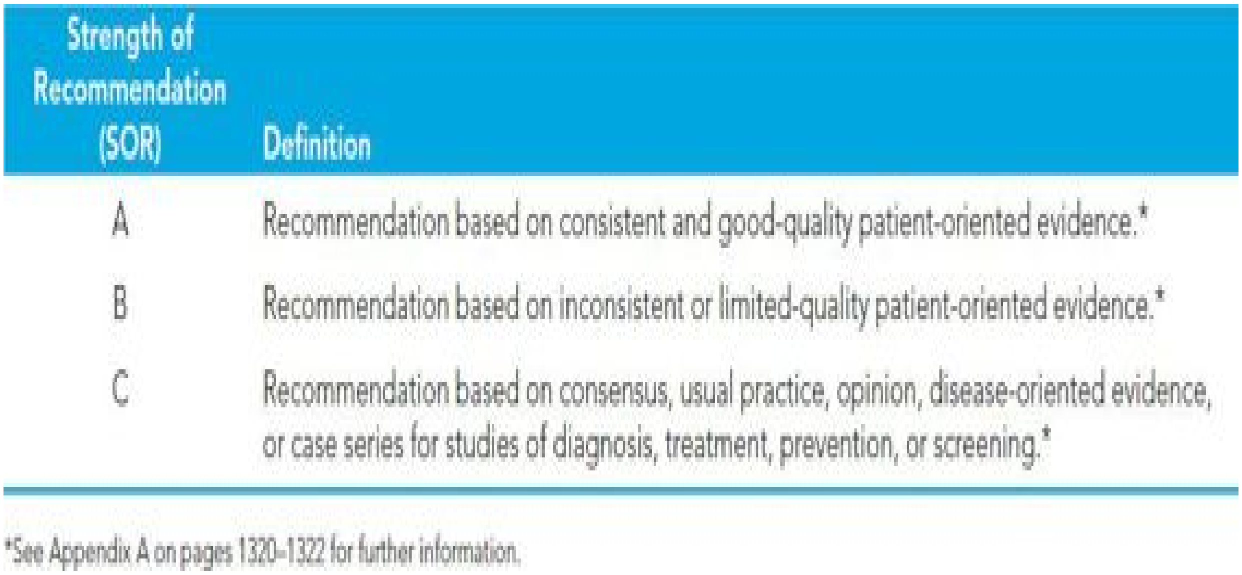
PART 9

THE GASTROINTESTINAL TRACT AND NUTRITIONAL DISORDERS



Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1320–1322 for further information.

53 FAILURE TO THRIVE

Vera Okwu, MD
Lori A. Mahajan, MD

PATIENT STORY

A 12-year-old African American boy with cerebral palsy-quadriplegia was brought to clinic as mother was having progressive difficulty feeding him (**Figure 53-1**). He had not been seen in the office since age 9 years when he plotted at the 20th percentile for both weight and length on the cerebral palsy-quadriplegia growth chart. Mother stated that she was having difficulty obtaining his supplemental 1.5cal/cc supplement that had been prescribed and her son was becoming progressively more selective regarding intake of solids. School officials also reported feeding difficulty. On examination, he appeared emaciated. Length, weight, and BMI were far below the 5th percentile. Labs including a celiac antibody panel, comprehensive metabolic panel, CBC with differential, sedimentation rate, and thyroid function studies were normal with the exception of mild lymphopenia and a low pre-albumin. Swallow evaluation showed oropharyngeal dysphagia characterized by residuals and delay in swallow onset. A trial of nasogastric (NG) feeds resulted in rapid weight gain with good tolerance. A gastrostomy was subsequently placed for supplemental feeds. Close follow-up was scheduled with the nutritional support team, his physician, and social services.

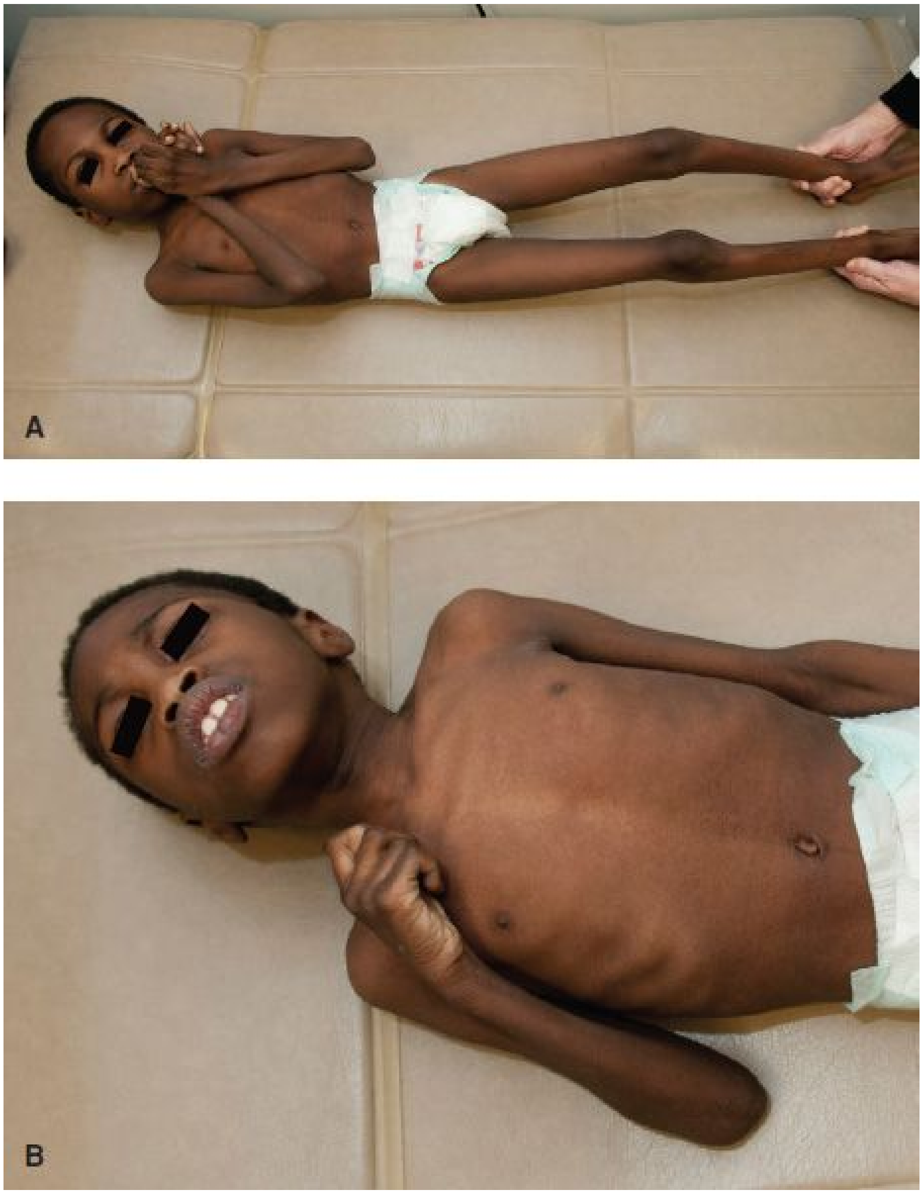


FIGURE 53-1 Cerebral palsy, quadriplegia and severe protein-calorie malnutrition in a 12-year-old boy. **A.** Note the extremely thin extremities. **B.** Close-up of the spasticity and extreme emaciation seen in his chest. (*Used with permission from Lori Mahajan, MD.*)

INTRODUCTION

Failure to thrive (FTT) is a clinical sign, rather than a diagnosis. A wide variety of medical conditions and psychosocial factors contribute to FTT. Potential long-term complications of FTT include permanent cognitive impairment with decreased IQ, short stature, and serious infections due to immune deficiency.

SYNONYMS

Malnutrition, nutritional insufficiency, growth failure.

EPIDEMIOLOGY

- Occurs more commonly in children living in poverty.
- Affects 5 to 10 percent of children in the primary care setting.[1]
- Up to 50 percent of children with FTT are not identified by health care providers.

ETIOLOGY AND PATHOPHYSIOLOGY

- More than 90 percent of cases are purely nutritional, with no identifiable underlying medical condition.
- Causes of FTT are currently classified into the following categories: inadequate caloric intake, inadequate absorption or increased losses, increased metabolic needs, or ineffective utilization.[1,2]

INADEQUATE CALORIC INTAKE

- Behavioral problems interfering with meals/inappropriate feeding habits.

- Dysfunctional parent-child relationship.
- Neglect (**Figure 53-2**).

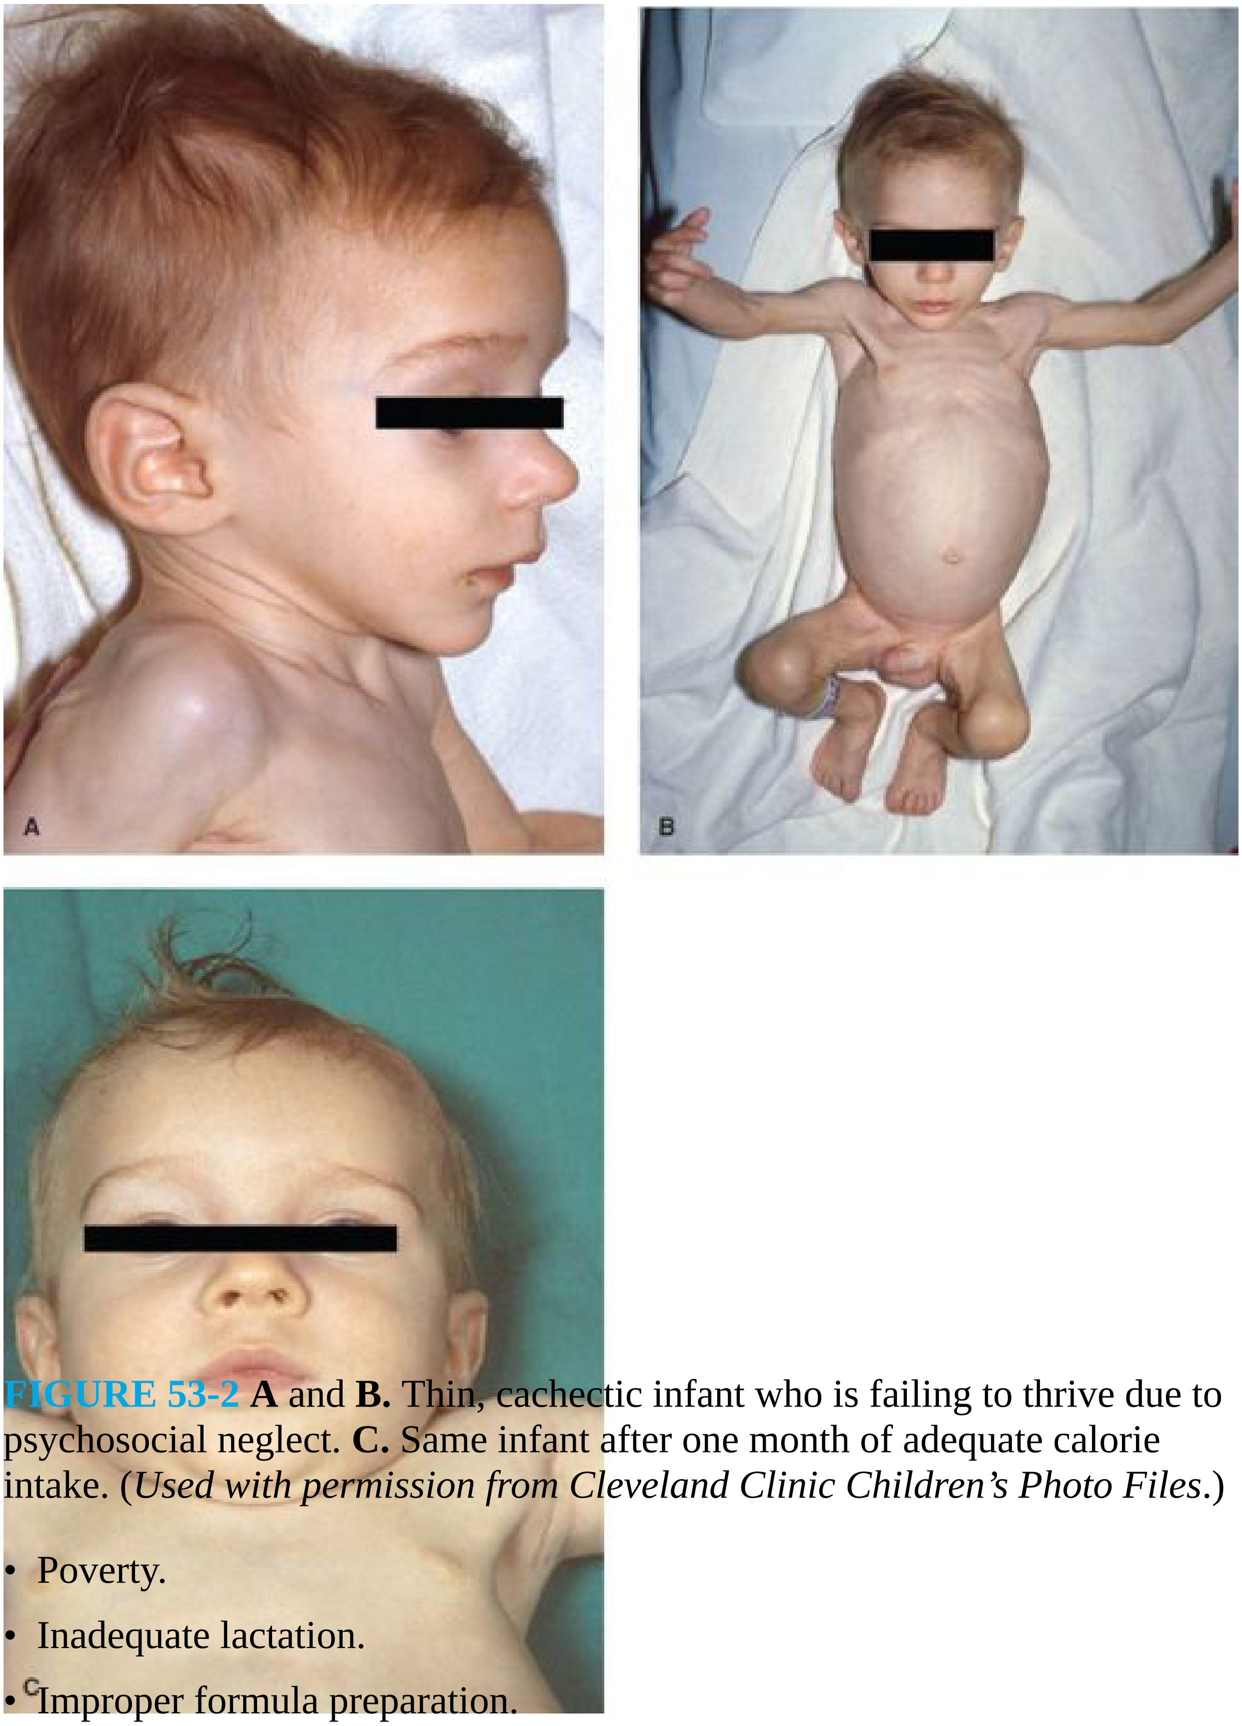

FIGURE 53-2 **A** and **B.** Thin, cachectic infant who is failing to thrive due to psychosocial neglect. **C.** Same infant after one month of adequate calorie intake. (*Used with permission from Cleveland Clinic Children's Photo Files*.)

- Poverty.
- Inadequate lactation.
- Improper formula preparation.

- Suck/swallow dysfunction (esophageal motility dysfunction, CNS, neuromuscular, anatomic-cleft lip, or palate) (**Figure 53-3**).

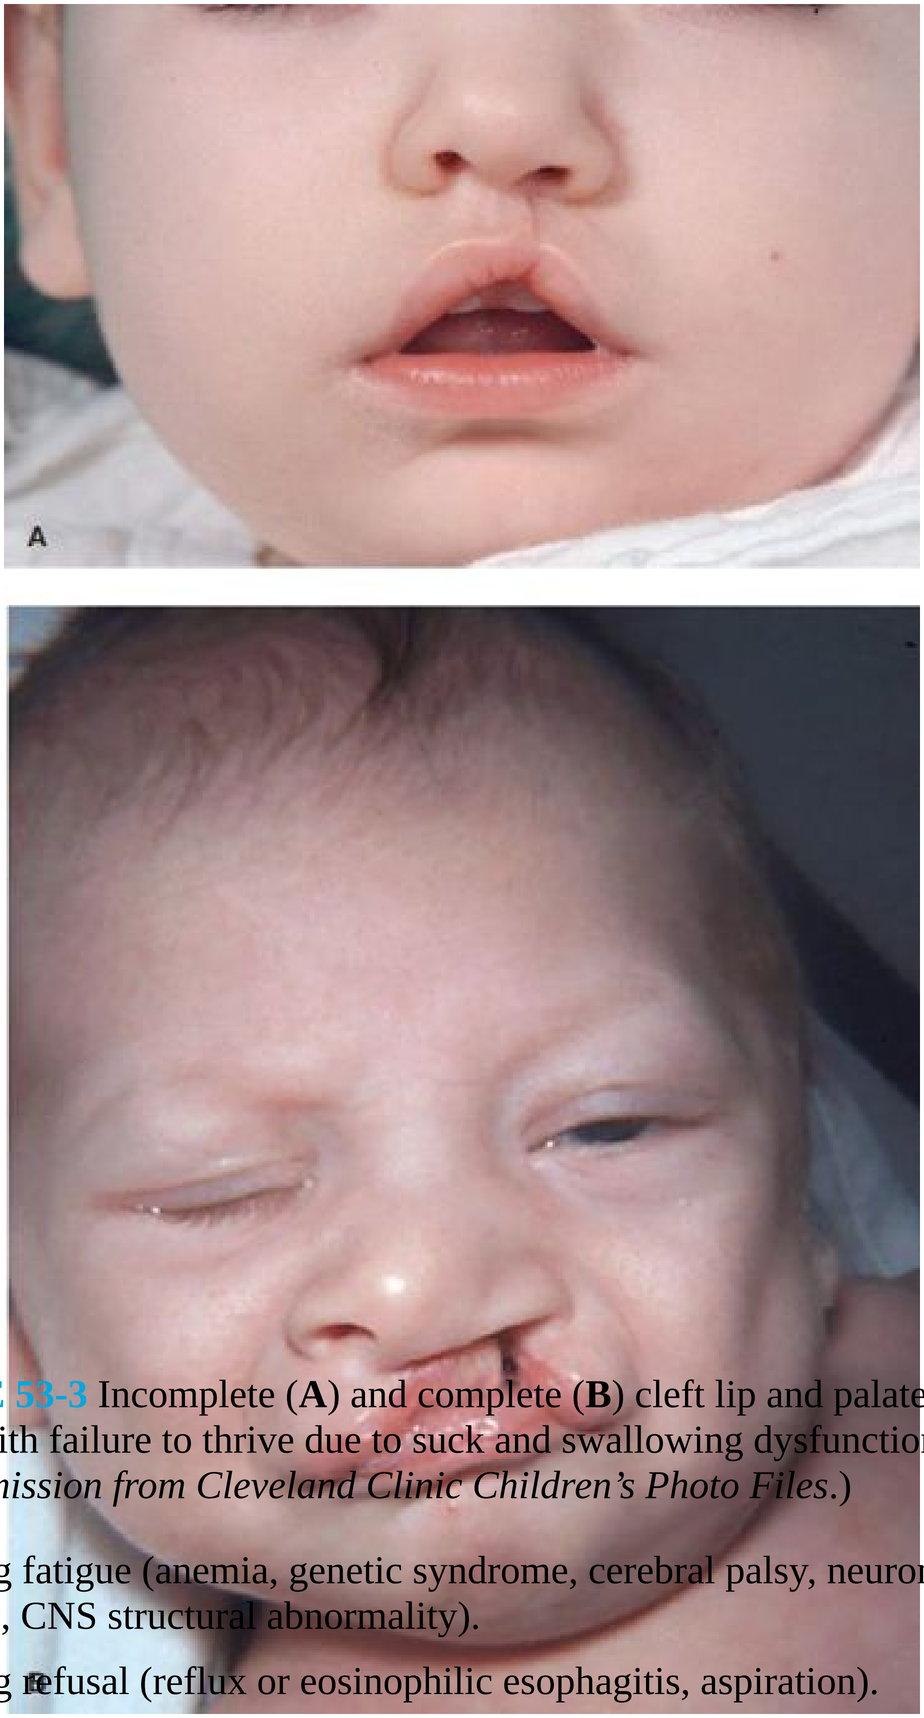

FIGURE 53-3 Incomplete (**A**) and complete (**B**) cleft lip and palate in two infants with failure to thrive due to suck and swallowing dysfunction. (*Used with permission from Cleveland Clinic Children's Photo Files*.)

- Feeding fatigue (anemia, genetic syndrome, cerebral palsy, neuromuscular disease, CNS structural abnormality).
- Feeding refusal (reflux or eosinophilic esophagitis, aspiration).

- Recurrent emesis.

INADEQUATE CALORIC ABSORPTION

- Necrotizing enterocolitis.
- Protein malabsorption (cow milk protein allergy, enterokinase deficiency).
- Pancreatic insufficiency (cystic fibrosis, chronic pancreatitis, Shwachman-Diamond syndrome).
- Liver disease.
- Celiac disease—See Chapter 60, Celiac Disease.
- GI tract infections.
- Carbohydrate malabsorption.
- Short bowel syndrome.
- Inflammatory bowel disease—See Chapter 59, Inflammatory Bowel Disease.

INCREASED CALORIC NEEDS

- Congenital heart disease—See Chapters 42 and 43, Acyanotic Congenital Heart Disease and Cyanotic Congenital Heart Disease.
- Chronic lung disease.
- Chronic systemic infection (congenital infections, HIV)—See Chapter 187, Congenital Infections.
- Chronic metabolic disorder (adrenal insufficiency, diabetes mellitus, hyperthyroidism, inborn errors of metabolism) (**Figures 53-4** and **53-5**).

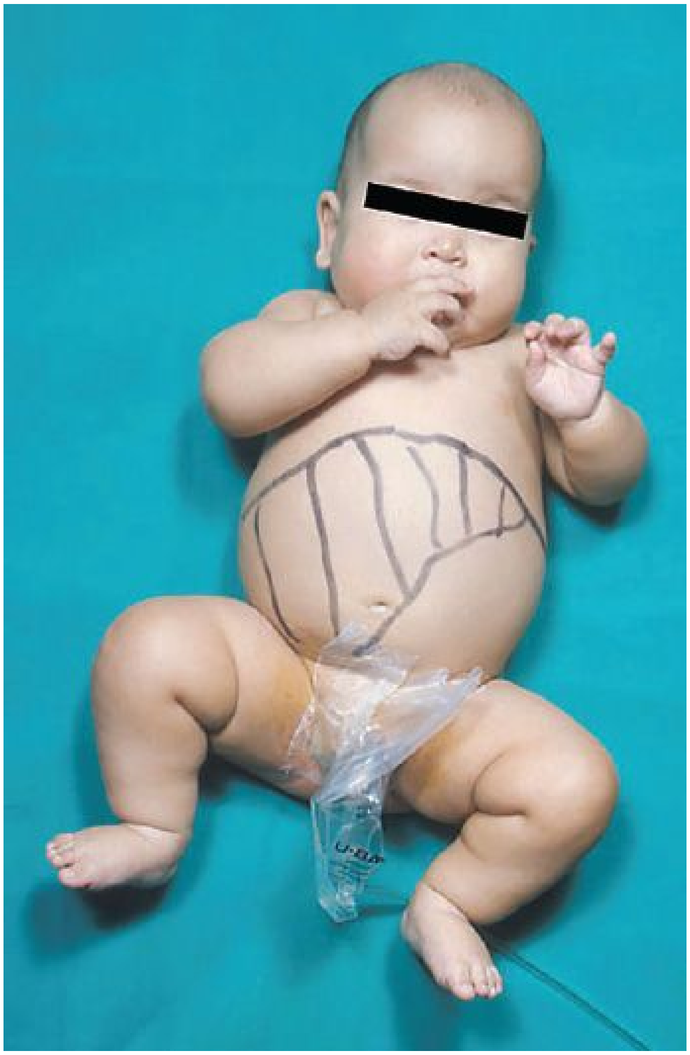

FIGURE 53-4 Hepatomegaly and growth failure in an infant who was found to have a glycogen storage disease. The presence of physical findings such as hepatomegaly should raise concern for an organic etiology for failure to thrive. (*Used with permission from Cleveland Clinic Children's Photo Files*.)

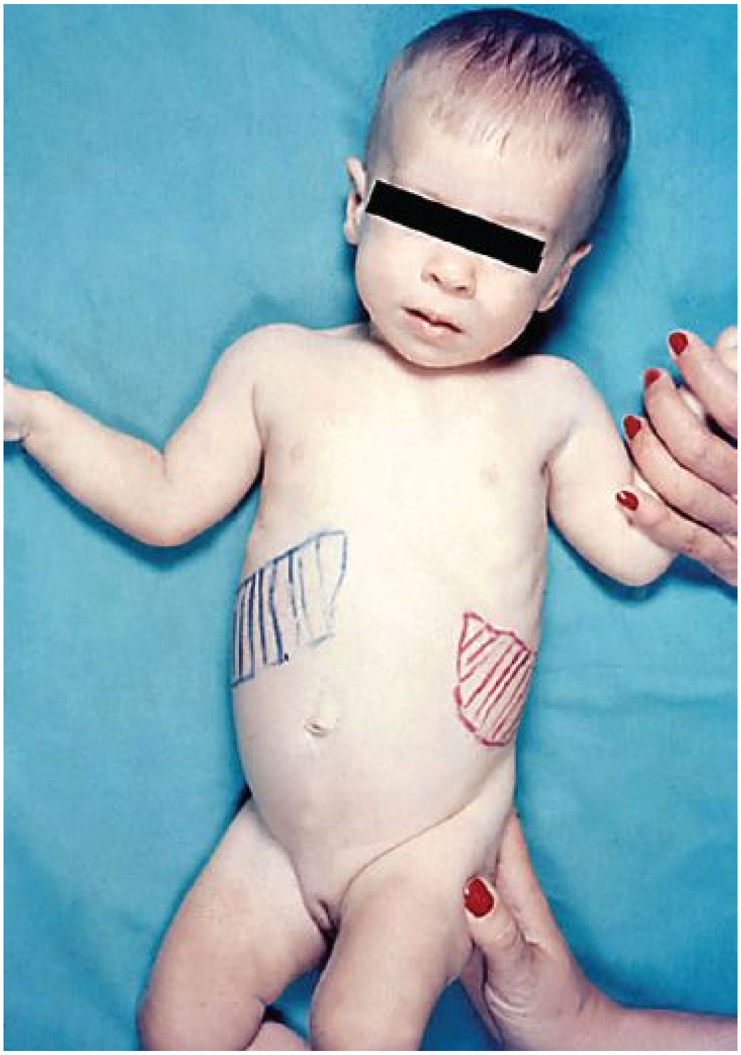

FIGURE 53-5 Hepatosplenomegaly and abdominal distension in a young infant who has severe developmental delay. This infant was diagnosed with Niemann-Pick syndrome, a lysosomal storage disorder. (*Used with permission from Cleveland Clinic Children's Photo Files*.)

- Kidney disease (renal tubular acidosis).
- Chronic systemic disease (systemic lupus erythematosus, juvenile idiopathic arthritis)—See Chapters 172 and 173, Juvenile Idiopathic Arthritis and Lupus—Systemic and Cutaneous.
- Malignancy.
- Inflammatory bowel disease—See Chapter 59, Inflammatory Bowel Disease.

- Genetic Syndromes (Trisomy 21, Turner, Russell-Silver syndromes)—See Chapters 221 to 228.

RISK FACTORS

- Hostile intrauterine environment (exposure to alcohol, illicit drugs, infection, anticonvulsants).
- Prematurity.
- Concomitant syndrome or congenital abnormality (cleft lip, cleft palate, congenital heart disease, etc.).
- Developmental delay.
- Any condition that interferes with adequate intake, interferes with intestinal absorption, or increases the underlying metabolic rate.
- Psychosocial factors including poverty, first born status of infant, poor parenting skills or feeding techniques, parental substance or physical abuse, or erroneous nutrition practices (administration of dilute formula, prolonged exclusive breastfeeding, and intentional caloric restriction due to fear of obesity).

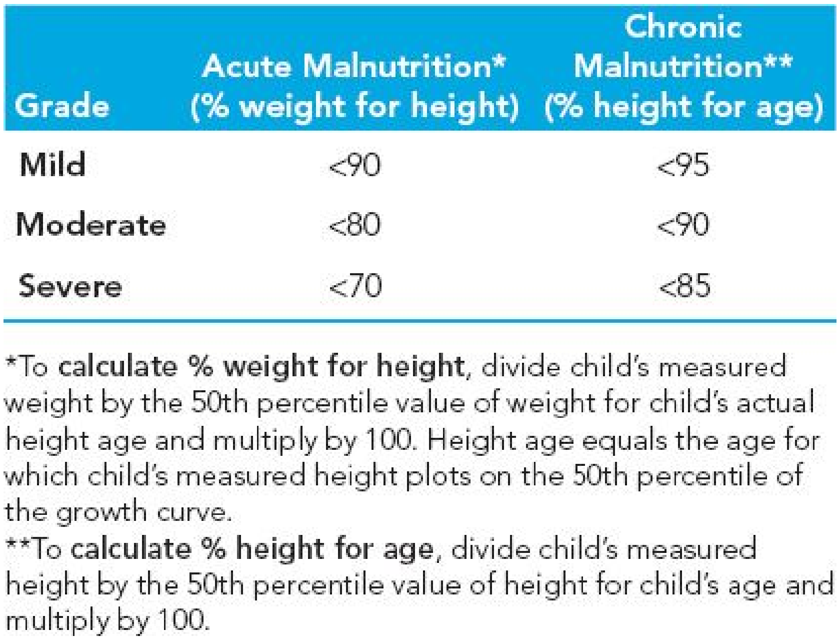
DIAGNOSIS

CLINICAL FEATURES

- Precise measurement of weight and length/height are essential.
- Common anthropometric criteria for FTT include:
    - Weight < 2nd percentile for gestation-corrected age and gender on > one occasion.
    - Weight < 80th percentile of ideal weight-for-age on a standard growth chart.

  - Weight to length ratio < 10th percentile.
  - Body mass index for age < 5th percentile.
- The World Health Organization growth charts should be used to assess the growth of children in the US under the age of 24 months.[3]
- Growth charts for prematurity should be used until 24 months.
- Genetic syndrome-specific (Achondroplasia, Cornelia de Lange Syndrome, Marfan Syndrome, Prader-Willi Syndrome, Rubinstein Taybi Syndrome, Trisomy 21, Turner Syndrome, Williams Syndrome) growth charts and special needs (Cerebral Palsy-Quadriplegic) growth charts exist and should be used.
- Growth standards for children < age 2 years are based on recumbent length; a stadiometer with fixed headboard and sliding footboard should be used.
- An accurate wall mounted stadiometer should be used for children ≥2 years of age.
- Degree of malnutrition is categorized by different systems as mild, moderate, severe (**Table 53-1**).[4]

TABLE 53-1 Grading of Malnutrition by Waterlow Classification[4]



Grade	Acute Malnutrition* (% weight for height)	Chronic Malnutrition** (% height for age)
Mild	<90	<95
Moderate	<80	<90
Severe	<70	<85

*To **calculate % weight for height**, divide child's measured weight by the 50th percentile value of weight for child's actual height age and multiply by 100. Height age equals the age for which child's measured height plots on the 50th percentile of the growth curve.

To **calculate % height for age, divide child's measured height by the 50th percentile value of height for child's age and multiply by 100.

- Decline in weight gain or height velocity due to underlying nutritional or endocrine etiologies need to be differentiated from constitutional causes (**Figure 53-6**).

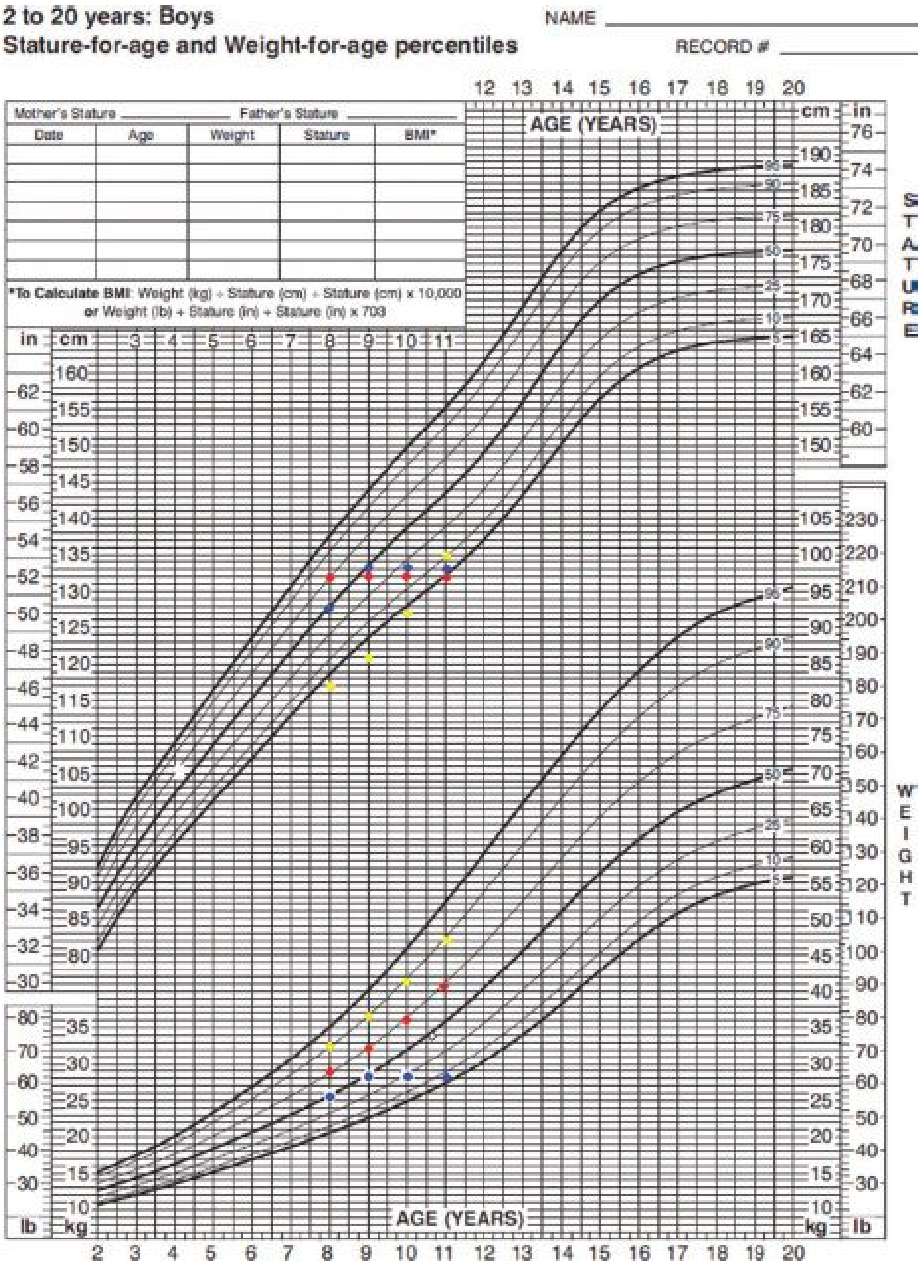


FIGURE 53-6 Typical growth curves seen in malnutrition (blue), growth hormone deficiency (red) and constitutional growth delay (yellow). (*Used with permission from Lori Mahajan, MD.*)

- A careful and detailed history, including dietary history, feeding history, medical/surgical history, family history, and social history should be obtained.
- The interaction between the parent and the child as well as attempted feeding should be observed.
- Careful physical examination may uncover findings that support an underlying condition (**Table 53-2**).[5]

TABLE 53-2 Physical Examination Red Flags in Evaluation of Failure to Thrive

LABORATORY TESTING

- Should be guided by the findings from the history and physical examination.

	Red Flag	Diagnostic Consideration
Vital Signs	Tachycardia	Anemia/increased metabolic demand
	Tachypnea	Pulmonary disease/infection
	Hypotension	Thyroid or adrenal insufficiency
	Hypertension	Renal or cardiac disease
General Appearance	Poor Hygiene	Neglect; limited resources
	Dysmorphic	Underlying genetic syndrome
Head	Microcephalic	Congenital infection, neurologic disorder, genetic syndrome
	Widened anterior fontanelle or delayed closure	Hypothyroidism, Hydrocephalus Vitamin D deficiency
	Alopecia	Thyroid disorder, fungal infection, systemic lupus erythematosus, diabetes mellitus, iron-deficiency anemia, vitamin A toxicity, trichotillomania
	Cataracts	Congenital infection, galactosemia
	Aphthous stomatitis	Crohn's disease
	Milk bottle carries	Neglect
	Horizontal brown lines on permanent teeth	Celiac disease
	Structural abnormalities: high arched or cleft palate, enlarged tongue, enlarged tonsils	Mechanical feeding impairment
	Drooling	Oromotor dysphagia
Neck	Thyroid enlargeçment	Thyroid disease
Lungs	Crackles, wheezes	Reactive airway disease, cystic fibrosis, chronic infection
Cardiovascular	Murmur	Congenital heart disease
	Digital clubbing	Cardiac disease, pulmonary disease or inflammatory bowel disease
Abdomen	Increased bowel sounds, distension	Malabsorption
	Hepatosplenomegaly	Primary liver or biliary disease, malignancy, glycogen storage disease
	Enlarged kidney(s)	Urinary obstruction, neuroblastoma
Rectal	Anal tags or fistula	Crohn's
	Empty vault with stool explosively expelled upon withdrawal of digit	Hirschsprung disease
Genitourinary	Ambiguous genitalia	Endocrinopathy
Neurologic	Accentuated deep tendon reflexes	Cerebral palsy, central lesion, hyperthyroidism
	Hypotonia	May cause ineffective latch
Skin/Nails	Bruising	Abuse
	Candidiasis	Immunodeficiency
	Orificial rash	Acrodermatitis enteropathica
	Nail spooning	Iron deficiency

- No standard laboratory studies recommended as the majority of studies in FTT are normal.
- If FTT persists despite nutritional intervention, a complete blood count, comprehensive metabolic panel, thyroid function tests, celiac panel, lead level, and a urinalysis may be obtained. Sweat chloride testing to rule out cystic fibrosis and pancreatic function tests may be indicated. Specific labs for macro- and micronutrient deficiencies should be based on physical findings.

IMAGING

- Recommended only if indicated by clinical history or examination.
- Studies that may be helpful include:
    - Pyloric ultrasound—To rule out pyloric stenosis in young infant with recurrent emesis.
    - Upper GI series—To rule out intestinal malrotation.
    - Modified barium swallow with speech pathologist present, gastric emptying scan.

DIFFERENTIAL DIAGNOSIS

- Most cases are due to psychosocial factors.
- Other considerations are listed under etiology and pathophysiology.

MANAGEMENT

NONPHARMACOLOGIC

- Treatment is customized according to identified physical, psychiatric, and socioeconomic contributing factors.

- A three day food diary may be required for assessment of baseline caloric intake.
- Age-appropriate nutritional therapy with close follow-up is advised if patient has inadequate intake for catch-up growth.
- Aggressiveness of repletion is dictated by the severity of malnutrition and can be managed in the outpatient setting in most cases.
- Inpatient observed feeding may be necessary when psychosocial contributing factors are suspected.
- For breastfed infants, frequent breastfeeding should be encouraged to stimulate milk production as well as consultation and close follow-up with a lactation consultant. Formula supplementation may be needed until catch-up growth has occurred.
- For formula-fed infants, information on how to concentrate the formula, and adding cereal or oils (vegetable, canola, or coconut) to increase caloric intake should be provided.
- For older children, adding butter, cream, oils, cheese, or peanut butter as dietary additives to increase the caloric density of foods and fluids should be attempted.
- Regularly scheduled outpatient and/or home visits should be arranged.
- Feeding techniques may need modified. If aspiration is a risk, feeds may need to be thickened and speech and occupational therapists consulted to work on swallowing techniques. Noises and distractions such as television may need removal during mealtime. Eating schedules need to be established with limits placed on snacks and length of times set for meals.

MEDICATIONS

- Medications should be prescribed for identified underlying medical conditions.
- Cyproheptadine is currently clinically used as an appetite stimulant for children with failure to thrive without underlying organic disease; however, no randomized control trials in this patient population have been completed to date. In a small trial, cyproheptadine was shown to be an

effective appetite stimulant with minimal side effects in children and adults with cystic fibrosis.[6] SOR B

SURGERY

- Some underlying anatomic/physiological etiologies for failure to thrive may be corrected surgically (e.g., pyloric stenosis, intestinal malrotation, Hirschsprung’s, etc.).
- If adequate calories cannot be safely or effectively consumed orally in the long term, consideration should be given to placement of a gastrostomy following a trial of nasogastric feeding. SOR C
- Central line placement may also be considered for parenteral nutrition if enteral feeds cannot be tolerated. SOR C

REFERRAL

- Multi-disciplinary approach is encouraged in the management of failure to thrive.
- Referral to Pediatric Gastroenterology, Pediatric Nutrition, and Social Work for persistent failure to thrive is important.
- Referral to other specialists is dependent on the etiology of failure to thrive.

PREVENTION AND SCREENING

- Appropriate anticipatory guidance, nutritional counseling, and close monitoring of the trend of the child’s growth chart at each well child visit may prevent some cases.
- Early consultation with pediatric dietician, social work, and home visiting nurse for ongoing evaluation and support for children/families of children at increased risk of failure to thrive.

PROGNOSIS

- Children with a history of failure to thrive are at increased risk for a recurrence.
- Nutritional deprivation in the infant and toddler age group can have permanent effects on growth and brain development.[7]

FOLLOW-UP

- Very close follow-up advised until catch-up growth has occurred. After catch-up growth achieved, follow-up should still occur 3 to 4 times per year for several years given the increased risk of recurrence.

PATIENT EDUCATION

- Parents should be educated early and often regarding appropriate nutrition for their children.
- Parents should also be educated on the importance of keeping well child visits.

54 ESOPHAGEAL DISORDERS: GASTROESOPHAGEAL REFLUX DISEASE AND EOSINOPHILIC ESOPHAGITIS

Sophia Ali, MD
Matthew Wyneski, MD

PATIENT STORIES

A 6-month-old boy presents with a history of gagging and emesis shortly after formula feedings. During these episodes, the child arches his back and becomes fussy according to his worried parents. His mother relates that the emesis is mostly partially-digested formula, and is non-bloody and non-bilious. These episodes occur 2 to 3 times per day, and the parents are very concerned because their child looks very uncomfortable during these episodes. His vital signs are stable. On physical exam, the pediatrician notes a well-nourished baby who is growing appropriately along the 50th percentile for all parameters, is happy and playful. The pediatrician diagnoses gastroesophageal reflux (**Figure 54-1**) and prescribes acid-suppression with an H2-blocker at a weight-appropriate dosing. His episodes of emesis, arching, and discomfort improve significantly.

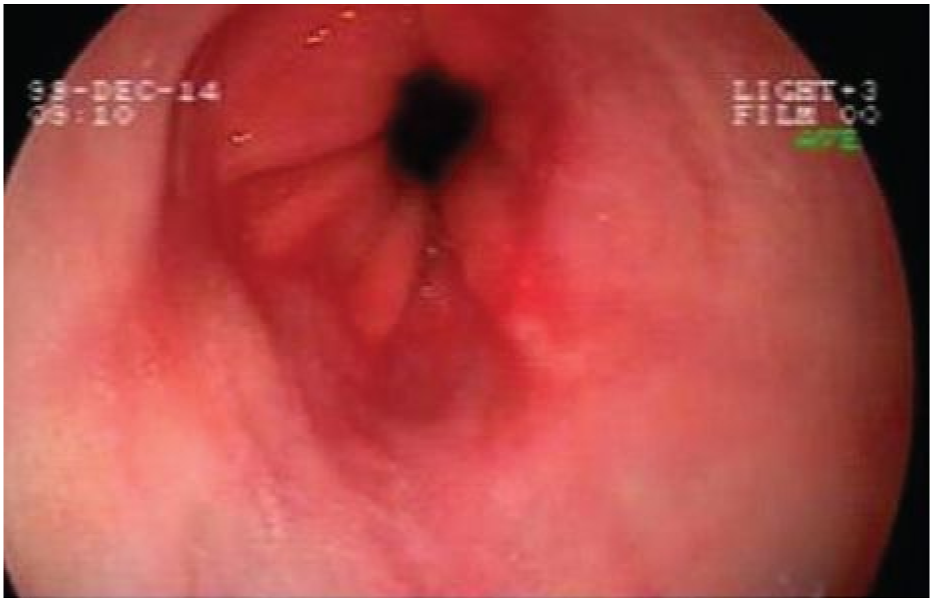

FIGURE 54-1 Reflux esophagitis seen on endoscopy. (*Provided by The NASPGHAN Foundation for Children's Digestive Health and Nutrition and the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition. www.naspghanfoundation.org and www.naspghan.org*.)

A 12-year-old boy presents with a chief complaint of "food sticking in his throat." He feels that it happens with several foods, and his mother states that his diet mostly consists of peanut butter sandwiches and steak. His past history is only significant for seasonal allergies. He feels that he has heartburn constantly. Trials of H2-blockers and proton pump inhibitors in the past resulted in little improvement of his symptoms. An endoscopy is performed and demonstrates white patches and concentric rings in the esophagus, with pathology results confirming a diagnosis of eosinophilic esophagitis (**Figures 54-2** and **54-3**).

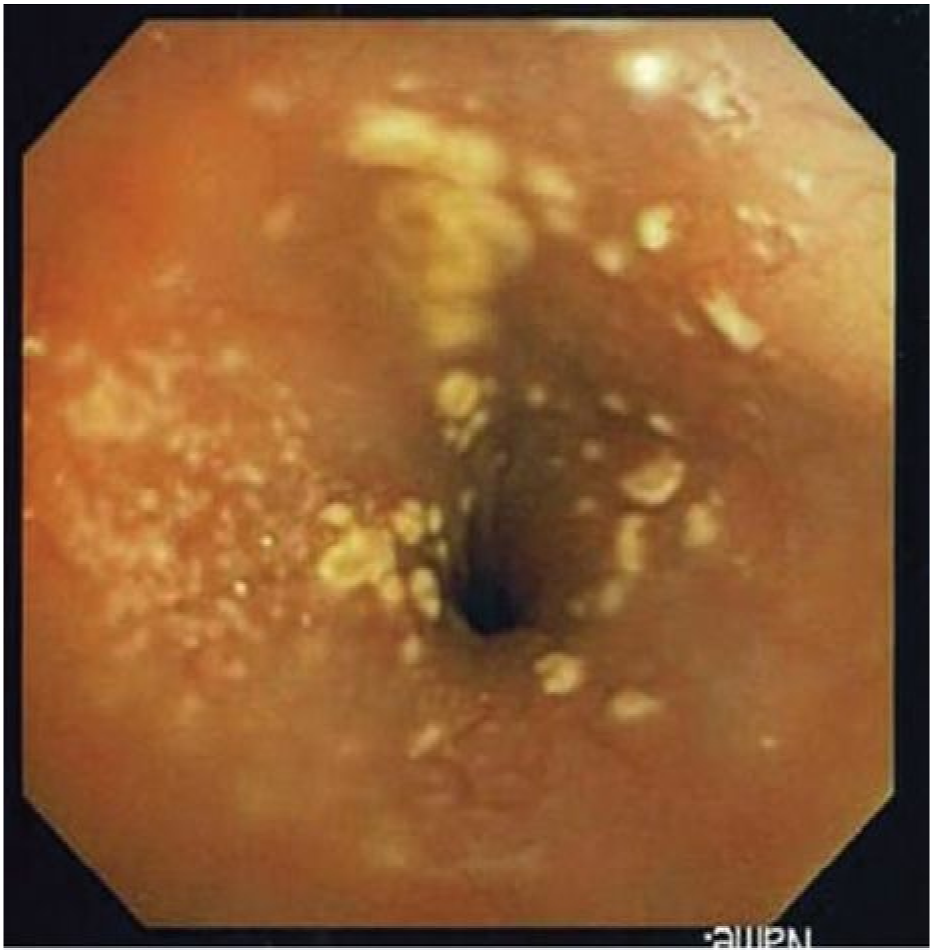

FIGURE 54-2 Classic eosinophilic microabscesses seen in the esophagus of a patient with eosinophilic esophagitis. (*Used with permission from Matthew Wyneski, MD.*)

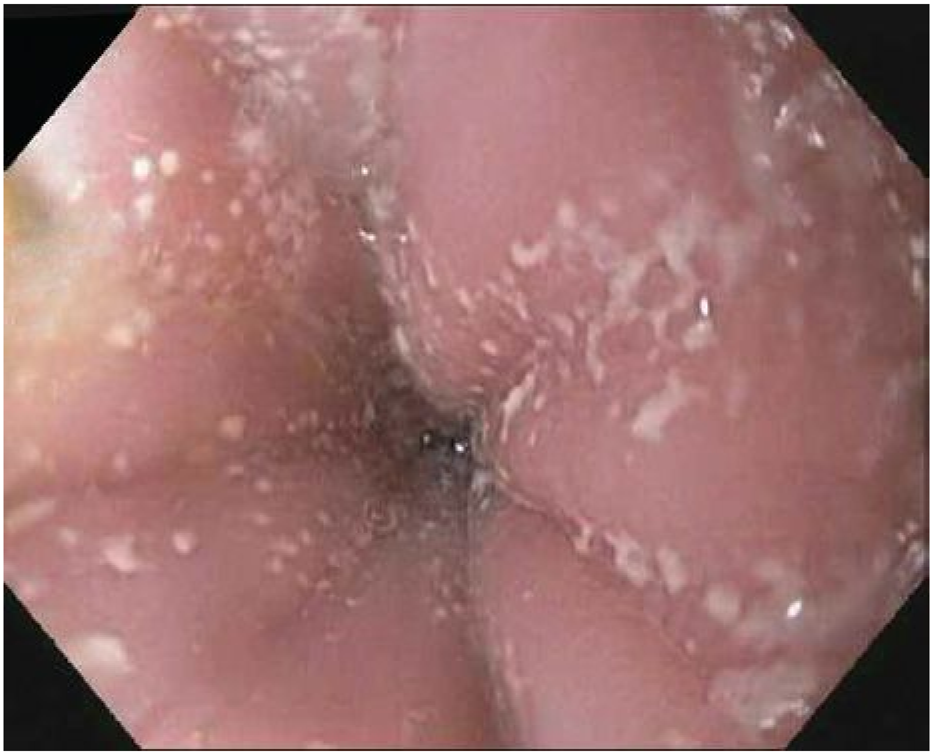

FIGURE 54-3 Microabscesses and trachealization (concentric esophageal rings) in a patient with eosinophillic esophagitis. (*Used with permission from Jonathan Moses, MD.*)

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a common pediatric problem in general practice. The manifestations and mechanisms of reflux vary between infants, children, and adolescents, and is brought to attention due to the discomfort it causes in all three age ranges. GERD is defined as the passage of gastric contents into the esophagus due to relaxation of the lower esophageal sphincter.

Eosinophilic esophagitis (EoE) is a Th-2 cell mediated immune disease which causes epithelial eosinophilia in the esophagus, leading to symptoms of dysphagia and reflux symptoms refractory to acid suppression.

SYNONYMS

Reflux, gastroesophageal reflux, acid reflux, heartburn.
Eosinophilic gastroenteritis.

EPIDEMIOLOGY

- Approximately 50 to 67 percent of infants aged 3 to 4 months have reflux as reported by parents.[1]
- Prevalence decreases to 5 percent at 12 months.[1]
- Approximately 7 to 8 percent of older children and adolescents experience reflux symptoms.[2]
- GERD is more common in children with neurologic impairment and has been reported in up to 77 percent in this population.[3]
- The estimated prevalence of EoE is reported in children to be around 1 in 10,000.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- Reflux results from inappropriate relaxation of the lower esophageal sphincter, allowing gastric juices and contents to reflux back into the esophagus.
- EoE is a chronic immune/antigen mediated disease which causes the build-up of eosinophils in the esophageal mucosa, leading to dysphagia, foreign body impaction, and refractory reflux symptoms.

RISK FACTORS

- Reflux risk factors include age, genetic predisposition, spicy foods, caffeine consumption, cigarette smoking, neurologic conditions such as cerebral palsy or seizure disorders, and Down Syndrome.
- EoE risk factors include other atopic diseases (asthma, eczema, or allergic rhinitis) as well as allergies to food antigens. Genetics also play a role in EoE; in 6.8 percent of cases, there is a family member with similar symptoms.[5]

DIAGNOSIS

CLINICAL FEATURES

- Reflux in infants—Regurgitation, hematemesis, feeding difficulties, wheezing or stridor, cough, apnea, irritability, and hoarseness.
- Reflux in children—Heartburn, emesis, dysphagia, chest pain, abdominal pain, persistent cough or wheezing, stridor, dental erosions, and hoarseness.
- EoE—Dysphagia, nausea, vomiting, retrosternal chest pain, regurgitation, food refusal, choking/gagging, throat pain, food impactions, or persistent reflux symptoms unresponsive to therapy.

DISTRIBUTION

- Both EoE and GERD are distributed in the esophageal regions, and reflux can manifest in the stomach as well.

LABORATORY TESTING

- For GERD, no specific laboratory workup is required.
- For EoE, eosinophilia on CBC or IgE testing is neither sensitive nor specific for the disease.
- May consider *Helicobacter pylori* stool antigen tests or breath testing when the diagnosis is not clear.

IMAGING/PATHOLOGIC TESTING

- Upper GI series may be performed to rule out other causes of emesis, including achalasia, hiatal hernia, malrotation, or gastric outlet obstruction, but should NOT be used to diagnose GERD.
- For reflux, esophageal pH impedance probe is the gold standard and can detect acid and nonacid reflux.
- Abdominal ultrasound can rule out pyloric stenosis, pancreatitis, and gallstones.
- Gastric emptying study can detect esophageal reflux, aspiration, gastroparesis, or gastric outlet obstruction; however, specificity ranges are not as high as pH impedance probe.[6]
- Endoscopy can reveal reflux esophagitis (**Figure 54-1**) but is usually performed to rule out other causes that can mimic reflux, such as stricture, peptic ulcer disease, and infectious esophagitis.
- In EoE, endoscopic biopsies demonstrating > 15 eosinophils per high-powered field are diagnostic (**Figure 54-4**).

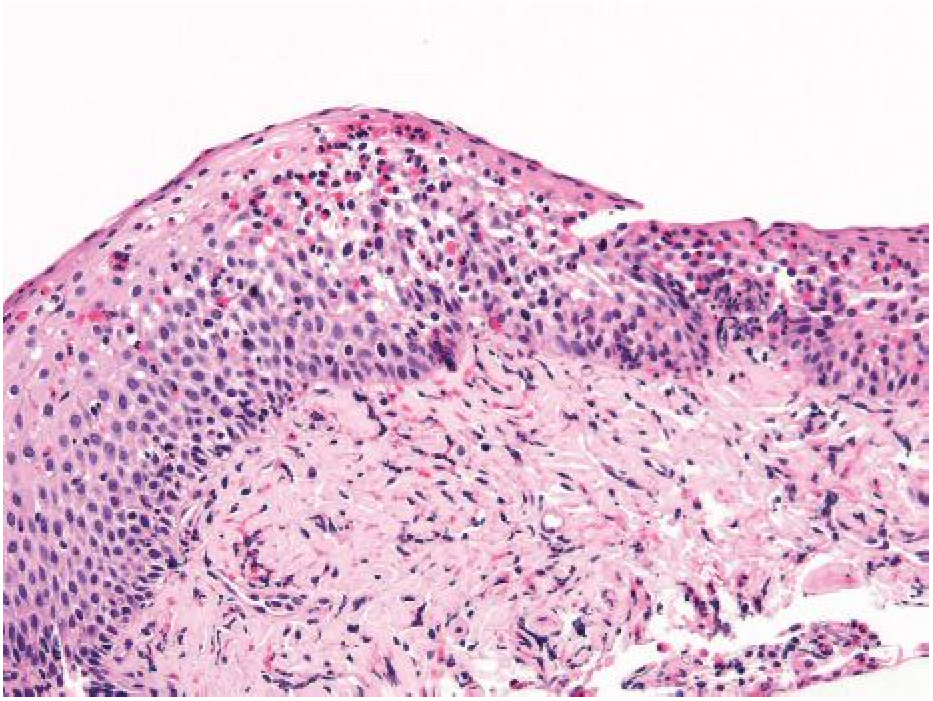

FIGURE 54-4 Eosinophilic infiltration characteristic of eosinophilic esophagitis. (*Used with permission from Thomas Plesec, MD.*)

DIFFERENTIAL DIAGNOSIS

- Malrotation—Usually presents acutely with bilious vomiting and ill appearance.
- *H. pylori* infection—Can mimic symptoms of reflux but contributes to peptic ulcer disease (see Chapter 55, Peptic Ulcer Disease).
- Foreign body impaction—May mimic EoE, but history and acuity are helpful in differentiating from EoE.
- Pyloric stenosis—Presents very early in life with projectile vomiting (see Chapter 57, Pyloric Stenosis).
- Pancreatitis—Usually associated with more severe abdominal pain.
- Celiac Disease—Often presents with growth abnormalities along with the gastrointestinal symptoms (see Chapter 60, Celiac disease).

- Inflammatory Bowel Disease—Usually can be differentiated on the severity of symptoms and growth disturbances (see Chapter 59, Inflammatory Bowel Disease).
- Spinal muscular atrophy syndrome—Presents early in life with generalized weakness.

MANAGEMENT

NONPHARMACOLOGIC

- For reflux, recommendations include lifestyle modifications include avoiding spicy foods, caffeinated beverages, chocolate, high-fat foods, overuse of non-steroidal anti-inflammatory drugs, acidic foods, juices, and carbonated beverages.[1,2] SOR Ⓐ
- For infants with reflux, propping up for 30 minutes after feeds and starting rice cereal or oatmeal at 4 months do not decrease esophageal acid exposure but do decrease the frequency of regurgitation.[7]
  - For eosinophilic esophagitis, avoiding foods that are allergen inducing, including peanuts, soy, eggs, and milk.[8] SOR Ⓑ
  - Eosinophilic esophagitis has also been shown to respond well to an elemental diet with nasogastric feedings of amino acid based formula.[8] SOR Ⓑ

MEDICATIONS

▶ Reflux

- Reflux medications are indicated when dietary modification and non-pharmacologic therapy are not sufficiently controlling symptoms.
- Options for medical therapy include:
  - Proton pump inhibitors, including omeprazole, lansoprazole, and esomeprazole.

        - Work to block H2-Na-K ATPase and stop acid production by parietal cells.
        - Side effects include headache, nausea, and diarrhea.
    - Histamine H-2 blockers, including famotidine and ranitidine.
        - Bind to H-2 receptors in the parietal cell in the stomach and block acid production.
        - Generally less effective than proton pump inhibitors.
        - Side effects include headaches and irritability.
    - Prokinetic agents including erythromycin and metoclopramide (Reglan):
        - Cause stomach to empty more rapidly.
        - Erythromycin is associated with hypertrophic pyloric stenosis in infants, and with prolonged QT syndrome in older children.
        - Metoclopramide may cause extrapyramidal side effects including tardive dyskinesia.
    - Sucralfate is a topical agent that contains sucrose, sulfate, and aluminum.
        - Binds to eroded regions of the stomach and is used more often for gastric ulcers than GERD or EoE.
        - Side effects include aluminum toxicity and bezoar formation.
    - Antacids (liquid or chewable forms) to decrease acid production may be used in older children. These may contain calcium, magnesium, or aluminum as the active ingredient.
        - Aluminum-containing antacids should be used with caution, as they have been associated with osteopenia, rickets, microcytic anemia, and neurotoxicity.

▶ Eosinophilic esophagitis

- Budesonide or fluticasone.[9] SOR Ⓑ
    - Liquid preparation mixed with honey or sugar taken orally to coat the esophagus.
    - Inhaled preparation is administered into the mouth and swallowed.
- Elemental diet has been shown to decrease EoE; however, this is very restrictive and difficult to implement.[8] SOR Ⓑ

- Elimination of food allergens has also proven effective.[8] SOR B

SURGERY

- Fundoplication is only considered for the most refractory cases of GERD as it is major surgery with significant risks. SOR C
  - Fundoplication can now be performed with laparoscopy. This procedure increases the lower esophageal sphincter pressure and elongates the esophagus.
  - Risk of complications is as high as 10 percent postoperatively.[6]
  - Prospective trials needed to explore success of fundoplication surgery.

PREVENTION AND SCREENING

- Prevention in infants and children can be achieved with proper and frequent burping, sitting child up for 30 minutes following feeds, and propping infant up at an angle when lying.
- In older children and adolescents, dietary changes are most effective in preventing reflux.
  - Avoiding caffeinated beverages, chocolate, acidic foods, spicy foods, and juices can be effective.
- For EoE, prevention of symptoms can be achieved by avoiding allergenic foods and transitioning to an elemental diet if needed.

PROGNOSIS

- Cases of Barrett’s esophagus have been reported in patients with EoE.[4]
- Reflux generally resolves by 9 to 12 months of age in infants.[6]

- Severe GERD can lead to complications including Barrett's esophagus, esophagitis, adenocarcinoma, and esophageal strictures.[6]
- Treatment with proton-pump inhibitors and topical corticosteroid therapy can improve long-term outcome of EoE.

PATIENT EDUCATION

- Advise and encourage patients and their parents to follow recommended dietary and positional changes to improve symptoms, and correct other predisposing factors.

55 PEPTIC ULCER DISEASE

Mindy A. Smith, MD, MS
Hend Azhary, MD

PATIENT STORY

A 10-year-old boy is brought in by his mother because of several episodes of vomiting. The most recent episode was small volume and had some brown-colored material in it. The boy tells you that he has had stomach pain off and on in the past few months and feels nauseated. He has not been having difficulty in school but his mother tells you that they will likely need to move soon as his father lost his job recently and has been unable to find work. The patient is the oldest of the 3 boys and shares a room with his brothers. He worries about his dad and hopes that he will be able to stay at his school. You discuss your concerns and recommend that the patient undergo esophagogastroduodenoscopy (EGD). His mother states that the children have health insurance through a state program and agrees to the testing. You start the patient on generic ranitidine. His EGD reveals a small pyloric ulcer and the biopsy specimens test positive for *Helicobacter pylori* (**Figure 55-1**). You prescribe 10 days of triple therapy with bismuth salts, amoxicillin, and metronidazole as the child’s insurance does not cover the more expensive alternative medications.

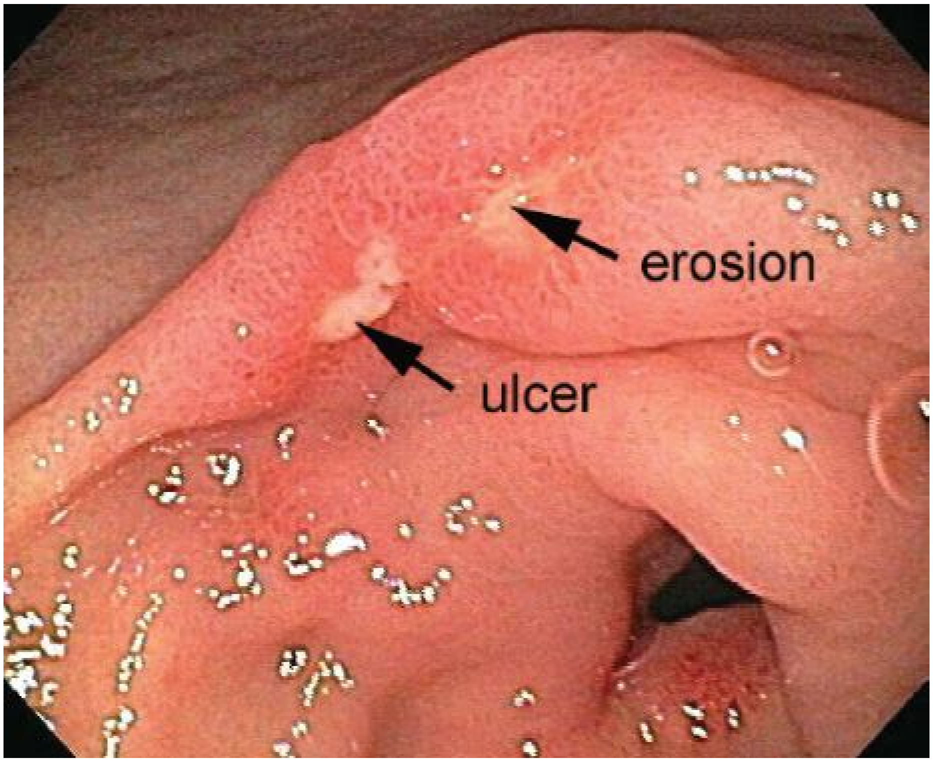

FIGURE 55-1 Endoscopic view of a pyloric ulcer and an erosion of the mucosa. (*Used with permission from Marvin Derezin, MD.*)

INTRODUCTION

Peptic ulcer disease (PUD) is a disease of the gastrointestinal (GI) tract characterized by a break in the mucosal lining of the stomach or duodenum secondary to pepsin and gastric acid secretion; this damage is greater than 5 mm in size and with a depth reaching the submucosal layer.[1] PUD can be either primary or secondary; the latter most often due to severe systemic illness (e.g., sepsis) or from ulcerogenic drug ingestion (e.g., nonsteroidal antiinflammatory drugs (NSAIDs) or steroids).

EPIDEMIOLOGY

- PUD is a common disorder affecting approximately 4.5 million people annually in the US. It encompasses both gastric and duodenal ulcers (**Figures 55-1** to **55-4**).[2]
- One-year point prevalence is 1.8 percent, and the lifetime prevalence is 10 percent in the US.[2]
- Prevalence is similar in both sexes, with increased incidence with age.[1]
- PUD is less common in children. In an Israeli study of 751 symptomatic children referred for endoscopy, peptic ulcers were found in 51 patients (6.8%).[3] *H. pylori* was positive in 112 (66.3%) patients and *H. pylori*-associated ulcers were more common in children older than age 10 years. A similar rate was demonstrated in a Chinese case series where 43 of 619 children (6.9%) undergoing upper endoscopy for investigation of upper gastrointestinal symptoms had primary PUD.[4] Authors of an Italian study (N = 2234 endoscopies in children) reported a lower rate of 3.4 percent positive endoscopies for PUD, rates similar to those reported in older endoscopy studies performed on symptomatic children (1.8% to 3.6%).[5] This is in somewhat less than the 8 percent prevalence of PUD in adults with dyspepsia who undergo endoscopy.[6]
- Rates of non-*H. pylori*-associated ulcers and erosions appear to be increasing among children.[7]
- Utilizing a US inpatient pediatric database (2008), the estimated incidence of peptic ulcer bleeding ranged from 0.5 to 4.4/100,000 individuals, with a total number of cases between 378 and 3250.[8]

ETIOLOGY AND PATHOPHYSIOLOGY

- Causes of PUD include:
    - Nonsteroidal antiinflammatory drugs (NSAIDs), chronic *H. pylori* infection, and acid hypersecretory states such as Zollinger-Ellison syndrome.[2]

  - Uncommon causes include *Cytomegalovirus* (especially in transplant recipients), systemic mastocytosis, Crohn disease (**Figures 55-3** and **55-4**), lymphoma, and medications other than NSAIDs (e.g., alendronate).[2]
  - Children with chronic renal failure (CRF) have been shown to have high basal levels of gastrin; in one study of children with CRF on continuous ambulatory peritoneal dialysis (N = 19), almost three quarters had abnormal upper gastrointestinal endoscopic findings including hemorrhagic gastritis or gastroduodenitis, gastric nodular gastritis, and polyps.[9]

- In a 5-year Canadian retrospective study of children admitted to a tertiary care center with PUD (N = 36, aged 3 months to 17 years), about half the cases were secondary; most of these resulting from severe underlying illness (11/17).[10] All children under age 10 years had secondary PUD.

- Infection with *H. pylori*, a short, spiral-shaped, microaerophilic Gram-negative bacillus, occurs in about half of the world's population and is the leading cause of PUD in adults. *H. pylori* infection is associated with up to 70 to 80 percent of duodenal ulcers in adults.[2] In patients who do not use NSAIDS, infection rates are lower at about 60 percent of those with ulcers.[11]

- *H. Pylori* infection is also associated with iron-deficiency anemia, gastric ulcer, gastric mucosa-associated lymphoid tissue (MALT) lymphoma, and distal gastric cancer.[12] In one study of school-aged Andean children, chronic *H. Pylori* infection was associated with slowed growth (0.022 cm/month [95% confidence interval 0.008 to 0.035] slower than H. pylori-negative children).[13]

- The role of *H. Pylori* infection in childhood PUD is unclear as infection less frequently causes clinical disease in this population. It is estimated that, at adolescence, approximately 65 percent of children in developing countries (range 7% to 87%) are infected with *H. pylori*.[12] Vertical transmission appears to occur, although maternal *H. pylori* IgG transfer may be protective.[14]

- In an older retrospective study of 40 children endoscopically diagnosed with gastritis, gastric ulcer, or duodenal ulcer, *H. pylori* was found in about half (48%) and was more commonly detected among those with primary gastritis (88%) than either primary (22%) or secondary (50%) duodenal ulcers.[15] This is similar to the rate of 53.5 percent *H. pylori*-positive PUD found in the Chinese study[4] but lower than rates reported in older studies where 73 to 80 percent of childhood peptic ulcers were associated with either NSAIDs or *H pylori*.[16,17]

- In a more recent European study of 518 children aged 1 to 14 years with *H. pylori* infection, 454 children (87.6%) had endoscopically proven gastritis and only 64 had an ulcer (12.3%).[5] Ulcer disease, however, was more common among Russian children in this sample than the remainder of European children (35% versus 6.7%, respectively).
- *H. pylori* colonize the deep layers of the gel that coats the mucosa and disrupt its protective properties causing release of certain enzymes and toxins. These make the underlying tissues more vulnerable to damage by digestive juices and thus cause injury to the stomach (**Figures 55-1** and **55-2**) and duodenum cells (**Figures 55-3** and **55-4**).[1] One theory is that children's developing immune system mounts a lesser inflammatory response reducing the risk of disruption to the gastric mucosa.[12] In the Chinese case series, all children with *H. pylori* disease had evidence of chronic active gastritis on the biopsy specimens.[4]

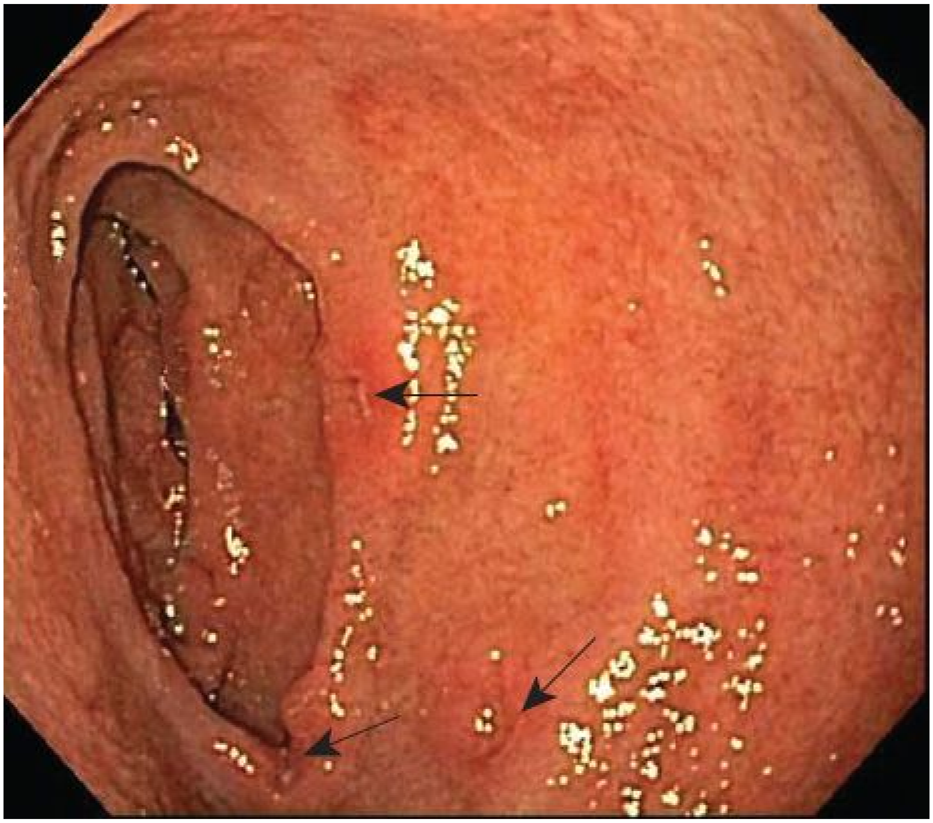

FIGURE 55-3 Several focal, deep ulcers (arrows) noted in the second portion of the duodenum in a patient with Crohn disease. (*Used with permission from Jonathan Moses, MD.*)

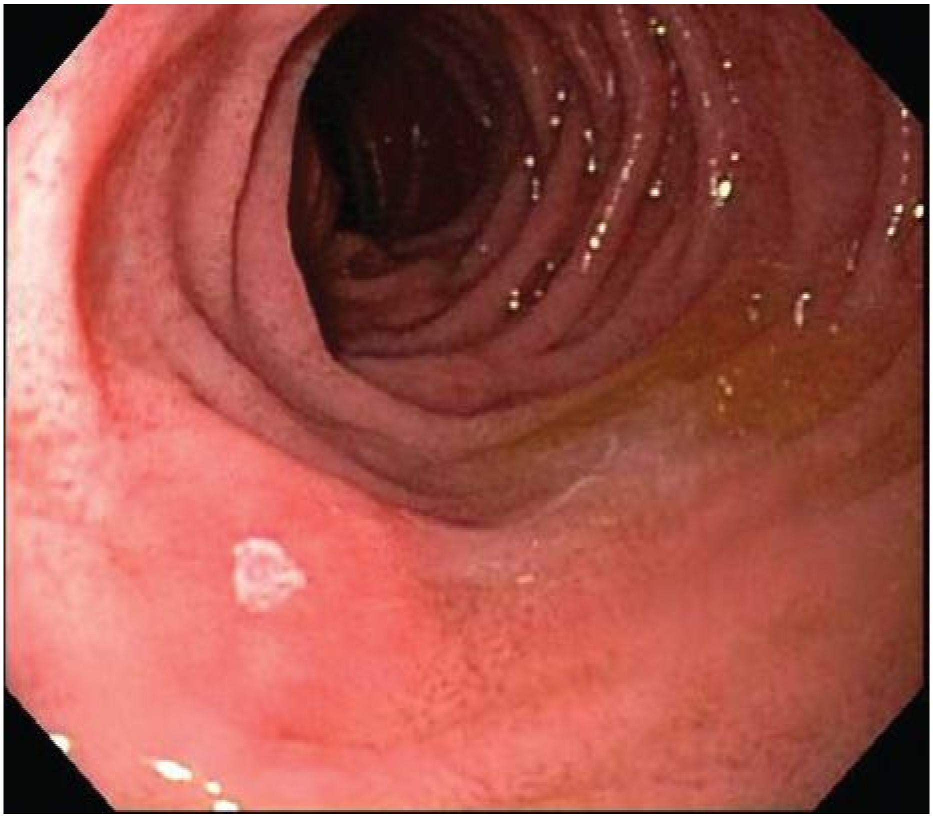

FIGURE 55-4 Solitary, large ulceration noted in the second portion of the duodenum in a patient with Crohn disease. (*Used with permission from Jonathan Moses, MD.*)

- NSAIDs are the second most common cause of PUD in adults and account for many *H. pylori*-negative cases. NSAIDs and aspirin inhibit mucosal cyclooxygenase activity reducing the level of mucosal prostaglandin causing defects in the protective mucous layer.
- There is a 10 to 20 percent prevalence of gastric ulcers and a 2 to 5 percent prevalence of duodenal ulcers in long-term NSAID users.[2] The annual risk of a life-threatening ulcer-related complication is 1 percent to 4 percent in long-term NSAID users, with older patients having the highest risk.[18]
- Polymorphisms of IL-1 gene cluster are associated with histological changes and IL-1b expression in the gastric mucosa in adults and children. In one study of Chinese children with peptic symptoms (N = 128), 60.7 percent of children with moderate or severe gastritis or gastric ulcer had the IL-1B-511TT/-31CC genotype.[19]

RISK FACTORS

- Severe physiologic stress—Burns, central nervous system trauma, surgery, and severe medical illness increase the risk for secondary (stress) ulceration.[11]
- Childhood physical abuse—In a Canadian population study, childhood physical abuse, reported by 1020 individuals (7.3%), was associated with diagnosed peptic ulcers (6.6% of those reporting abuse versus 2.7% of those not reporting abuse [OR 1.68; 95% CI 1.22-2.32]).[20]
- Smoking—Evidence that tobacco use is a risk factor for duodenal ulcers in not conclusive, with several studies producing contradictory findings. However, smoking in the setting of *H. pylori* infection may increase the risk of relapse of PUD.[21] A recent US population study reported an odds ratio (OR) of 1.99 for current and 1.55 for former tobacco use.[22]
- Alcohol use—Ethanol is known to cause gastric mucosal irritation and nonspecific gastritis. Evidence that consumption of alcohol is a risk factor for duodenal ulcer is inconclusive.[21] The preceding population study reported an OR of 1.29 for former alcohol use.[22]
- Medications—Corticosteroids alone do not increase the risk for PUD; however, they can potentiate ulcer risk in patients who use NSAIDs concurrently.[11]
- Other risk factors for gastrointestinal ulcers include, African-American race (OR 1.20), obesity (OR 1.18), chronic renal insufficiency (OR 2.29), and three or more doctor visits in a year (OR 1.49).[22] There appears to be an association between duodenal ulceration and celiac disease.[23]
- Risk factors for *H. pylori* infection include socioeconomic factors such as lower family income, household crowding, number of children sharing the same room, parents’ education, and sharing a bed with children.[12]

DIAGNOSIS

CLINICAL FEATURES

- Symptoms of *H. pylori*-related PUD in children are nonspecific and include epigastric pain, nausea and/or vomiting, anorexia, iron deficiency anaemia, and hematemesis.[12]
- In the Chinese case series, thirty children (70%) presented with acute gastrointestinal bleeding and only 19 had a history of epigastric pain.[4] This was not true in either the study of Italian children where only 21 percent with *H. pylori*-positive PUD had acute bleeding (eight required emergency surgery)[5] or the Canadian study where only one child with primary PUD required emergency surgery.[10] These figures are similar to a 10-year US study of 61 children with PUD of whom 31 had primary PUD, most commonly presenting as abdominal pain or bleeding; in this study, one third required surgery for intractable pain, perforation, or massive recurrent hemorrhage.[24]
- Reported differences between *H. pylori*-positive and *H. pylori*-negative PUD in children include male predominance, older age at presentation, and lower recurrence rates in the former.[5]

TYPICAL DISTRIBUTION

- Most duodenal ulcers occur in the first portion of the duodenum.[1] In the Chinese case series, most children had duodenal ulcers (N = 37/43) with 30 (81%) occurring in the first portion of the duodenum.[4] In the Canadian study, duodenal ulcers were nearly three times more common than gastric ulcers.[10]
- Of the six gastric ulcers found in the Chinese study, four were central and two were pyloric.[4]

LABORATORY STUDIES

- Routine laboratory tests are not helpful in most patients with uncomplicated PUD.[11]
- Noninvasive tests include serum *H. pylori* antibody detection, fecal antigen tests, and ^{13}C-urea breath tests (C-UBT); the latter two, if positive, indicate active disease.[25] Although a large number of high quality pediatric studies have demonstrated high accuracy, sensitivity and specificity of C-UBT and stool antigen testing, a positive test does not confirm or exclude the presence of an ulcer, gastritis or other pathology and endoscopy continues to be standard care in children with suspected PUD.[12]
- Evidence-based guidelines from the European and North American Societies of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN and NASPGHAN) do not recommend testing for *H. pylori* infection in children with functional abdominal pain, as infection has not been shown to be associated with recurrent abdominal pain[12] and the primary goal of clinical investigation is to determine the underlying cause of the gastrointestinal symptoms and not solely the presence of *H. pylori* infection.[26]
    - Testing for *H. pylori* infection should be considered in children with first-degree relatives with gastric cancer and those with refractory iron-deficiency anemia.[26] SOR Ⓒ
    - For children undergoing esophagogastroduodenoscopy (EGD), gastric biopsies (antrum and corpus) for histopathology should be obtained for the diagnosis of *H. pylori* infection.[26] However, initial diagnosis of *H. pylori* infection can be based on either positive histopathology + positive rapid urease test or a positive culture. SOR Ⓑ
    - The ^{13}C-urea breath test (SOR Ⓐ) or stool antigen test (SOR Ⓑ) can be used to determine whether *H. pylori* has been eradicated.[26]
- In a prospective cohort study of 50 symptomatic children aged 2 to 18 years, invasive rapid urease test (via endoscopy with gastric biopsy) combined with non-invasive serology was the optimum approach to the diagnosis of *H. pylori* infection in symptomatic children.[27]
- Serum enzyme-linked immunosorbent assay (ELISA) is the least accurate test and is useful only for diagnosing the initial infection.

- Serum gastrin testing may be useful in patients with recurrent, refractory, or complicated PUD and in patients with a family history of PUD to screen for Zollinger-Ellison syndrome.[1]

IMAGING

- Upper endoscopy is the procedure of choice for the diagnosis of duodenal and gastric ulcers (**Figures 55-1** to **55-4**).[2]
- Endoscopy provides better diagnostic accuracy than barium radiography and affords the ability to biopsy for the presence of malignancy and *H. pylori* infection. Endoscopy is usually reserved for the following situations:[18]
- Patients with red flag signs (e.g., bleeding, dysphagia, severe pain, abdominal mass, recurrent vomiting, weight loss).
    - Patients who fail initial therapy.
    - Patients whose symptoms recur after appropriate therapy.
- Barium upper gastrointestinal (UGI) series is an acceptable alternative to endoscopy but is not as sensitive for the diagnosis of small ulcers (<0.5 cm) and does not allow for biopsy with gastric ulcer.[25]

DIFFERENTIAL DIAGNOSIS

Disease processes that may present with “ulcer-like” symptoms include:

- Nonulcer or functional dyspepsia (FD)—The most common diagnosis among patients seen for upper abdominal discomfort; it is a diagnosis of exclusion. Dyspepsia has been reported to occur in up to 30 percent of the US population.
- Recurrent abdominal pain of childhood (RAP)—Also a diagnosis of exclusion, defined as three episodes of abdominal pain occurring in the space of three months, severe enough to affect daily activities. Associated

with stressful life events, proposed etiologies include gastrointestinal motility disorders, food sensitivities/allergy, and abdominal migraine.[28]

- Gastroesophageal reflux—Classic symptoms are heartburn (i.e., substernal pain that may be associated with acid regurgitation or a sour taste) aggravated by bending forward or lying down, especially after a large meal. Endoscopy is considered if symptoms fail to respond to treatment (e.g., histamine-2-receptor agonist, proton pump inhibitor [PPI]) or red flag signs and symptoms occur; see Chapter 54, Esophageal Disorders).
- Gastroduodenal Crohn disease—Symptoms include epigastric pain, nausea, and vomiting. On endoscopy, patients often have *H. pylori*-negative gastritis or duodenal ulcers (**Figures 55-3** and **55-4**), and may develop gastric outlet obstruction. Extraintestinal manifestations include erythema nodosum, peripheral arthritis, conjunctivitis, uveitis, and episcleritis. Endoscopy shows an inflammatory process with skip lesions, fistulas, aphthous ulcerations, and rectal sparing. Small bowel involvement is seen on imaging with longitudinal and transverse ulceration (cobblestoning) in addition to segmental colitis and frequent stricture (see Chapter 59, Inflammatory Bowel Disease).

MANAGEMENT

- The approach to children with PUD includes use of H_2-receptor antagonists (e.g., cimetidine, ranitidine) and antibiotic treatment for *H. pylori* eradication when present.
- An early case series from Hong Kong using surveillance endoscopy demonstrated the effectiveness of 6-week therapy with H_2-receptor antagonists with complete ulcer healing in 22/29 children with duodenal ulcers and all 3 children with gastric ulcer.[29] Recurrence rates for duodenal ulcer (35%) were much lower for children on nightly maintenance therapy (1/9 versus 8/17). Ranitidine should be used with caution in low birthweight infants as use is associated with increased risk of infection, necrotizing enterocolitis, and mortality.[30]

- For all patients with PUD, counsel to avoid smoking, alcohol, and NSAIDs.
- The goals of treatment of active *H. pylori*-associated ulcers are to relieve dyspeptic symptoms, promote ulcer healing, and to eradicate *H. pylori* infection. Eradication of *H. pylori* is better than ulcer-healing drug therapy for duodenal ulcer healing[8] and greatly reduces the incidence of ulcer recurrence.
- First-line eradication regimens are: 12,26 SOR B
    - Triple therapy with a proton pump inhibitor [PPI] (1–2 mg/kg/day) + amoxicillin (50 mg/kg/day, maximum 2 g/day) + metronidazole (20 mg/kg/day, maximum 1 g/day) given twice daily for 10 to 14 days.
    - PPI + amoxicillin + clarithromycin (20 mg/kg/day) given twice daily for 10 to 14 days.
    - Bismuth salts (8 mg/kg/day) + amoxicillin + metronidazole.
    - Sequential therapy: PPI + amoxicillin for 5 days followed by PPI + amoxicillin + metronidazole for 5 days.
- The worldwide empiric use of traditional triple therapy with PPI, clarithromycin, and amoxicillin in adults no longer provides an acceptable cure rate (cure rate below 80%) because of the increasing prevalence of clarithromycin resistance.[9] For children, the ESPGHAN and NASPGHAN recommend antibiotic susceptibility testing for clarithromycin before initial clarithromycin-based triple therapy in areas/populations with a known high resistance rate (>20%) of *H. pylori* to clarithromycin.[26]
- If initial treatment for *H. pylori* fails, ESPGHAN and NASPGHAN recommend one of the following:[26]
    - EGD, with culture and susceptibility testing to guide therapy if not performed before initial treatment.
    - Fluorescence in situ hybridization (FISH) on previous paraffin-embedded biopsies if clarithromycin susceptibility testing has not been performed before initial treatment.
    - Modify therapy by adding an antibiotic (quadruple therapy), using different antibiotics (e.g. PPI, amoxicillin, levofloxacin [10 mg/kg/day,

maximum 500 mg/day]),[12] adding bismuth, and/or increasing dose (e.g., PPI at 2 mg/kg/day), and/or duration (14 days) of therapy.

- Fluoroquinolone resistance is an emerging problem in the adult population; levofloxacin should be cautiously used in children who were previously exposed to this drug.[12]
- Treat NSAID-induced ulcers with cessation of NSAIDs, if possible, and an appropriate course of standard ulcer therapy with a H_2-receptor antagonist or a PPI. If NSAIDs are continued, prescribe a PPI. SOR A

PREVENTION

- Authors of a metaanalysis found the use of prophylactic H_2 blockers to prevent stress ulcers in adults was not necessary in patients receiving enteral nutrition and that such therapy was associated with pneumonia and higher risk of hospital mortality.[31] In another metaanalysis of adult patients, PPIs were similar to H_2-receptor antagonists in terms of stress-related UGI bleeding prophylaxis, pneumonia, and mortality among patients admitted to intensive care units.[32]
- Because *H. pylori* infection is often acquired during childhood, a vaccine would be optimal for preventing many cases of gastritis and PUD. Thus far, however, human vaccine trials have shown only moderate effectiveness and adjuvant-related adverse effects.[12]

PROGNOSIS

- In the Canadian retrospective study, most children (67%) with primary duodenal ulcer disease had recurrent symptoms and 40 percent of them required surgery for intractable disease.[10] None of the children with secondary PUD had chronic or recurrent disease.

- In other studies, the recurrence rate of endoscopically-proven peptic ulcers in children was 43 percent within one year[33] and 47 percent among children monitored until adulthood.[34] In the more recent Chinese study, the annual ulcer recurrence rates were much lower at 5.2 percent (95% CI 4.2–6.3) for children with *H. pylori*-positive and 11.4 percent (95% CI 9.1–13.6) for children with *H. Pylori*-negative ulcers.[4] In this study, multivariate logistic regression suggested *H pylori*–negative status and ulcer size >1 cm were independent risk factors for recurrence.[4] As with adults, eradication of *H. pylori* infection dramatically reduces recurrence.[12]
- The incidence of perforation is approximately 0.3 percent per patient year and the incidence of obstruction is approximately 0.1 percent per patient year.[11]

FOLLOW-UP

- Although not recommended in adult patients with uncomplicated ulcers due to infection, confirmation of *H. pylori* eradication is recommended in children, preferably with C-UBT.[12,26] Stool sampling can be used for confirmation in small children in whom collecting breath samples is difficult. Based on adult studies, discontinue antibiotics for at least 4 weeks and acid-suppressive drugs, particularly PPIs, for at least 2 weeks prior to testing.[12]
- Persistent *H. pylori* infection requires additional treatment.
- Children with non-*H. pylori* PUD with continued symptoms should be considered for maintenance antisecretory therapy.

PATIENT EDUCATION

- Patients with PUD should be encouraged to eat balanced meals at regular intervals, avoid alcohol use, smoking, and NSAIDs; stress reduction counseling might be helpful in individual cases.
- Parents should be advised to contact their health provider if their child experiences sudden sharp, persistent pain, bloody/tarry stools, or bloody or coffee ground emesis.

56 FOREIGN BODY INGESTION

Eugene K. Vortia, MD
Lori A. Mahajan, MD

PATIENT STORY

A 2-year-old boy presented to his primary care physician’s office with decreased oral intake and cough of 4 days duration. He had been very irritable with a markedly decrease in intake of solids. He was seen in an urgent care 2 days prior and was discharged home with a prescription for an antibiotic but his symptoms did not improve. On examination, he had a low-grade fever with increased oral secretions and transmitted upper airway sounds but no localized wheezing. A chest radiograph performed to assess for pneumonia revealed a coin in the proximal esophagus (**Figure 56-1**). Due to increased oral secretions and the duration of symptoms, he was referred for immediate endoscopy. The coin was removed with ulceration of the underlying esophageal mucosa at the site of impaction noted. Oral intake soon returned to normal. He was prescribed a 1-week course of sucralfate with no long-term complications noted.

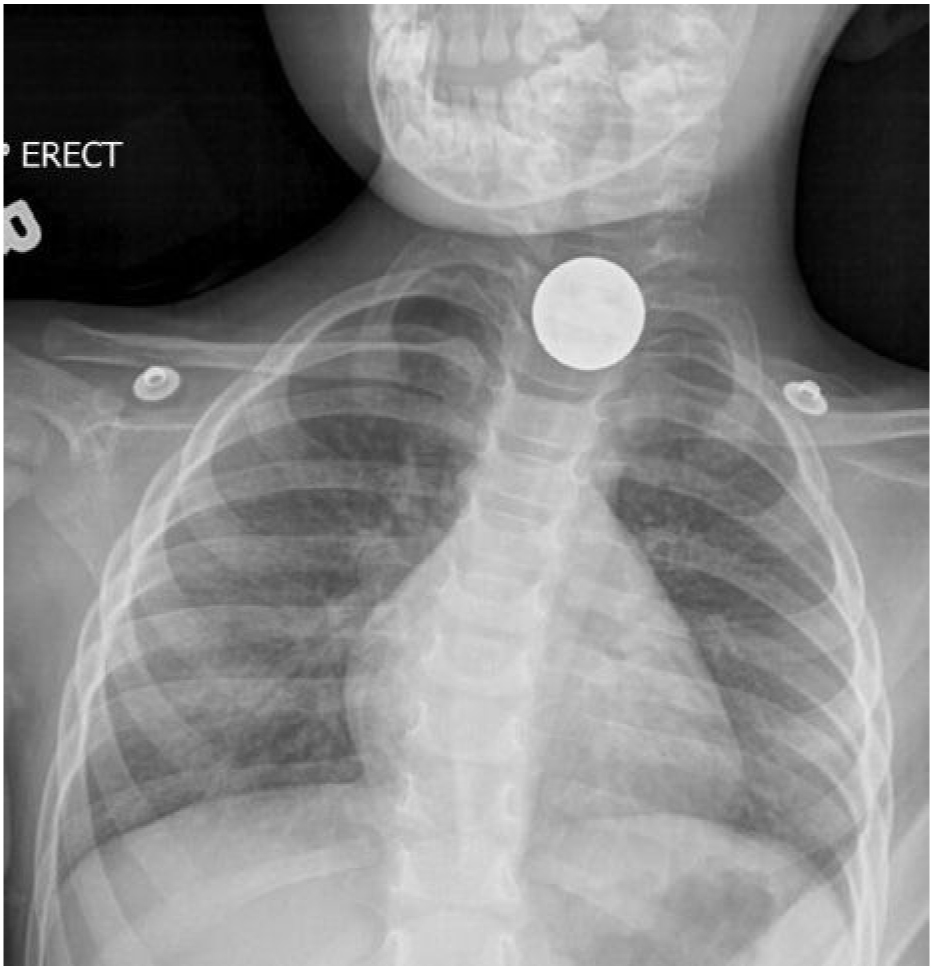

FIGURE 56-1 Coin in the proximal esophagus of a 2-year-old boy (AP view). It was causing a cough over the previous 4 days. It was impacted at the upper esophageal sphincter. (*Used with permission from Eugene Vortia, MD.*)

INTRODUCTION

- Foreign body ingestion is a frequent cause of emergency room visits in children and is accidental in most cases. Fortunately, 90 percent of ingested foreign bodies pass spontaneously without complication. Most children with an impacted foreign body have no underlying gastrointestinal anomalies. Food is classified as a foreign body when it leads to impaction, particularly in the esophagus. Steak, hotdogs, and chicken are the primary cause of esophageal foreign body impaction in teenagers and adults.

SYNONYMS

- Gastrointestinal foreign bodies.
- Swallowed foreign bodies.
- Esophageal food impaction.

EPIDEMIOLOGY

- More than 100,000 instances of foreign body ingestion were reported in 2010, with most of these cases reported in children and adolescents.[1]
- 75 percent of all foreign body ingestions occur in children, with a peak incidence between the ages of 6 months and 6 years.[2]
- 90 percent of all ingested foreign bodies in children are coins.
- Most ingested foreign bodies result in an uneventful outcome, with a complication rate of less than 1 percent.
- Only 10 percent of ingested foreign bodies require intervention to remove them.
- There were more than 3,300 reported cases of button battery ingestion in the US between 2008 to 2010 with 50 major complications and 7 deaths, all in children less than 6 years of age.[3]
- An estimated 1,700 ingestions of magnets from magnet sets were treated in US emergency departments between January 1, 2009 and December 31, 2011, with 70 percent of the victims less than 12 years of age and 20 patients requiring surgery.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- Ingestion of button batteries (**Figure 56-2**) is of particular concern given the high risk of severe complications and possible death.

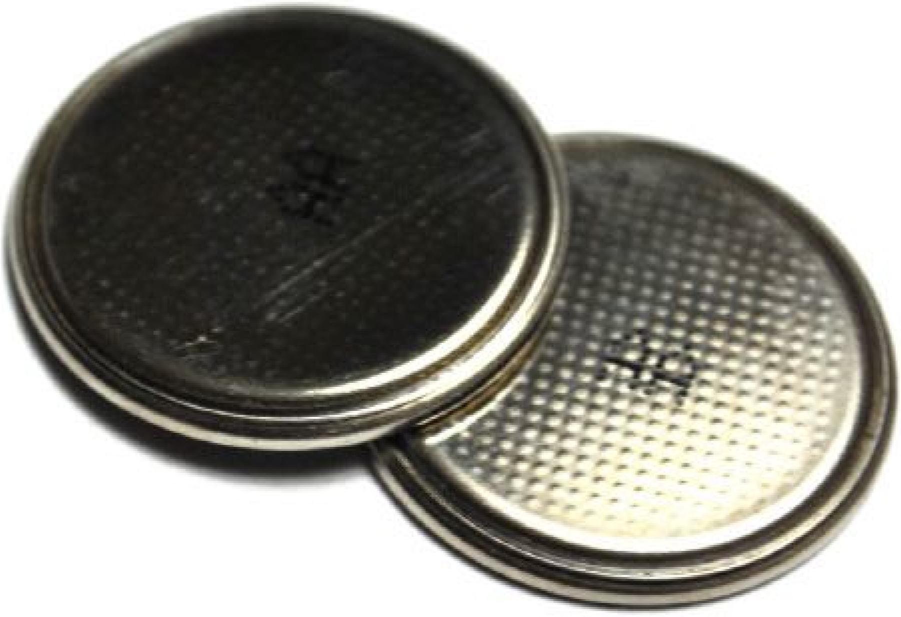

FIGURE 56-2 Button batteries are commonly swallowed by children and present a high risk of severe complications and possible death. (*Used with permission from Eugene Vortia, MD.*)

- Small powerful “rare earth” magnets (**Figure 56-3**) marketed as adult desk toys, stress relievers, and science kits present the potential for serious complications when two or more are swallowed within a short period of time.

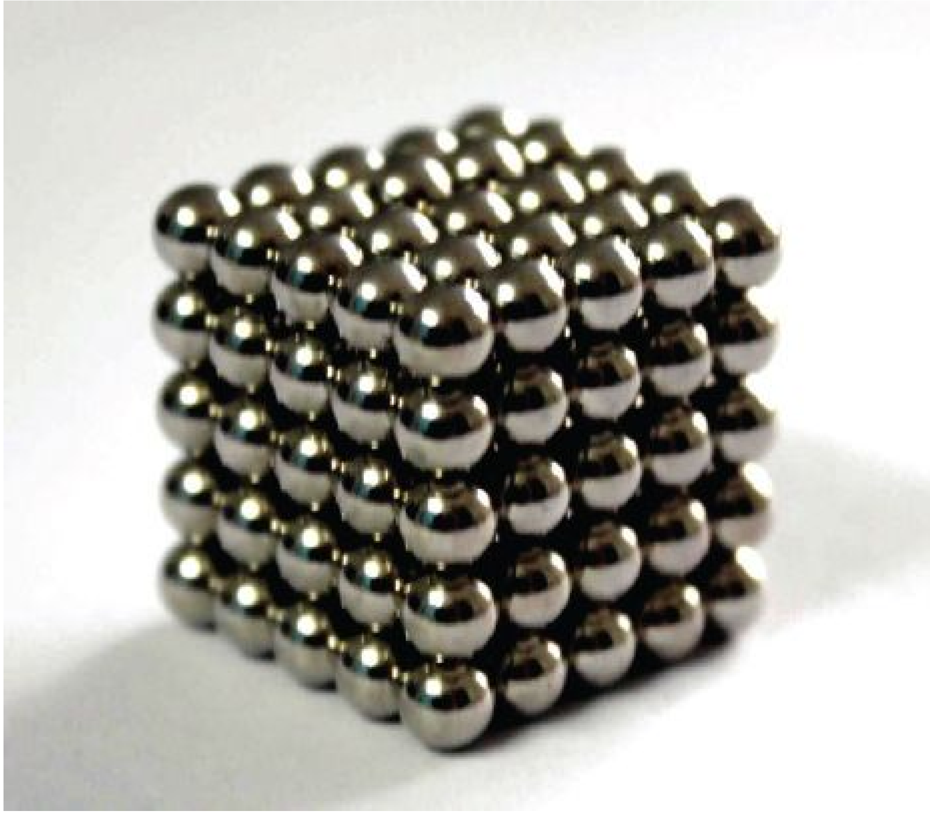

FIGURE 56-3 Rare earth magnets or Neodymium magnets are particularly dangerous when swallowed, especially if more than one is swallowed within a short period of time. (*Used with permission from Vera Okwu, MD.*)

- Impaction and obstruction often occurs at areas of anatomical narrowing (strictures, surgical anastomoses, duodenal C-loop) or physiologic sphincters (upper and lower esophageal sphincters, pylorus, ileocecal valve).

ESOPHAGUS

- There are three areas of anatomical narrowing in the esophagus where foreign bodies are most likely to become impacted in children:
  - Upper esophageal sphincter (70% of cases; **Figure 56-4**).

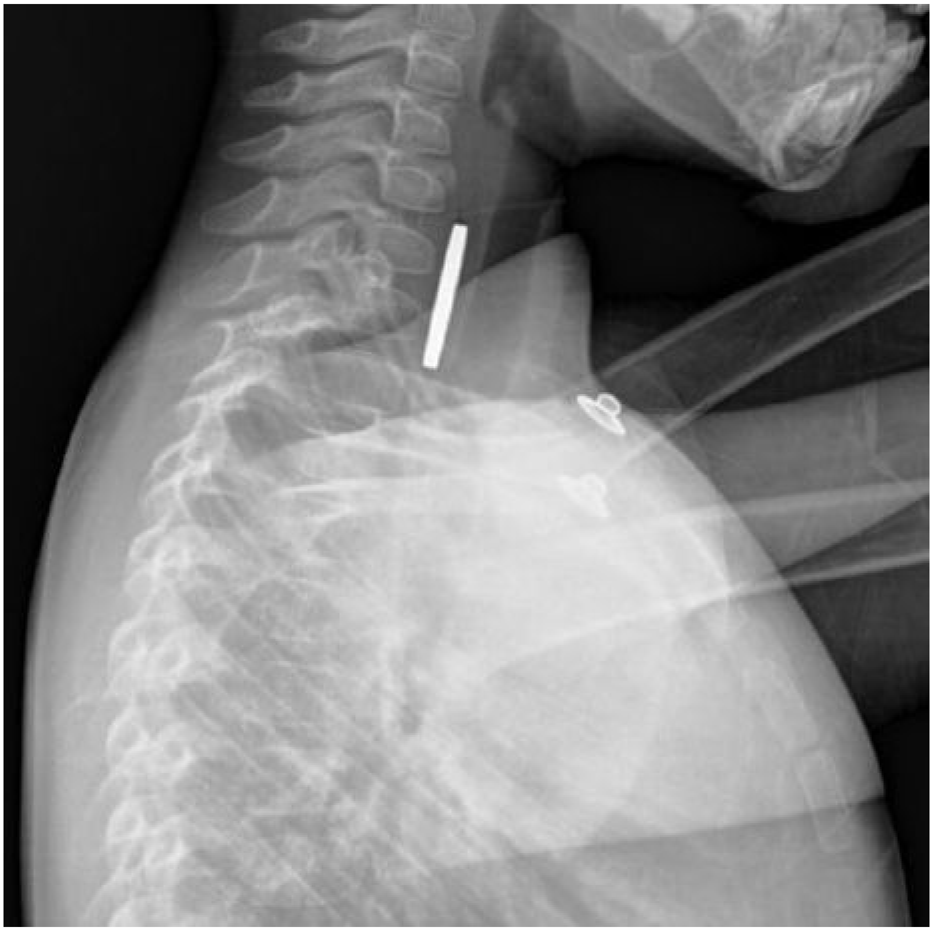

FIGURE 56-4 Lateral view of coin in proximal esophagus. (*Used with permission from Eugene Vortia, MD.*)

- Mid-esophagus (at the aortic indentation; **Figure 56-5**).

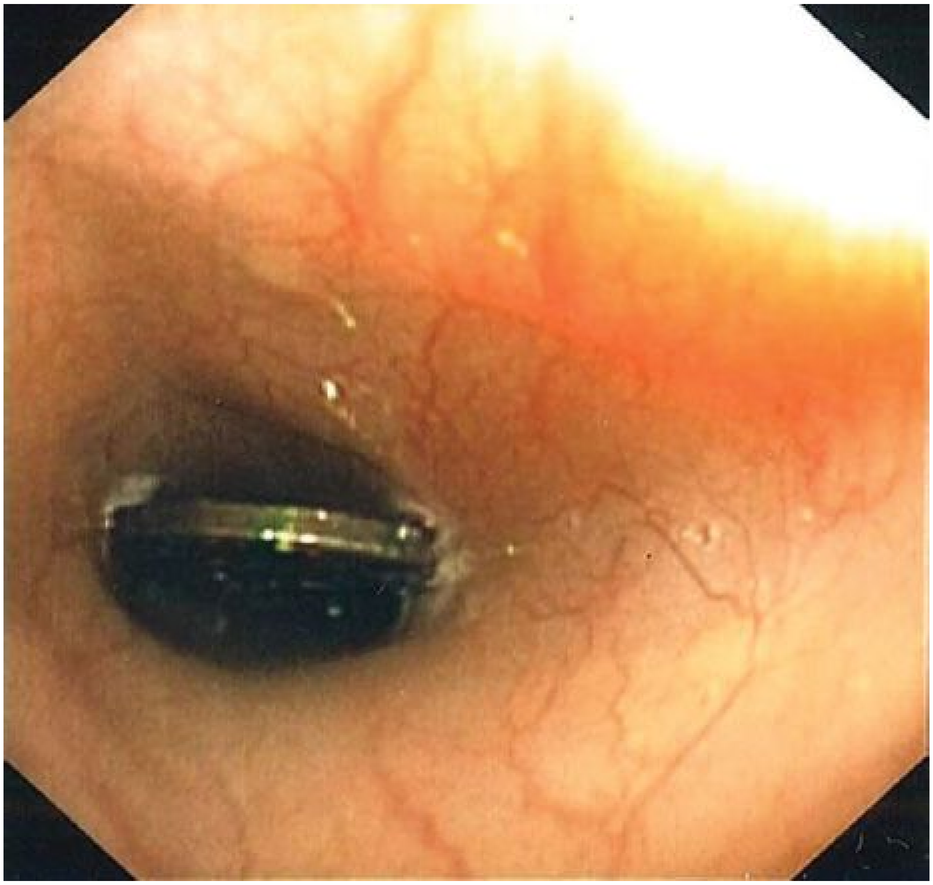

FIGURE 56-5 Endoscopic view of coin impacted in mid-esophagus. (*Used with permission from Katharine Eng, MD.*)

  - Lower esophageal sphincter (LES) (**Figure 56-6**).

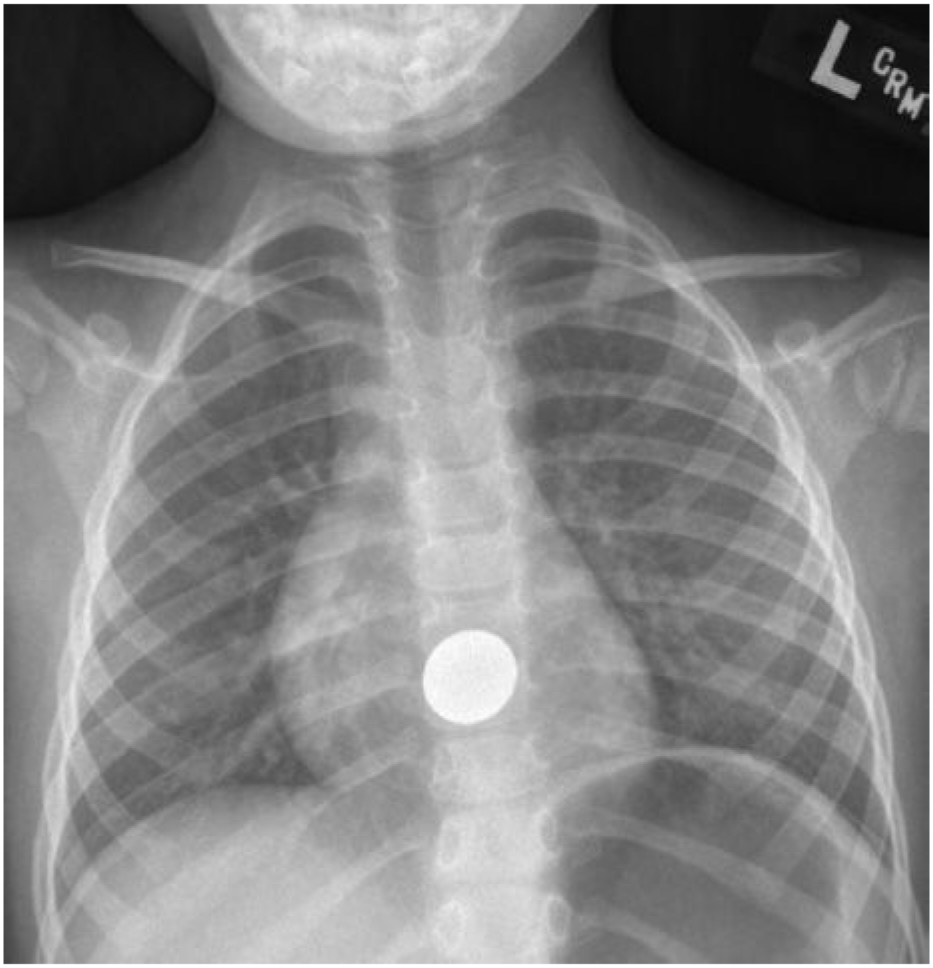

FIGURE 56-6 Coin in lower esophagus (PA view). It was impacted at the lower esophageal sphincter. (*Used with permission from Katharine Eng, MD.*)

STOMACH AND LOWER GASTROINTESTINAL TRACT

- Swallowed objects that reach the stomach pass spontaneously and uneventfully through the gastrointestinal tract in 90 percent of cases.
- As a general rule, objects >2 cm in diameter or >6 cm in length are not likely to make it past the pylorus or the duodenum and will require endoscopic removal.[5]

- With the possible exception of multiple magnet ingestion and some sharp objects, the vast majority of objects that successfully reach the small or large intestine will pass without complications.

RISK FACTORS

- Poor parental supervision or neglect.
- Psychological disorders.
- Attention seeking behavior (in older children).
- Certain factors increase the likelihood of impaction in the gastrointestinal tract after foreign body ingestion:
  - Age less than 3 years.
  - Large foreign bodies (>2 cm in diameter or >6 cm in length).
  - Functional and structural abnormalities of the esophagus:[6–8]
    - Eosinophilic esophagitis.
    - Esophageal strictures from previous esophageal surgery or reflux disease.
    - Achalasia.
    - Esophageal webs/rings.

DIAGNOSIS

CLINICAL FEATURES

- Presentation is usually straightforward but may be subtle, causing delayed diagnosis.
- The site of impaction is often not accurately localized and does not correlate with the area of discomfort in younger children.

- The nature of the presenting symptom is most often based on the type of foreign body ingested, the size and location of the foreign body, and the duration of the impaction.
- Younger children often present with drooling, poor feeding, vomiting, choking, coughing, and respiratory distress.
- Persistent mild respiratory symptoms and “recurrent” aspiration pneumonias in young children may in some cases precede identification of an esophageal foreign body during routine radiography.
- Older children often present with dysphagia, odynophagia, choking, and chest pain.
- Massive, life-threatening gastrointestinal hemorrhage due to erosion of a long-standing retained esophageal foreign body into adjacent vascular structures has been reported.
- Serious complications (perforation or strictures) are more commonly associated with ingestion of button batteries, large sharp objects, or multiple magnets.
- Proximal esophageal perforation may lead to pneumomediastinum with neck erythema, swelling, crepitus, or tenderness.
- Peritonitis or symptoms related to small-bowel obstruction may be present in rare cases.

LABORATORY TESTING

- Laboratory testing is not usually required except in the case of ingestion of foreign bodies composed of or coated with toxic substances such as lead.

IMAGING

- Initial evaluation of children with known or suspected foreign body ingestion should include biplane radiographs (posteroanterior and lateral) of the chest and abdomen to locate, enumerate and confirm the type and size of the ingested object(s).

- Esophageal coins (**Figures 56-1**, **56-4**, and **56-6**) most often appear in a coronal alignment on a posteroanterior radiograph view, whereas coins lodged in the trachea usually appear "enface" on the lateral view.
- A "double-contour" configuration or a "halo" on plain radiograph may distinguish a disk battery from a coin (**Figure 56-7**).

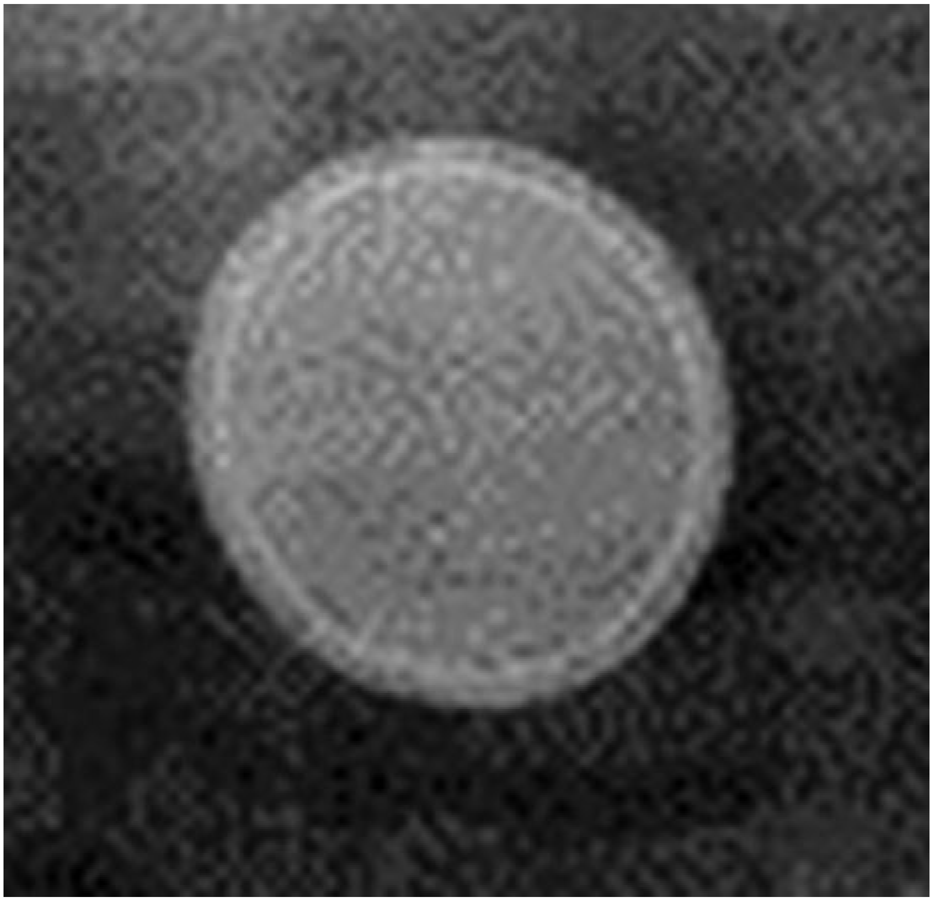

FIGURE 56-7 Radiograph of a button battery showing the "double contour" or "halo." (*Used with permission from Nisha Patel, MD.*)

- In cases of magnet ingestion, the radiograph should be examined carefully to assess for the presence of multiple magnets in close proximity which may mimic a single magnet (**Figure 56-8**).

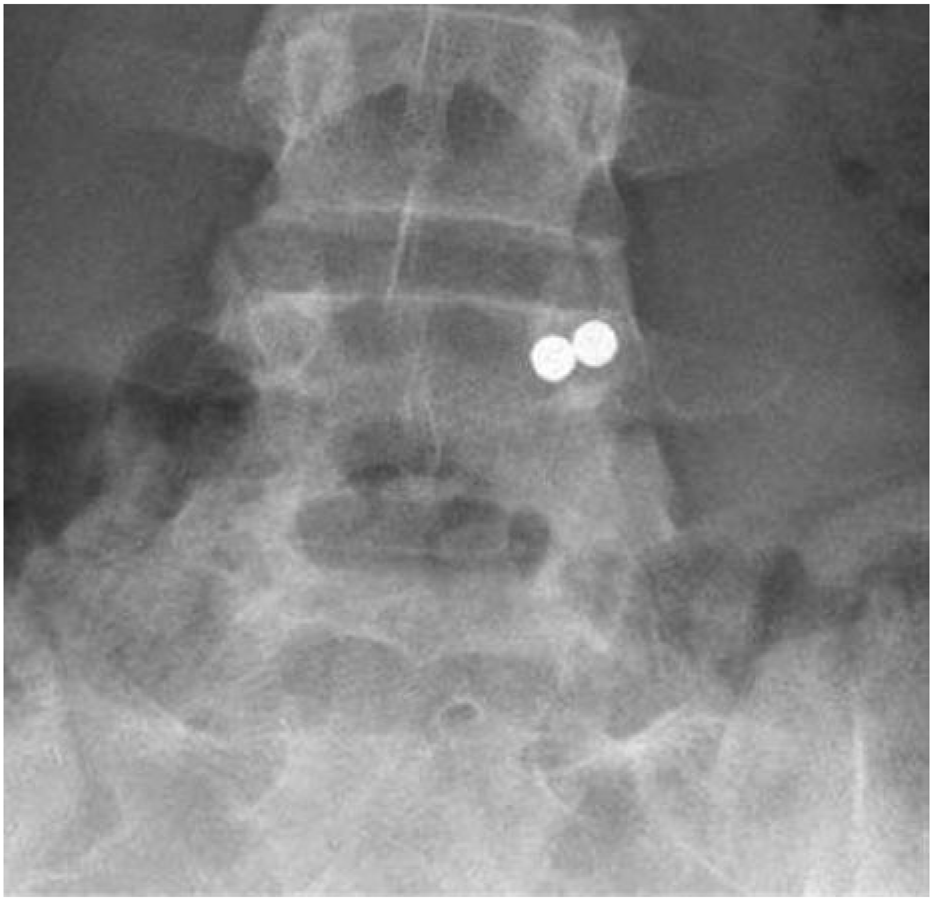

FIGURE 56-8 Radiograph showing two magnets in close proximity in the small bowel. It may not be possible to tell if they are attached across the bowel wall or within the bowel lumen. (*Used with permission from Vera Okwu, MD.*)

- A contrast examination should not be performed because of increased aspiration risk and the potential of complicating planned endoscopic procedures.

DIFFERENTIAL DIAGNOSIS

There are numerous differential diagnoses that must be considered in the case of reported foreign body ingestion. In addition, other predisposing disorders may be brought to light after an ingested foreign body has been retained in the gastrointestinal tract. These include:

- Tracheal Foreign Bodies—Can usually be differentiated from esophageal foreign bodies on radiographs as previously discussed.
- Acute bronchiolitis (see Chapter 48, Bronchiolitis)—Usually URI symptoms and fever are present.
- Reactive Airway Disease (see Chapter 49, Asthma)—History of previous wheezing episode can be elicited.
- Aspiration Pneumonia—History of choking and an infiltrate on CXR is present.
- Eosinophilic esophagitis (see Chapter 54, Esophageal Disorders).
- Munchausen Syndrome—Should be suspected with unusual ingestions or when the history does not align with the findings.
- Pica.
- Parental neglect.

MANAGEMENT

- Support airway with suctioning of secretions and supplemental oxygen if indicated.
- Ensure that patients with esophageal impaction remain fasting until foreign body removal can be performed to decrease the risk of aspiration.
- Under the following circumstances, emergent specialty consultation is indicated:
    - Signs or symptoms of airway compromise.
    - Evidence of esophageal obstruction such as the inability to swallow secretions.
    - Signs or symptoms of intestinal obstruction such as abdominal pain or vomiting.
    - Esophageal foreign body presentation 24 or more hours after presumed time of ingestion, or an unknown time of ingestion.
    - Multiple magnet ingestions within a short time.

  - Retained disk battery in the esophagus (within 2 hours).
  - Sharp objects (nonstraight pins, needles, razors, or multiple straight pins).
  - Long objects (>6 cm).

- With the exception of cases involving multiple magnets, disk batteries in the esophagus and sharp objects, asymptomatic patients able to handle oral secretions may have the procedure delayed for up to 24 hours.
- In asymptomatic patients with an esophageal foreign body, repeat radiograph immediately prior to endoscopic intervention if significant delay after initial assessment has occurred to establish that the object has not passed to the stomach.
- In most cases, with the exception of cases involving multiple magnets, large objects (>2 cm in diameter or >6 cm in length) and sharps, objects confirmed to pass into or beyond the stomach can be managed with an expectant approach since they are likely to successfully pass through the intestines and out the body without complication.
- Referral for endoscopic removal is required if symptoms such as persistent abdominal pain or vomiting develop as these may indicate pyloric obstruction.
- If there is no evidence of gastric/intestinal foreign body passage in the stool by 4 weeks post-ingestion, repeat abdominal x-ray is recommended. Referral for further evaluation is indicated if the foreign body is still present.

SPECIAL SITUATIONS

► Battery ingestions

Button batteries (**Figures 56-2** and **56-7**) result in high rates of serious complications due to discharge of current and leakage of caustic material. They must be immediately removed as esophageal perforation may occur within 4 hours or less of ingestion.

- For batteries confirmed to be in the stomach, follow-up radiographs should be performed after 48 hours. Referral for endoscopic removal is indicated if the battery is still in the stomach.

► Sharp foreign bodies

- Presence of a sharp foreign body (**Figure 56-9**) requires immediate referral for consideration of surgical or endoscopic retrieval.

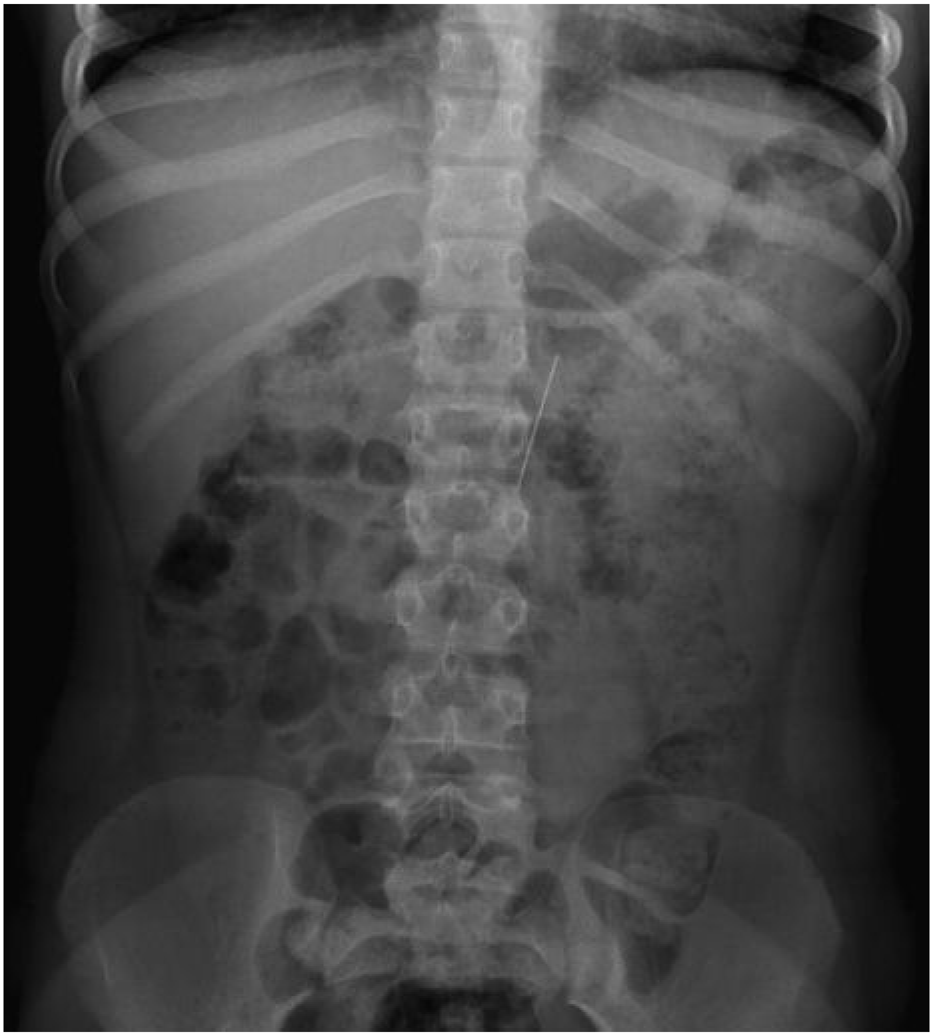

FIGURE 56-9 Straight pin on abdominal radiograph (PA view). (*Used with permission from Nisha Patel, MD.*)

- Single straight pins with a bulbous head will most often successfully navigate the gastrointestinal tract by peristaltic action without injury, with the blunt end leading and the sharp end trailing. Expectant management with close follow-up is recommended.

▶ Magnets

- Confirmed single magnet ingestions result in few gastrointestinal complications and may be clinically followed. Care should be taken to not mistake multiple magnets in close proximity as a single magnet (**Figure 56-8**).
- Ingestion of multiple magnets may result in the magnets attracting each other through the bowel wall and causing pressure necrosis with perforation or entero-enteric fistula formation. Early referral for possible endoscopic or surgical intervention is, therefore, indicated.

▶ Food impaction

- Meat impacted in the esophagus should be removed within 12 hours to minimize mucosal damage. Referral for consultation recommended even if esophageal food impaction resolves spontaneously due to the high rate of underlying pathology.

▶ Non-radio-opaque foreign bodies

- Management of non-radio-opaque foreign bodies (**Figure 56-10**) most often depends on adequate history regarding the length, size and sharpness of the object as well as the presence of symptoms.

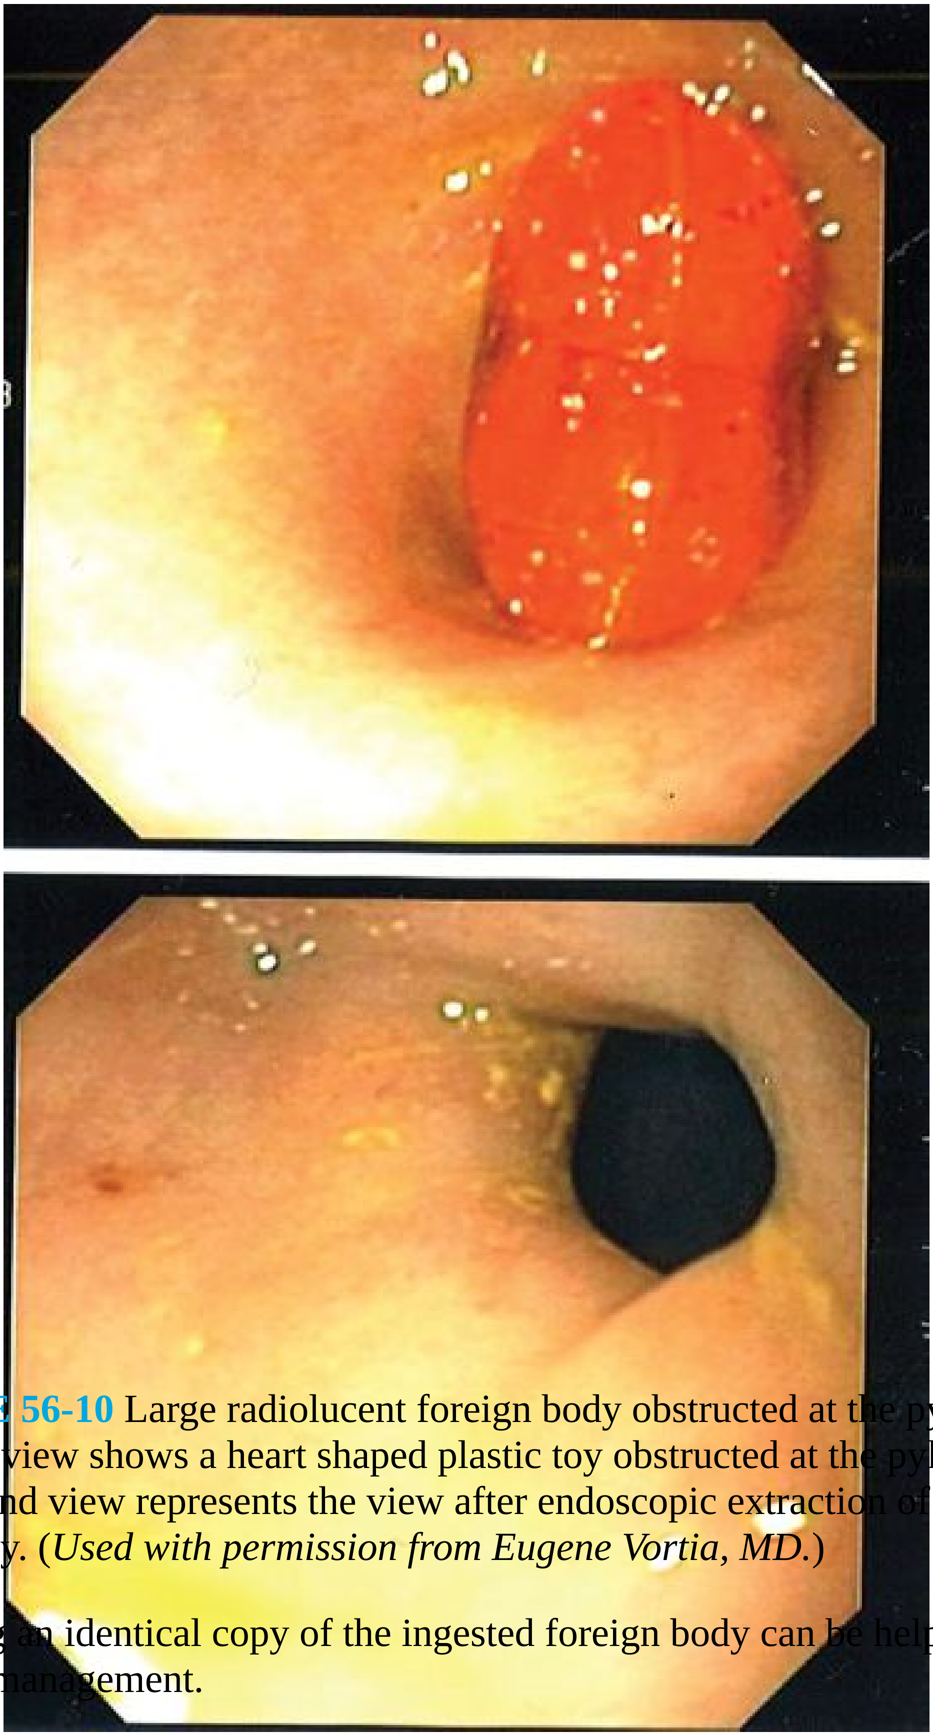

FIGURE 56-10 Large radiolucent foreign body obstructed at the pylorus. The first view shows a heart shaped plastic toy obstructed at the pylorus. The second view represents the view after endoscopic extraction of the plastic toy. (*Used with permission from Eugene Vortia, MD.*)

- Having an identical copy of the ingested foreign body can be helpful to guide management.

- Abdominal CT scan or ultrasound may be considered to provide more information.

MEDICATIONS

- Smooth muscle relaxants such as glucagon have been used with success in adults with foreign bodies impacted at lower esophageal sphincter but this approach has not been uniformly successful in children. SOR C
- The use of laxatives to hasten transit of ingested foreign bodies through intestinal tract does not lead to an improved clinical outcome and is not recommended. SOR C
- Meat tenderizers for esophageal meat impaction are **contraindicated** due to the risk of hypernatremia and esophageal injury.
- Administration of a pro-emetic such as ipecac is **contraindicated**.

SURGERY

- Surgical intervention may be needed if endoscopic retrieval is not possible:
    - Multiple magnets attracting each other through the bowel wall are not able to traverse the gastrointestinal tract.
    - After ingestion of multiple sharp straight pins or other sharp objects.
    - Any object obstructing the gastrointestinal tract that cannot be endoscopically removed.
- Patients with life-threatening complications from foreign body ingestion (perforation/hemorrhage).

REFERRAL

- Refer all cases of foreign body impaction to an appropriate specialist or referral center for retrieval.

- For button batteries in the esophagus, patients should be transported to a referral center within 2 hours regardless of symptoms in order to decrease the risk of serious complication.
- Any child with suspected multiple-magnet ingestion, ingestion of a multiple straight pins, or double-ended sharp objects should be emergently referred for consideration of endoscopic or surgical retrieval.

PREVENTION AND SCREENING

- Improve caregiver education regarding toy and food safety.
- Use special care in the handling and disposal of button batteries.
- Ensure that small magnets, especially the exceedingly powerful rare earth magnets are kept away from children.
- Maintain a high index of suspicion for foreign body ingestion, especially if the eating pattern of a child abruptly changes.
- Inform families to promptly report all foreign body ingestions, particularly magnets, button batteries, and sharp objects to their physician or proceed to the emergency room for further evaluation.

PROGNOSIS

- The prognosis is excellent in most cases of foreign body ingestion.
- Patients with ingestion of multiple magnets, multiple straight pins, large sharp objects, and button batteries generally do well after treatment but have a more guarded prognosis because of an increased incidence of late complications.

FOLLOW-UP

- Patients with ingestion of multiple magnets, multiple straight pins, large sharp objects, and button batteries require follow-up because of the risk of late complications.
- After removal of an esophageal foreign body most asymptomatic patients do not need further follow-up unless significant underlying esophageal mucosal disease was identified at endoscopy.
- All patients who develop new gastrointestinal symptoms after conservative therapy should be referred for specialist evaluation.
- With the exception of large, sharp or long objects and magnets, asymptomatic patients with gastric foreign bodies should monitor their stool for the object and if confirmed to pass, require no further follow-up.
- Abdominal radiographs may be used to localize objects that have not passed in 4 weeks.

57 PYLORIC STENOSIS

Skyler Kalady, MD
Neil Vachhani, MD

PATIENT STORY

A 4-week-old male presents to outpatient clinic with vomiting, which began two weeks ago and has become progressively worse. He is now vomiting after every feed. The vomit is projectile, non-bilious, and non-bloody. He seems hungry but over the past day, he has become fussy and urine output has decreased. He has no fever, respiratory symptoms, diarrhea, or rashes.

On examination, the infant appears alert but mildly dehydrated. His exam reveals fullness in the epigastric region. A quiet, a peristaltic wave is noted (**Figure 57-1**).

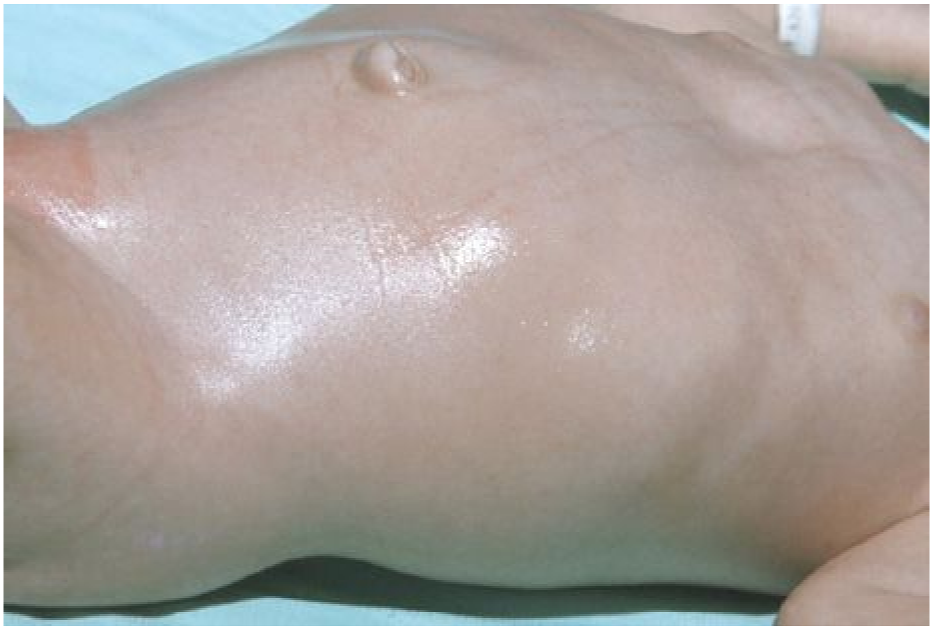

FIGURE 57-1 A peristaltic wave was visualized in this infant with pyloric stenosis. (*Used with permission from Cleveland Clinic Children's Hospital*

Photo File)

Ultrasound of the abdomen confirms the diagnosis of pyloric stenosis. Laboratory studies reveal hypochloremic, hypokalemic, and metabolic alkalosis. He is admitted for intravenous hydration and undergoes laparoscopic pyloromyotomy the following day. He is discharged home a day later, tolerating breast milk with resolution of his vomiting.

INTRODUCTION

Pyloric stenosis is defined as the progressive thickening and elongation of the pyloric channel ultimately resulting in partial or complete gastric outlet obstruction.

SYNONYMS

Infantile hypertrophic pyloric stenosis (IHPS).

EPIDEMIOLOGY

- IHPS occurs in 0.5–4/1000 live births. Estimates vary by region and surveillance method.[1]
- There is a clear gender bias with males affected more than females 4 to 5: 1.[1–4]
- A genetic component is theorized with increased rates in twins and other relatives.[1,2]
- First-born children are affected more often.[1]

- Maternal race and/or ethnicity alter prevalence. IHPS is more common in white and Hispanic families than African or Asian descent.[1]
- IHPS is the most common condition requiring surgery in early infancy.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- The underlying etiology of IHPS remains unknown.
- Causes are likely multifactorial with genetic and environmental contributions.
- Pyloric sphincter function is abnormal. The muscle fails to relax due to decreased nitric oxide synthase production and abnormal smooth muscle receptors.[1]
- Over time and with activation of local growth factors, the pylorus gradually thickens producing outlet obstruction. In compensation, the stomach dilates, thickens, and peristalses leading to emesis with every feed.

RISK FACTORS

- Genetic factors clearly play a role. There is a 200-fold increase in monozygotic twins and a 20-fold increase in dizygotic twins and siblings, as compared to individuals without affected relatives.[2]
- Erythromycin treatment used for pertussis prophylaxis increases risk for IHPS up to 10-fold perhaps due to its action as a motilin agonist.[1,4]
- Additional relative risk factors including maternal smoking during pregnancy, preterm delivery, small weight for gestational age, cesarean section, congenital malformations, and bottle feeding have been recently implicated.[3,5]

- Smith-Lemli-Opitz and Cornelia de Lange syndromes confer a great risk of IHPS.[4]

DIAGNOSIS

CLINICAL FEATURES

- Symptoms classically occur between 3 to 6 weeks of age, rarely starting after 12 weeks.
- The patient develops projectile, nonbilious, nonbloody emesis immediately following feeds.
- The patient remains vigorous and hungry until hydration is compromised.
- When the abdomen is relaxed following emesis, a pyloric “olive” or mass may be palpable by the skilled examiner.
- With dehydration and weight loss, a gastric peristaltic wave may be visualized moving from left to right in the upper abdomen prior to emesis (**Figure 57-1**).
- Jaundice is seen in 5 to 14 percent of cases.[4,6]

LABORATORY TESTING

- Laboratory testing is adjunctive but not diagnostic.
- An electrolyte panel typically reveals hypochloremic, hypokalemic, or metabolic alkalosis. However, with increased clinician awareness and advances in imaging, many patients are now diagnosed prior to developing electrolyte abnormalities.
- Unconjugated hyperbilirubinemia is relatively common likely due to transiently decreased levels of hepatic glucuronoyl transferase from poor feeding.

IMAGING

- Ultrasound is currently the imaging modality of choice when performed by an experienced operator.[4,7] It is highly sensitive and specific and does not utilize radiation. Findings include thickening of the pyloric muscle and elongation of the pyloric channel (**Figures 57-2** and **57-3**).

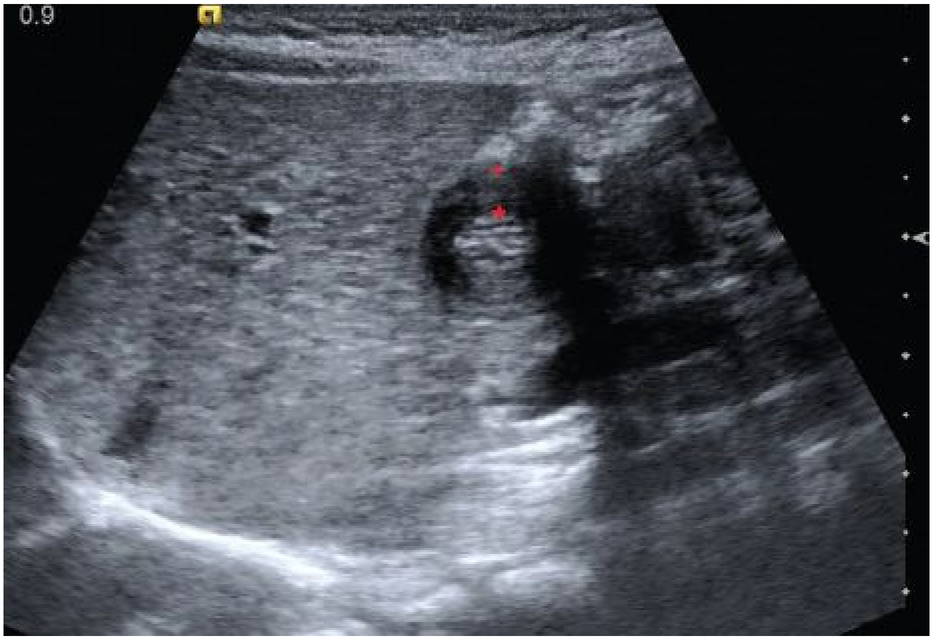

FIGURE 57-2 Transverse ultrasound through the pylorus showing thickening of the muscular wall (red marks). (*Used with permission from Neil Vachhani, MD.*)

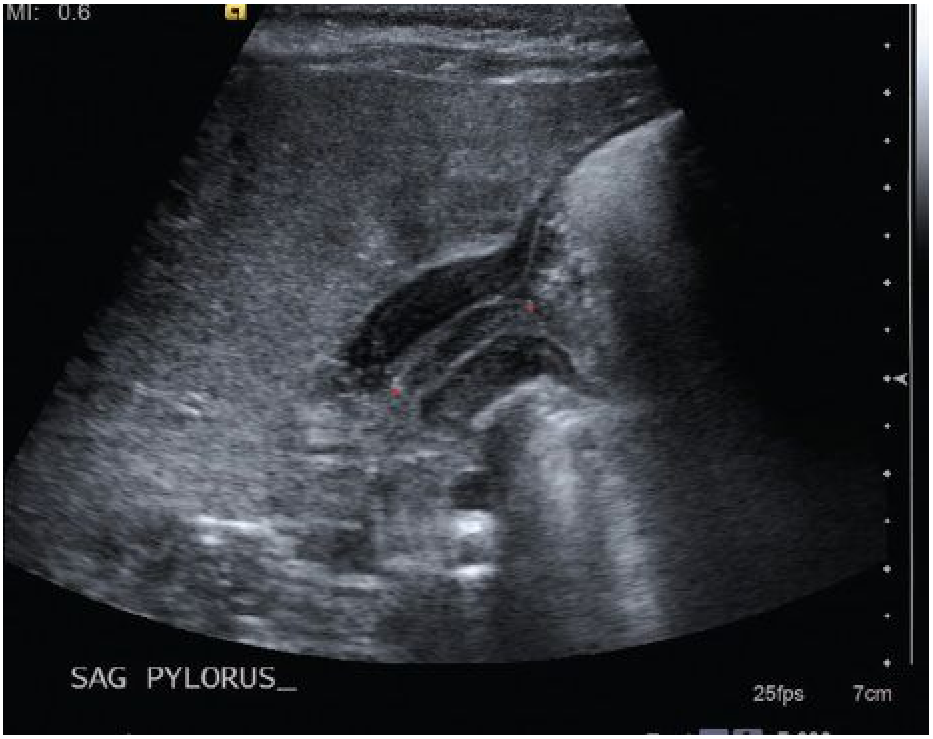

FIGURE 57-3 Longitudinal ultrasound through the pylorus showing elongation of the pyloric channel (red dots) and thickening of the muscular wall. (*Used with permission from Neil Vachhani, MD.*)

- Upper GI examination is less operator-dependent and can be used when there is limited ultrasound experience.[7] It also has high sensitivity and specificity but utilizes ionizing radiation. It demonstrates delayed passage of contrast as well as a small amount of contrast traversing the pyloric channel (string sign; **Figure 57-4**).

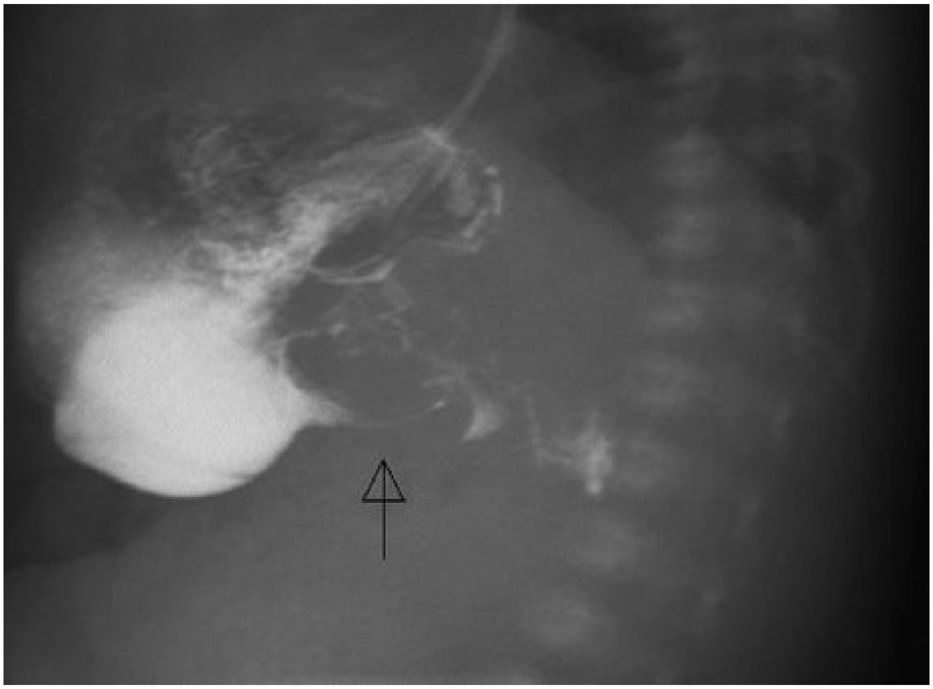

FIGURE 57-4 Lateral view from an Upper GI examination shows a small amount of barium passing through the pyloric channel (arrow) known as the “string sign.” (*Used with permission from Neil Vachhani, MD.*)

- Abdominal radiograph is not sensitive for diagnosing pyloric stenosis and is not routinely indicated. If obtained, it often shows a distended stomach with a paucity of distal bowel gas.[7] Undulation of the stomach contour can be seen due to hyperperistalsis (caterpillar sign; **Figure 57-5**).

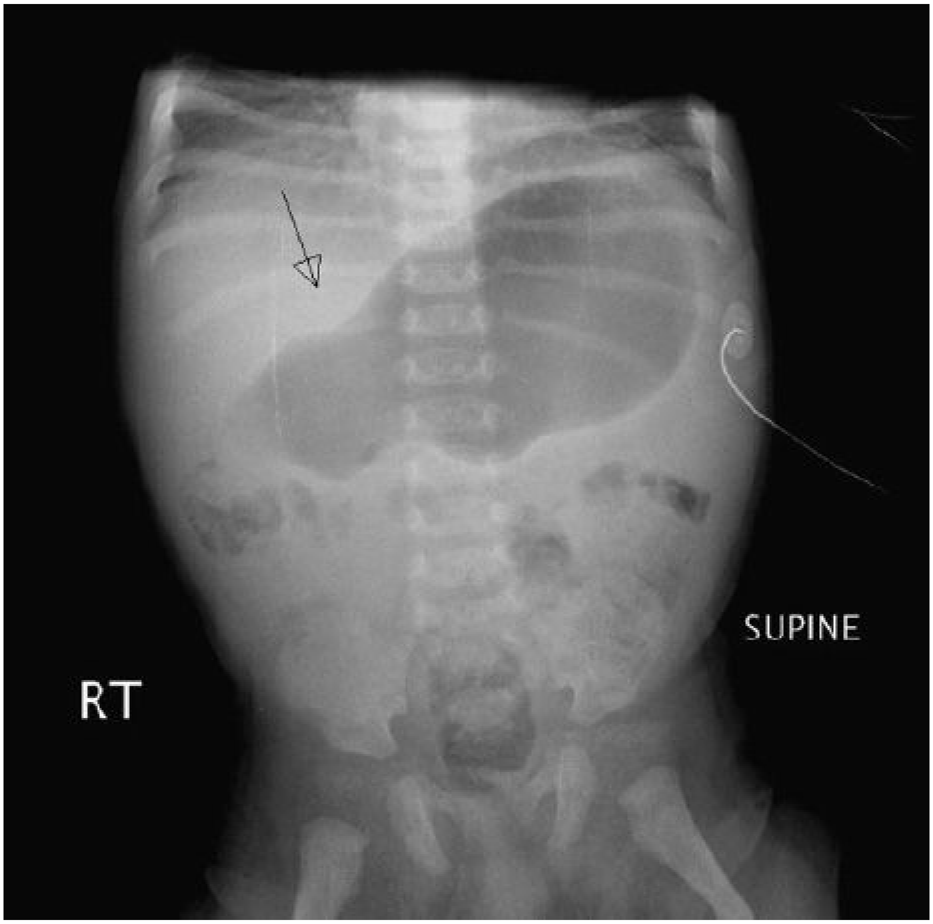

FIGURE 57-5 Supine anteroposterior abdominal radiograph shows a gas filled distended stomach. Undulation of the gastric contour, known as the “caterpillar sign” (arrow) is due to gastric hyperperistalsis. (*Used with permission from Neil Vachhani, MD.*)

DIFFERENTIAL DIAGNOSIS

Common entities:

- Gastroesophageal reflux (GER)—Similar to IHPS, patients have non-bilious emesis following feeds. However, patients with GER should not have projectile vomiting or develop dehydration (see Chapter 54, Esophageal Disorders).

- Milk protein allergy—Emesis may be related to feeds but ultimately signs of colitis predominate with hematochezia rather than projectile vomiting and dehydration.
- Gastroenteritis—Viral infection can typically be differentiated from IHPS with presence of a sick contact, diarrhea and self resolution over a few days.

Less common entities with important differences in the history:

- Doudenal atresia/stenosis—Signs of obstruction should be present from birth.
- Hirschsprung’s Disease—Delayed passage of meconium followed by emesis should differentiate this entity (see Chapter 62, Anal and Rectal Disorders).
- Adrenal crisis—Patients should present with lethargy, poor feeding, and vomiting and become progressively ill. Labs reveal hyperkalemic, metabolic acidosis. Many states have newborn screening programs to aid in diagnosing this condition.
- Infection—Presence of fever or temperature instability in an ill patient with vomiting could suggest UTI, bacteremia, or meningitis.
- Malrotation with volvulus should be considered immediately with any bilious emesis.

MANAGEMENT

SURGERY

- Pyloromyotomy is the definitive treatment for IHPS.[4] SOR Ⓐ
- Infants with dehydration or electrolyte derangement require volume resuscitation and correction of electrolyte abnormalities via intravenous fluids prior to surgery.[4] SOR Ⓐ

- Both laparoscopic and open pyloromyotomy are well studied and effective. However, recent meta-analyses suggest the laparoscopic approach is preferable with less wound infection, decreased length of stay and shorter time to feeding.[8,9] SOR Ⓐ
- Patients are generally discharged home after 24 to 48 hours once they are tolerating feeds without emesis.[4]

NONPHARMACOLOGIC

Prolonged nasoduodenal feeds were studied in the remote past, but good surgical outcomes render this prior approach outdated and impractical.[10]

MEDICATIONS

- In rare instances when a patient cannot undergo surgery, successful treatment with intravenous followed by oral atropine sulfate has been described.[11]

REFERRAL

Referral to a medical center staffed by pediatric anesthesiologists and surgeons is the current standard of care.

PREVENTION AND SCREENING

- Research into genetic and environmental factors will lead to further insight in this arena.
- Currently, avoidance of erythromycin therapy in young infants is recommended.

PROGNOSIS

- Prognosis for patients with pyloric stenosis is excellent following surgical correction.
- One study reported an increased chance of developing chronic abdominal pain in patients with IHPS as compared to controls (25% versus 5.8%).[12]

FOLLOW-UP

Routine follow-up with a primary care physician is recommended.

PATIENT EDUCATION

Projectile vomiting in a newborn requires urgent medical attention.

58 INTUSSUSCEPTION

Allison W. Brindle, MD
Ellen Park, MD
John DiFiore, MD

PATIENT STORY

An 11-month-old previously healthy male infant is brought to the Emergency Department (ED) for a 1-day history of fussiness and vomiting. His parents report that throughout the day he has had periods of crying and has been inconsolable, drawing his knees in towards his chest. Crying episodes last for about 20 minutes. Between episodes, he had been content. He then developed vomiting immediately after an episode of crying. He passed a bowel movement that appeared to have blood and mucus in the stool. He became more lethargic between crying episodes and his parents have become quite concerned. In the ED, he appeared moderately dehydrated, appeared sleepy, and was noted to have tenderness on palpation of the abdomen. After stabilization with intravenous fluids the physician ordered an abdominal ultrasound, which was concerning for intussusception (**Figure 58-1A–C**). The pediatric radiologist was able to reduce the intussusception with an air enema under fluoroscopic guidance. The patient tolerated the procedure well and recovered completely.

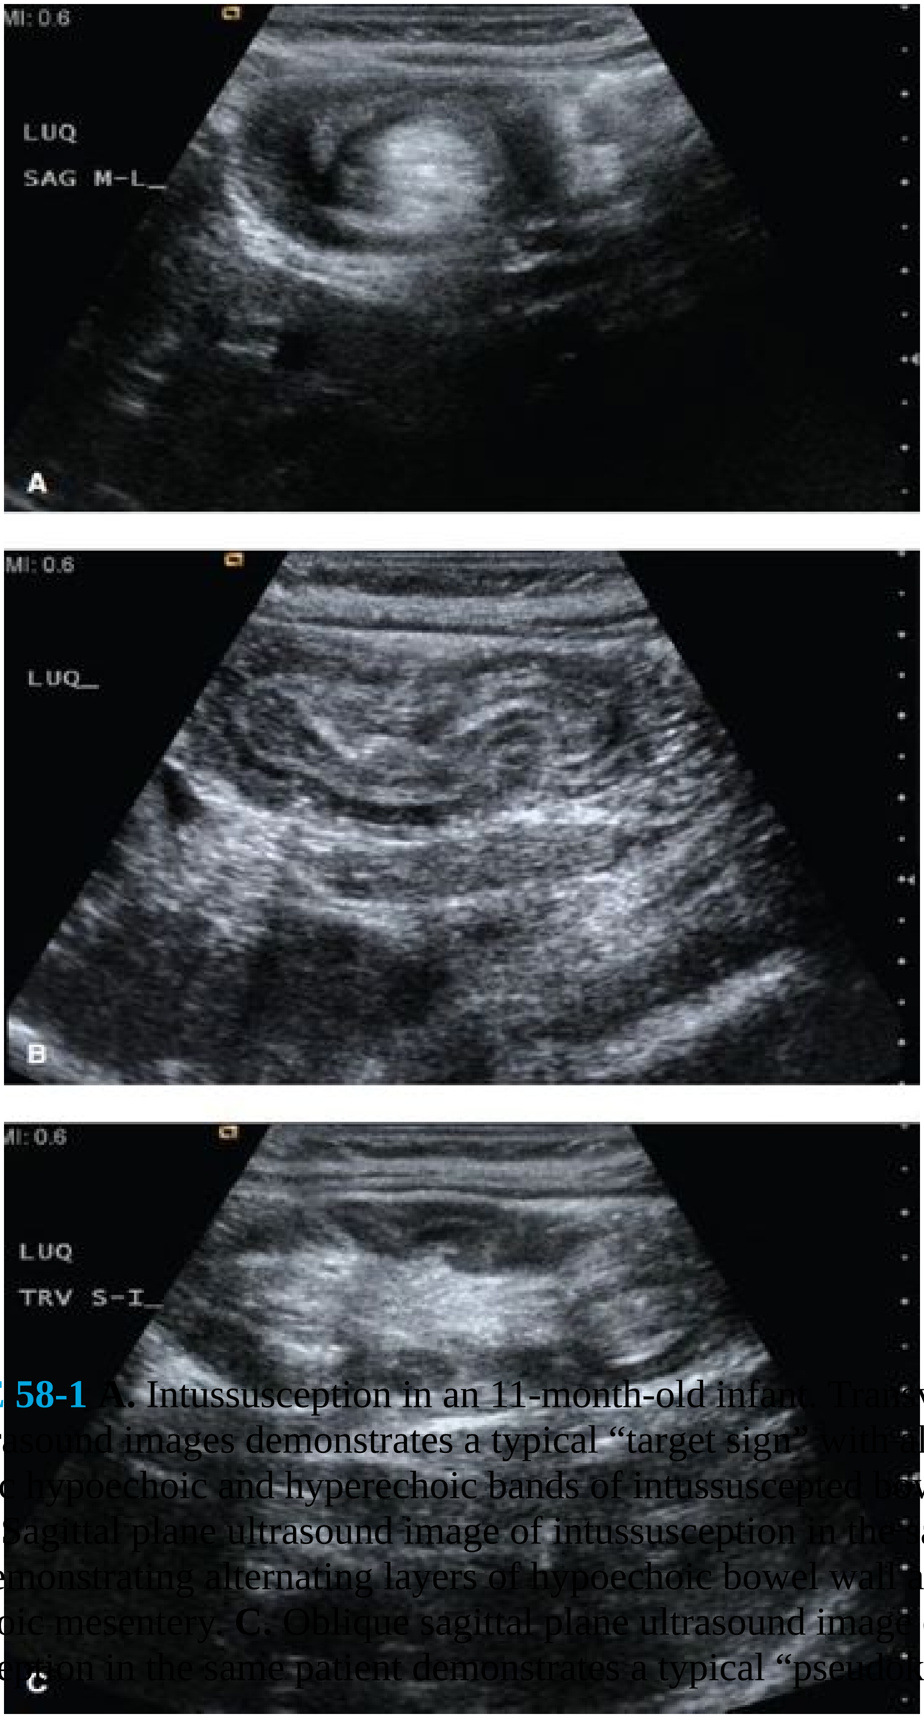

FIGURE 58-1 **A.** Intussusception in an 11-month-old infant. Transverse plane ultrasound images demonstrates a typical “target sign” with alternating concentric hypoechoic and hyperechoic bands of intussuscepted bowel walls. **B.** Sagittal plane ultrasound image of intussusception in the same patient demonstrating alternating layers of hypoechoic bowel wall and hyperechoic mesentery. **C.** Oblique sagittal plane ultrasound image of intussusception in the same patient demonstrates a typical “pseudokidney

sign” with hypoechoic bowel wall mimicking the appearance of renal cortex and hyperechoic mesentery the renal sinus fat. (*Used with permission from Ellen Park, MD.*)

INTRODUCTION

Intussusception refers to the “telescoping” or invagination of one portion of the intestine (the intussusceptum) into a more distal portion, the intussuscipiens. It leads to an intestinal obstruction.

EPIDEMIOLOGY

- Most commonly diagnosed in children between the ages of 3 months and 36 months.
- It is the most common form of intestinal obstruction in children less than 2 years of age.[1–3]
- Male predominance.
- Between 1998 and 1999, there was an increased incidence of intussusception in infants who had received the tetravalent rhesus–based rotavirus vaccination (RotaShield, Wyeth Laboratories, Inc., Marietta, PA).[4] This vaccine was then taken off the market.
- Post marketing surveillance of RotaTeq TM, a currently available pentavalent rotavirus vaccine, did not show an increased incidence of intussusception, and rotavirus immunization continues to be a recommended immunization in the primary immunization series.[5,6]

ETIOLOGY AND PATHOPHYSIOLOGY

- Most cases of intussusception are idiopathic.
- It is thought that lymphoid hyperplasia of the Peyer’s Patches can act as a lead point in idiopathic cases.
- Seasonal variation of the incidence of intussusception suggests a correlation with common gastrointestinal viruses, such as adenovirus.
- The most common type of intussusception is ileocolic when the ileum enters the cecum. Ileoileocolic, colocolic, or small bowel-small bowel intussusceptions have also been described, but are less frequent.
- When the intussusceptum invaginates into the intussuscipiens, the surrounding mesentery is pulled with it. This leads to intestinal edema.
- Complications of intussusception include intestinal ischemia, perforation, peritonitis, and death.
- Lead points for the intussusception are more common in children older than 2 years of age. Lead points may include: Meckel’s diverticulum, polyp, cyst, hematoma, or lymphoma.

RISK FACTORS

- Henoch-Schonlein purpura can cause a small bowel hematoma, which acts as a lead point for intussusception.
- Cystic fibrosis: thick inspissated stool is the lead point.
- Post-operative intussusception: within several days of intra-abdominal surgery (**Figure 58-2**).

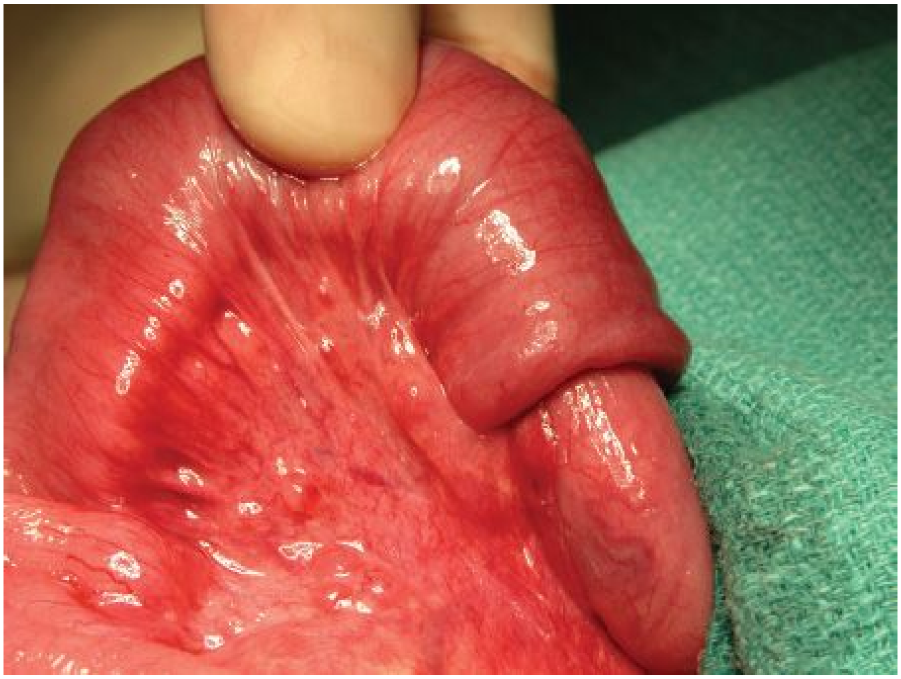

FIGURE 58-2 Small bowel-small bowel post-operative intussusception (intussusception within the small bowel after previous abdominal surgery). This was successfully reduced in the operating room without bowel resection. (*Used with permission from John DiFiore, MD.*)

- Prior intussusception: Intussusception can recur in 5 to 10 percent of idiopathic cases.

DIAGNOSIS

CLINICAL FEATURES

- Key Historical Features
  - Common historical features of intussusception are:
    - Lethargy[7]
    - Abdominal Pain—The pain typically occurs in colicky paroxysms and can be quite severe.[8]

- Emesis—Usually emesis begins as nonbilious. However, as the disease progresses, bilious emesis can occur.
- “Currant Jelly” Stools (containing gross blood and mucus) can be seen in up to 50 to 60 percent of patients.
- Fever may be present, but typically is a later finding.

PHYSICAL EXAMINATION FINDINGS

- Usually the patients are ill-appearing and very irritable, although the child may have alternating episodes of appearing well.
- Abdominal Mass—“Sausage” shaped mass in the right lower quadrant may be palpated.
- Guaiac positive stool on rectal examination.

IMAGING

- Plain film radiographs are not diagnostic of intussusception. However, they can be used to guide the need for further imaging studies. A study of the use of three view radiographs (supine, prone, and left lateral decubitus views) showed that the presence of air in the ascending colon on all 3 views of the series can decrease the likelihood of intussusception in a patient with an otherwise low clinical index of suspicion.[9] Free intraperitoneal air on abdominal x-ray is a contraindication for performing therapeutic enema.
- Ultrasound is the imaging modality of choice to diagnose intussusception with greater than 98 percent sensitivity (**Figure 58-1 A–C**). Using ultrasound as a diagnostic tool will reduce radiation exposure in children who do not have intussusception and increase the likelihood of successful reduction in those who do.
- CT scan—Intussusception can be visualized on CT scan and has a higher sensitivity for detection of lead points. However, because CT is not also a therapeutic modality (as is ultrasound) and because it has a higher radiation exposure for the child, it is not the imaging study of choice.

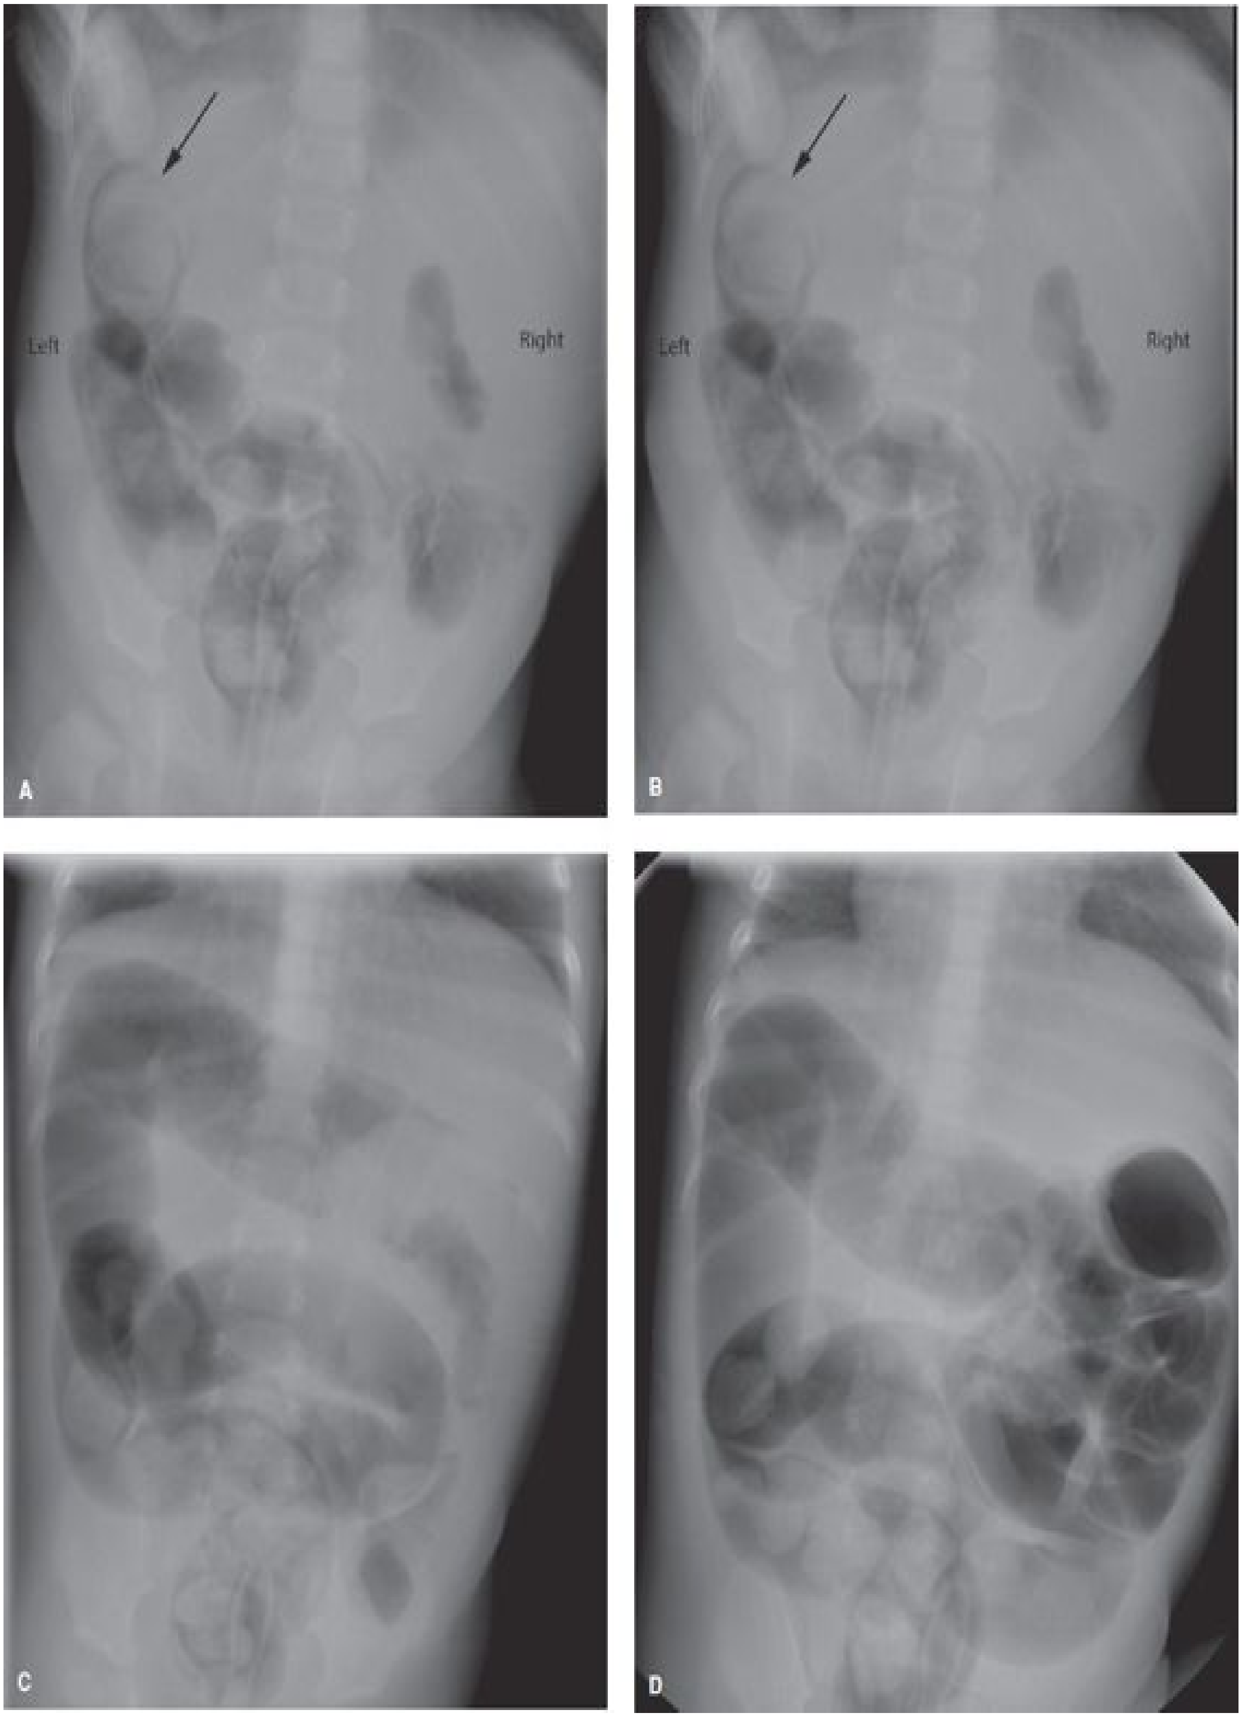
- Fluoroscopy combined with hydrostatic or pneumatic enema can be both diagnostic and therapeutic.

DIFFERENTIAL DIAGNOSIS

- Gastroenteritis or enterocolitis—Children with gastroenteritis can have abdominal pain and diarrhea. However, the colicky character of pain associated with intussusception as well as the development of bloody stools is less typical of viral gastroenteritis. Patients with bacterial enterocolitis look persistently ill between episodes of cramps and diarrhea.
- Meckel’s diverticulum—Although this may cause bloody stool, it is typically painless.
- Small bowel obstruction—Other etiologies of small bowel obstruction should also be considered. However, since most of these are fixed, they lack the intermittent, colicky nature of intussusception.

MANAGEMENT

- Initial treatment of intussusception in clinically stable and fluidresuscitated patients is nasogastric decompression and emergent reduction. Spontaneous reduction may occur in approximately 5 percent of patients.
- Non-operative reduction of ileocolic intussusception can be completed with either hydrostatic or pneumatic enema using fluoroscopic guidance achieving an 80 to 95 percent success rate (**Figure 58-3 A–E**).[10] SOR Ⓐ Ultrasound may be used to guide the procedure as well.



Left
Right
A
Left
Right
B
C
D

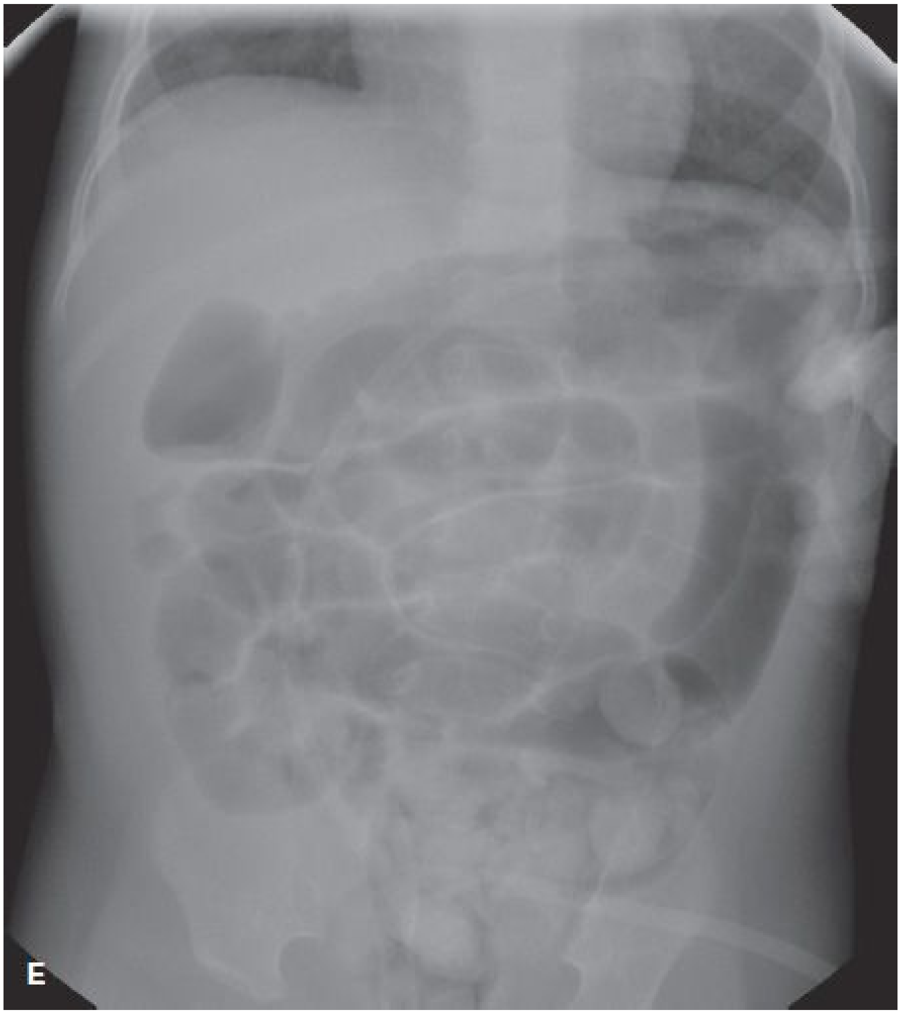


FIGURE 58-3 **A–E**. Air contrast enema reduction of an ileocolic intussusception in an 11-month-old boy obtained in prone position. Intussusception is initially demonstrated as a soft tissue mass (arrow) at the level of the splenic flexure (**A**). With continued air insufflation, intussusception is seen to move toward the cecum, and air eventually freely refluxes into the distal ileum as the ileocolic intussusception is reduced (**B–E**). (*Used with permission from Ellen Park, MD*).

- Contraindications for therapeutic enema reduction are peritonitis, sepsis/shock, and free intraperitoneal air on radiographs.
- The primary risk of nonoperative reduction is perforation of the bowel (overall rate of perforation is less than 1%), and in pneumatic reduction there is increased risk for tension pneumoperitoneum.

SURGERY

- A pediatric surgical team should be available for all attempts of non-operative therapeutic enema reduction in the event of perforation (approximately 1% of attempted reductions).
- Surgery may be indicated if an enema procedure fails to reduce the intussusception.
- Surgical reduction and possible resection is necessary for ileo-ileo intussusception (**Figure 58-2**).
- Surgery is also necessary in patients who are acutely ill and patients with perforation.
- Manual reduction may be attempted during the surgical procedure, but more likely will be a resection with anastomoses.
- Surgery may be necessary to resect an identified lead point.

REFERRAL

- Suspected or diagnosed intussusception should be managed at a medical center staffed with pediatric radiology and pediatric surgery services.

PROGNOSIS

- The usual course of untreated intussusception is bowel obstruction, perforation, peritonitis, sepsis, and shock.
- Nonsurgical reduction in spontaneous ileocolic intussusception is successful in 80 to 95 percent of patients, especially if treated within the first 24 to 48 hours.
- Morbidity and mortality rates increase if the intussusception has been present for more than 48 hours.
- Recurrence rate of intussusception is 10 percent; more than 50 percent of these will occur during the first 48 hours after successful reduction. Each

recurrence can be managed as if it were the initial instance. However, multiple recurrences may be associated with a pathologic lead point.

FOLLOW-UP

- Patients should be observed in the hospital for approximately 24 hours post reduction.
- Gastric decompression with nasogastric suction is often continued until bowel function has returned and the patient has had a bowel movement.
- Upon the return of bowel function, feeding can be advanced.

PATIENT EDUCATION

- Parents should be aware that abdominal pain and irritability in a young child warrants medical attention.
- Most cases of intussusception on infants and children are idiopathic and not associated with a lead point.
- Recurrences occur in 10 percent of patients after successful nonsurgical reduction.

59 INFLAMMATORY BOWEL DISEASE

Nisha Patel, MD
Naim Alkhouri, MD

PATIENT STORY

A 12-year-old female presents with cramping abdominal pain, a ten pound weight loss, diarrhea, and bloody stools. Physical examination is remarkable for oral aphthous ulcers, mild right lower quadrant tenderness, and perianal skin tag at six o’clock position. Further laboratory work up reveals anemia (hemoglobin 7.2 g/dL) and elevated erythrocyte sedimentation rate (41 mm/hr). She was referred to pediatric gastroenterology and underwent an esophagogastroduodenoscopy and colonoscopy, which was visually and histologically remarkable for gastritis, duodenitis, pan-colitis, and terminal ileitis (**Figure 59-1** and **59-2**). She was diagnosed with Crohn disease.

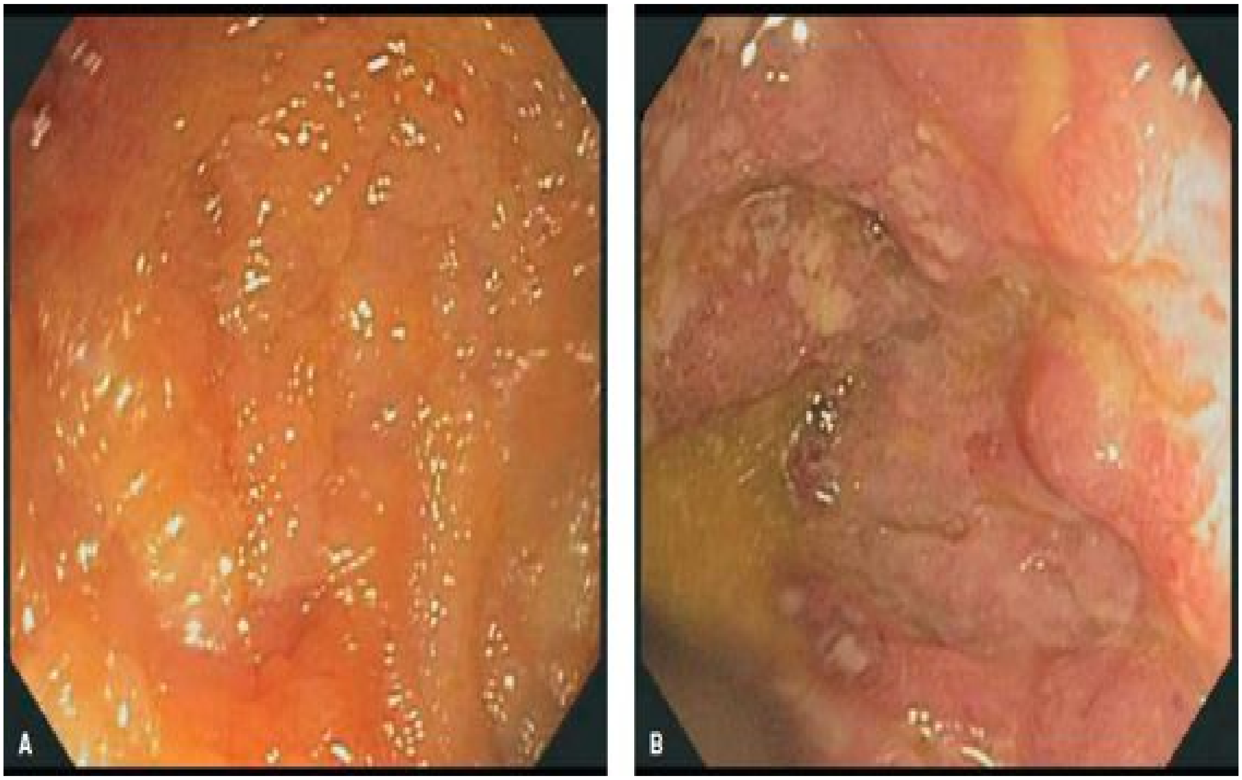

FIGURE 59-1 **A.** Normal terminal ileum. Note the Peyer's patches and nodularity. **B.** Crohn ileitis. Note the edematous mucosa with aphthous ulcerations and mucopurulent exudate. (*Used with permission from Nisha Patel, MD.*)

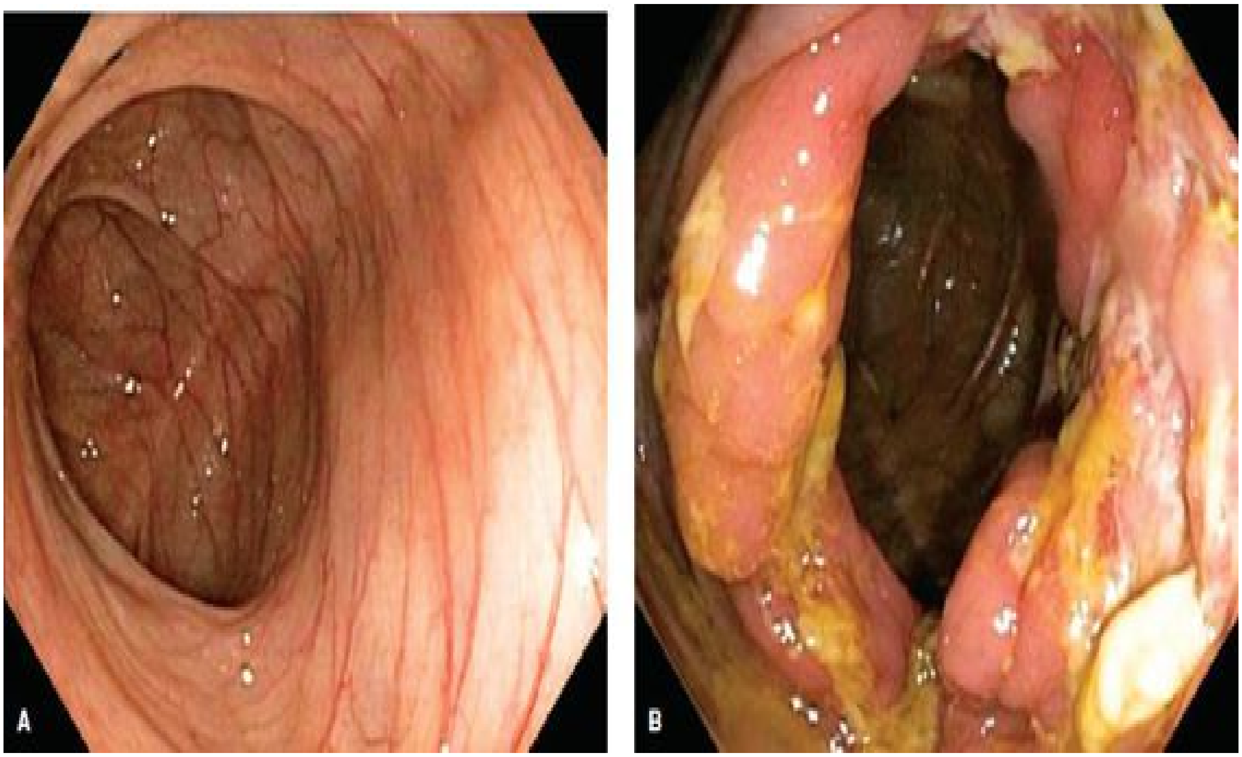

FIGURE 59-2 **A.** Normal colonic mucosa is shiny, with normal folds and normal vascular pattern. **B.** Severe Crohn disease with deep ulcerations, erythema, friability, and patchy cobblestoning pattern with exudates. (*Used with permission from Nisha Patel, MD.*)

INTRODUCTION

Inflammatory bowel disease (IBD) refers to two chronic conditions of the gastrointestinal tract: Crohn disease (CD) and ulcerative colitis (UC), that frequently have their presentations in the late childhood and adolescence. IBD is one of the most common chronic diseases of childhood and adolescents.

SYNONYMS

Crohn’s Disease, Ulcerative Colitis (UC), Indeterminate Colitis.

EPIDEMIOLOGY

- Pediatric-onset inflammatory bowel disease (IBD) has been significantly increasing in prevalence and incidence worldwide over the past few decades.[1]
- It is currently estimated that as many as 1.4 million persons in the US and 2.2 million persons in Europe suffer from these diseases.[2] More than 20 percent of patients present during childhood and diagnosed before the age of 10 years and fewer than 5 percent diagnosed before age 5 years.[3]
- The mean age at diagnosis of pediatric IBD in the US is 12.5 years.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- IBD is characterized by chronic inflammation of the gastrointestinal tract and encompasses two entities: CD and UC.
- The pathogenesis of IBD remains elusive, but involves an interaction between a genetic predisposition, defects of host immunoregulation, environmental factors, and an imbalance in the intestinal microbiota (dysbiosis). Dysbiosis (also called dysbacteriosis) is considered crucial for the development of chronic intestinal inflammation.

RISK FACTORS

- Up to 25 percent of children who develop IBD have a positive family history of IBD. Children who have a first-degree relative affected by either UC or CD have a 10 to 13 times higher risk for developing IBD.[4]

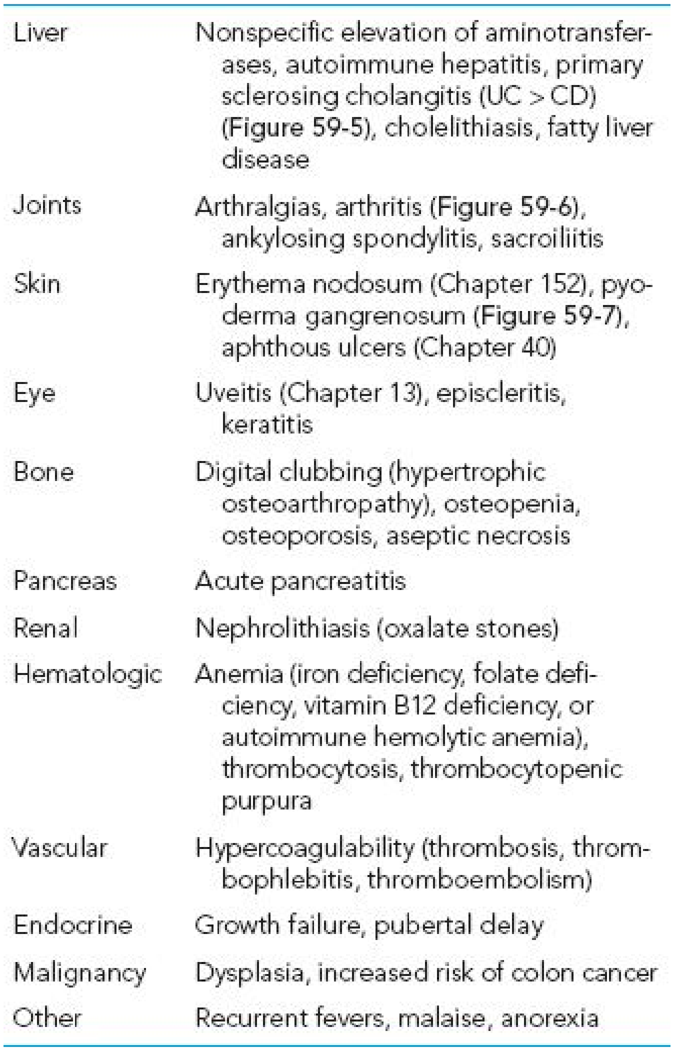
- Monozygotic twin concordance is approximately 50 percent for CD and nearly 20 percent for UC.[5]
- Genetic linkage analyses and genome-wide association studies have identified numerous IBD candidate genes. *NOD2/CARD15* gene, located on chromosome 16q has been associated with CD.
- Anti-Saccharomyces cerevisiae antibody (ASCA) is found in 50 to 60 percent of patients who have CD.
- Perinuclear antineutrophil antibody (pANCA) is detected in approximately 70 percent of patients with UC.

DIAGNOSIS

CLINICAL FEATURES

- Both CD and UC have overlapping features, but the cardinal symptoms of CD are:
  - Cramping abdominal pain, which can be diffuse or localized to the right lower quadrant.
  - Diarrhea (urgency, tenesmus, and nighttime awakening for bowel movements).
  - Weight loss.
  - Recurrent aphthous-stomatitis.
  - Growth failure.
  - Perianal disease (tags, fissures, fistulae, and abscesses).
- The classic presentation of UC is diarrhea, hematochezia, and abdominal cramping associated with fecal urgency.
- One third of patients with IBD can present with extraintestinal manifestations prior to manifesting intestinal symptoms (**Table 59-1**).

TABLE 59-1 Extraintestinal Manifestations of IBD



Liver	Nonspecific elevation of aminotransferases, autoimmune hepatitis, primary sclerosing cholangitis (UC > CD) (Figure 59-5), cholelithiasis, fatty liver disease
Joints	Arthralgias, arthritis (Figure 59-6), ankylosing spondylitis, sacroiliitis
Skin	Erythema nodosum (Chapter 152), pyoderma gangrenosum (Figure 59-7), aphthous ulcers (Chapter 40)
Eye	Uveitis (Chapter 13), episcleritis, keratitis
Bone	Digital clubbing (hypertrophic osteoarthropathy), osteopenia, osteoporosis, aseptic necrosis
Pancreas	Acute pancreatitis
Renal	Nephrolithiasis (oxalate stones)
Hematologic	Anemia (iron deficiency, folate deficiency, vitamin B12 deficiency, or autoimmune hemolytic anemia), thrombocytosis, thrombocytopenic purpura
Vascular	Hypercoagulability (thrombosis, thrombophlebitis, thromboembolism)
Endocrine	Growth failure, pubertal delay
Malignancy	Dysplasia, increased risk of colon cancer
Other	Recurrent fevers, malaise, anorexia

DISTRIBUTION

- CD can involve any portion of the gastrointestinal tract from the mouth to anus. It predominately affects the distal ileum and colon and can present in a patchy or discontinuous pattern. The inflammation is typically transmural and can be associated with intestinal granulomas (pathognomonic), strictures, fistulas, and abscesses (**Figures 59-1** and **59-2**).
- UC involves the rectum and colon in a continuous pattern and the inflammation is typically confined to the superficial mucosa. Crypt abscesses are common in UC (**Figure 59-3**).

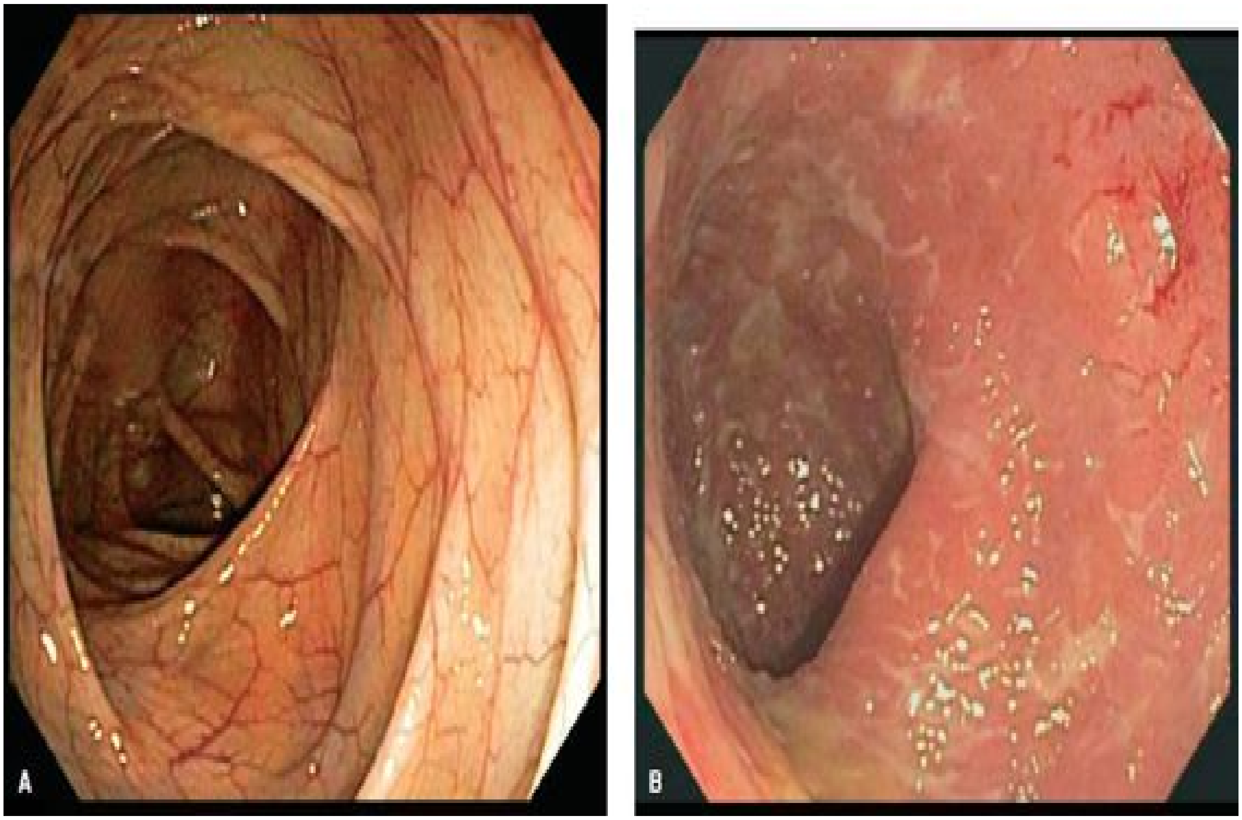


FIGURE 59-3 **A.** Normal colon. **B.** Severe ulcerative colitis. Note the continuous pattern of erythema, loss of vascularity, superficial ulcerations and exudate with friability in areas of endoscope contact. (*Used with permission from Nisha Patel, MD.*)

LABORATORY STUDIES

- Complete blood count (CBC) with differential, complete metabolic profile, erythrocyte sedimentation rate, C-reactive protein, and albumin.
- Stool studies (culture, *Clostridium difficile*, ova, & parasite) to exclude infectious etiologies, fecal calprotectin, and lactoferrin.
- Ancillary tests—IBD serologic panels: pANCA, ASCA, Anti Omp C (outer membrane protein of *Escherichia coli*).
    - IBD serologic panels are not recommended for screening or as an isolated diagnostic tool. False-positive results can create unwarranted

anxiety and lead to excessive invasive testing. It should be noted that nearly 1/3 of patients who have a positive serologic panel do not have IBD. Serologic panels are most useful in children who have indeterminate colitis to differentiate CD from UC.[1]

IMAGING

- Upper gastrointestinal series—Can assess areas or stenosis and abnormal separation of bowel loops
- Computed Tomography Enterography scan (**Figure 59-4**)—Can assess for intestinal wall thickening and acute complications of IBD, such as abscess formation and fistulizing or stricturing disease.

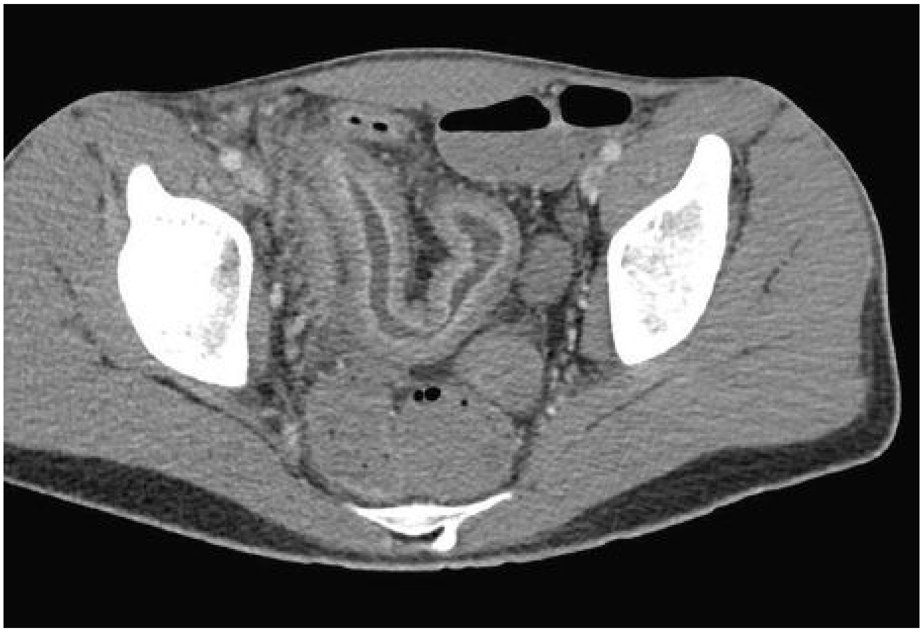

FIGURE 59-4 CT scan showing transmural thickening of the terminal ileum in a patient with Crohn disease. (*Used with permission from Nisha Patel, MD.*)

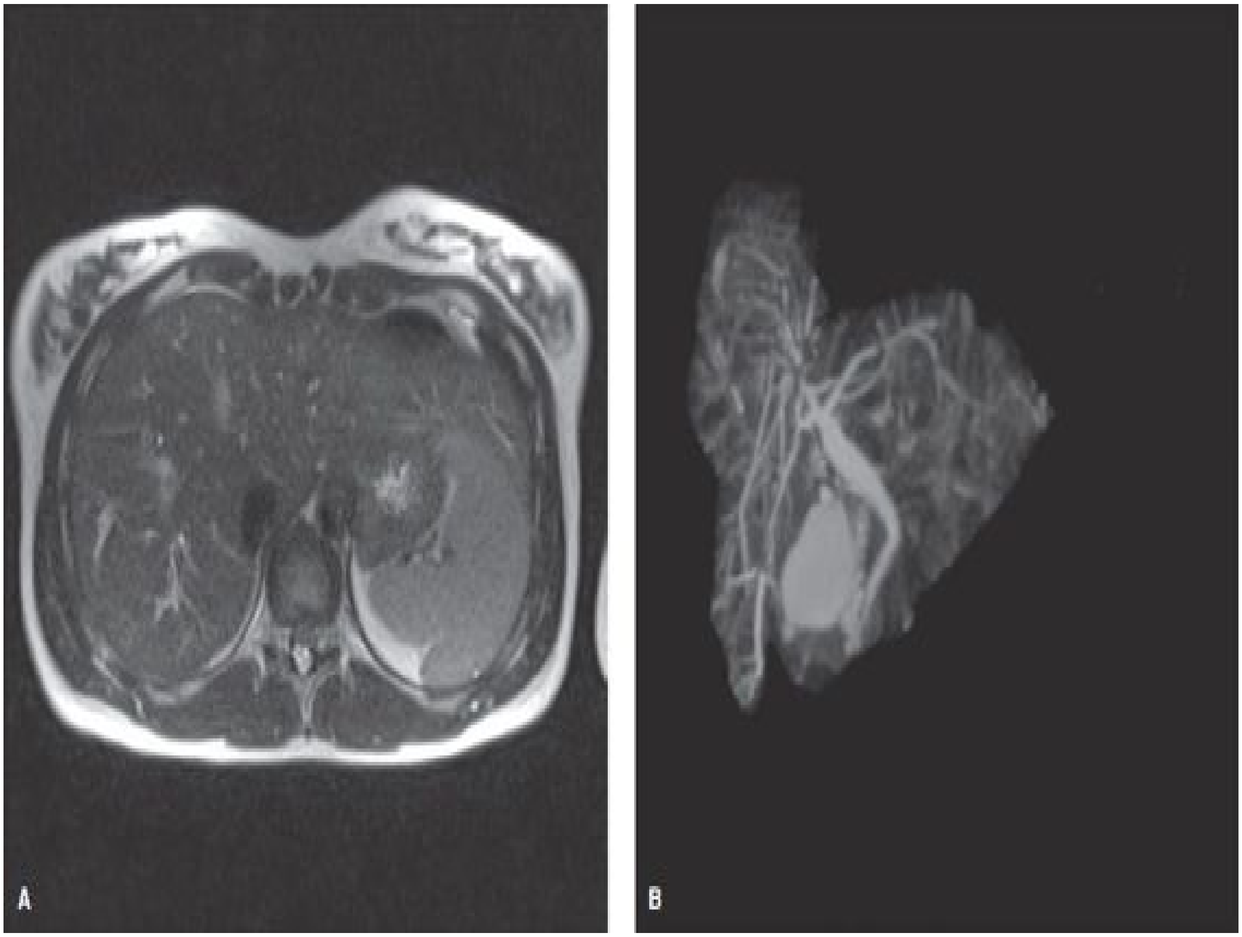

FIGURE 59-5 Magnetic resonance cholangiopancreatography (MRCP): Primary Sclerosing Cholangitis (PSC). Typical symptoms include chronic fatigue, anorexia, pruritus, and jaundice. Elevated gammaglutamyltranspeptidase and alkaline phosphatase values along with results of cholangiography and liver biopsy help confirm the diagnosis. Note the areas of intrahepatic bile duct strictures alternating with normal-caliber ducts (**A**) forming a "beaded appearance" (**B**). Close-up of the biliary tree showing same "beaded" appearance. (*Used with permission from Nisha Patel, MD.*)

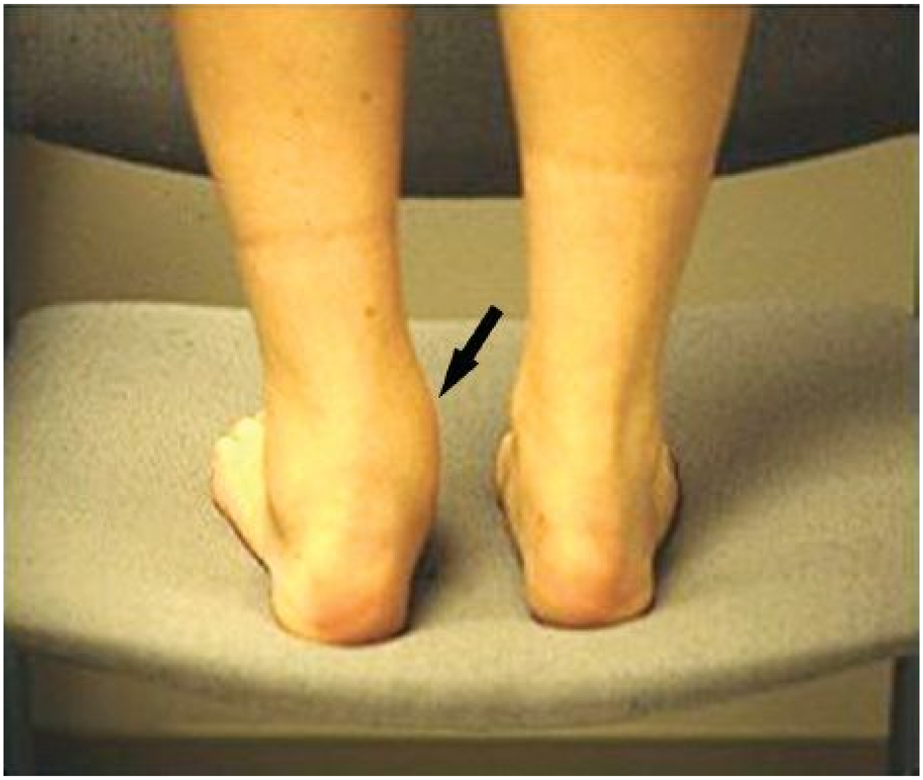

FIGURE 59-6 Seronegative spondyloarthropathy in the ankle of a patient with Crohn disease. Note the swelling (arrow) of the left ankle that is a due to joint effusion and enthesopathy. (*Used with permission from Andrew Zeft, MD.*)

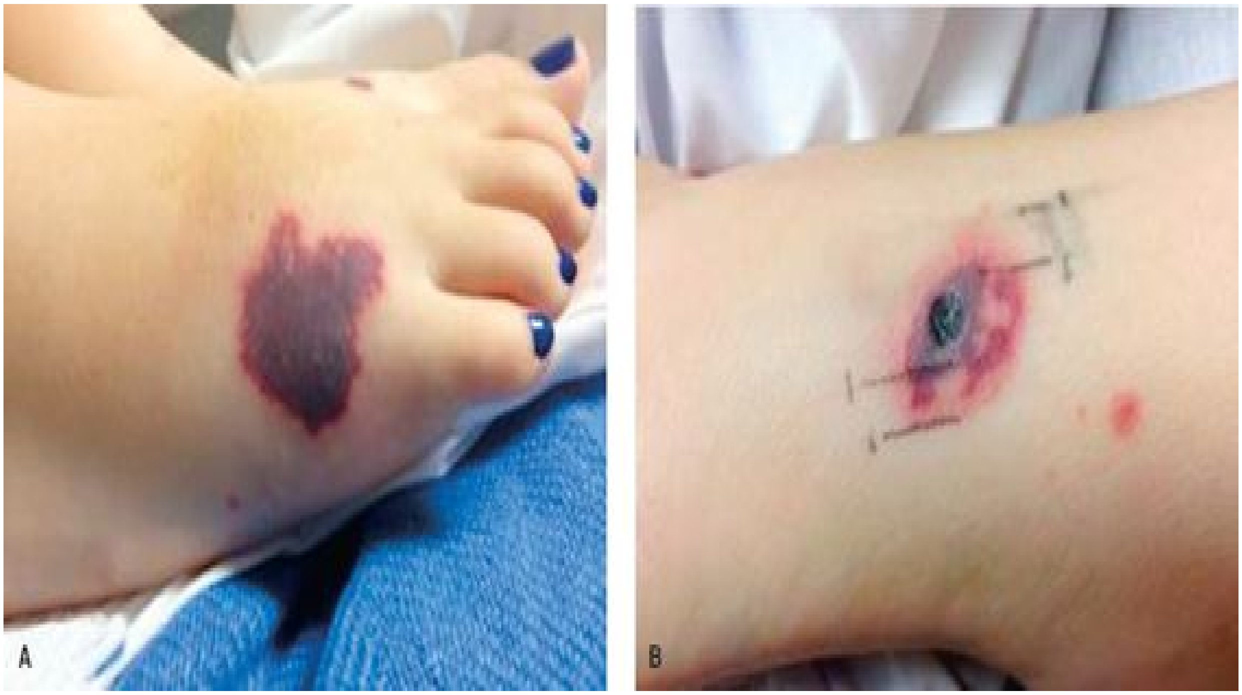

FIGURE 59-7 Pyoderma gangrenosum (PG) is a rare noninfectious neutrophilic dermatosis which starts as a sterile pustule that rapidly progress and turns into painful ulcers of variable depth and size with violaceous borders. Lower extremities are most commonly affected. **A.** A small ulcer is barely visible within the violaceous area on the foot in this early case of PG. **B.** Visible ulcer on the lower leg in PG. (*Used with permission from Michael J. Nowicki, MD.*)

- Magnetic resonance imaging (MRI) or MR enterography (MRE)—No radiation exposure and has greater than 90 percent sensitivity and specificity for detecting small bowel disease.

Wireless video capsule endoscopy (VCE)—Can assess small bowel which is not accessible routine endoscopy.

ENDOSCOPY

- Endoscopy including esophagogastroduodenoscopy and colonoscopy with biopsy is gold standard for diagnosing IBD.
- Noncaseating granulomas on pathology are pathognomonic for CD (**Figure 59-8**).

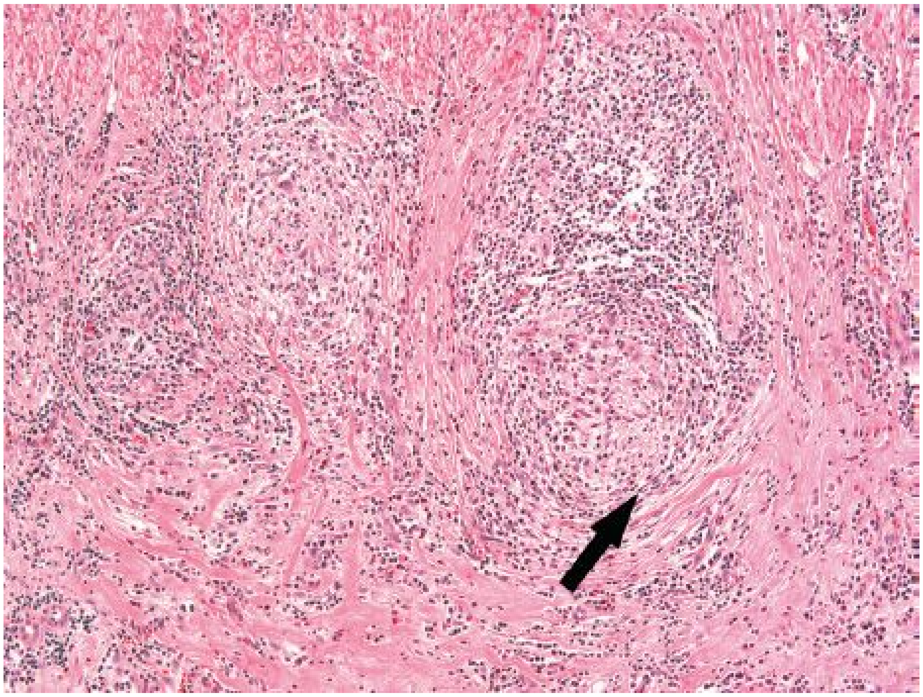

FIGURE 59-8 Noncaseating granulomas on histopathology is diagnostic of Crohn disease. (*Used with permission from Thomas Plesec, MD.*)

DIFFERENTIAL DIAGNOSIS

- Infectious enterocolitis—Enteric pathogens such as *Salmonella, Shigella, Campylobacter, Escherichia coli* 0157:H7, *Yersinia*, and *Aeromonas*—These usually cause more acute symptoms than IBD and are not associated with growth failure.
- Pseudomembranous colitis *(Clostridium difficile)*—Usually associated with antibiotic use and produces more acute symptoms.
- Lymphocytic colitis—Can be seen as a complication of opportunistic infection in immunocompromised hosts and can be differentiated from IBD based on epidemiology and pathology.
- Eosinophilic enterocolitis—Most commonly affects the stomach and small intestine but can extend to the colon. Peripheral eosinophilia and biopsy of the bowel can differentiate this from IBD.
- Henoch-Schonlein purpura—Can usually be differentiated because of the presence of palpable purpura and arthritis (see Chapter 179, Henoch Schonlein Purpura).
- Hemolytic-uremic syndrome—Differentiated by the presence of hemolytic anemia, thrombocytopenia and acute renal failure (see Chapter 69, Hemolytic Uremic Syndrome).
- Periodic fevers syndromes, such as TRAPS (TNF receptor-associated periodic syndrome) and PFAPA (periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis)—Usually associated with significant diarrhea, but abdominal pain and fever can be common (see Chapter 176, Periodic Fever Syndromes).
- Rheumatologic disorders—Many characteristics overall with pediatric IBD, such as weight loss, malaise, recurrent fevers, and joint involvement.
- Intestinal tuberculosis and CD have similar clinical, radiographic, and endoscopic features and can be remarkably difficult to differentiate.

Intestinal tuberculosis typically involves the ileocolonic region, and the ulcerative form is most common. A patient who has risk factors for tuberculosis should have a tuberculin skin test placed.

MANAGEMENT

The main goals of therapy are:

- Induction and maintenance of remission.
- Prevention of disease complications (fistula, stricture, abscess, and cancer).
- Maintenance of normal growth and development.

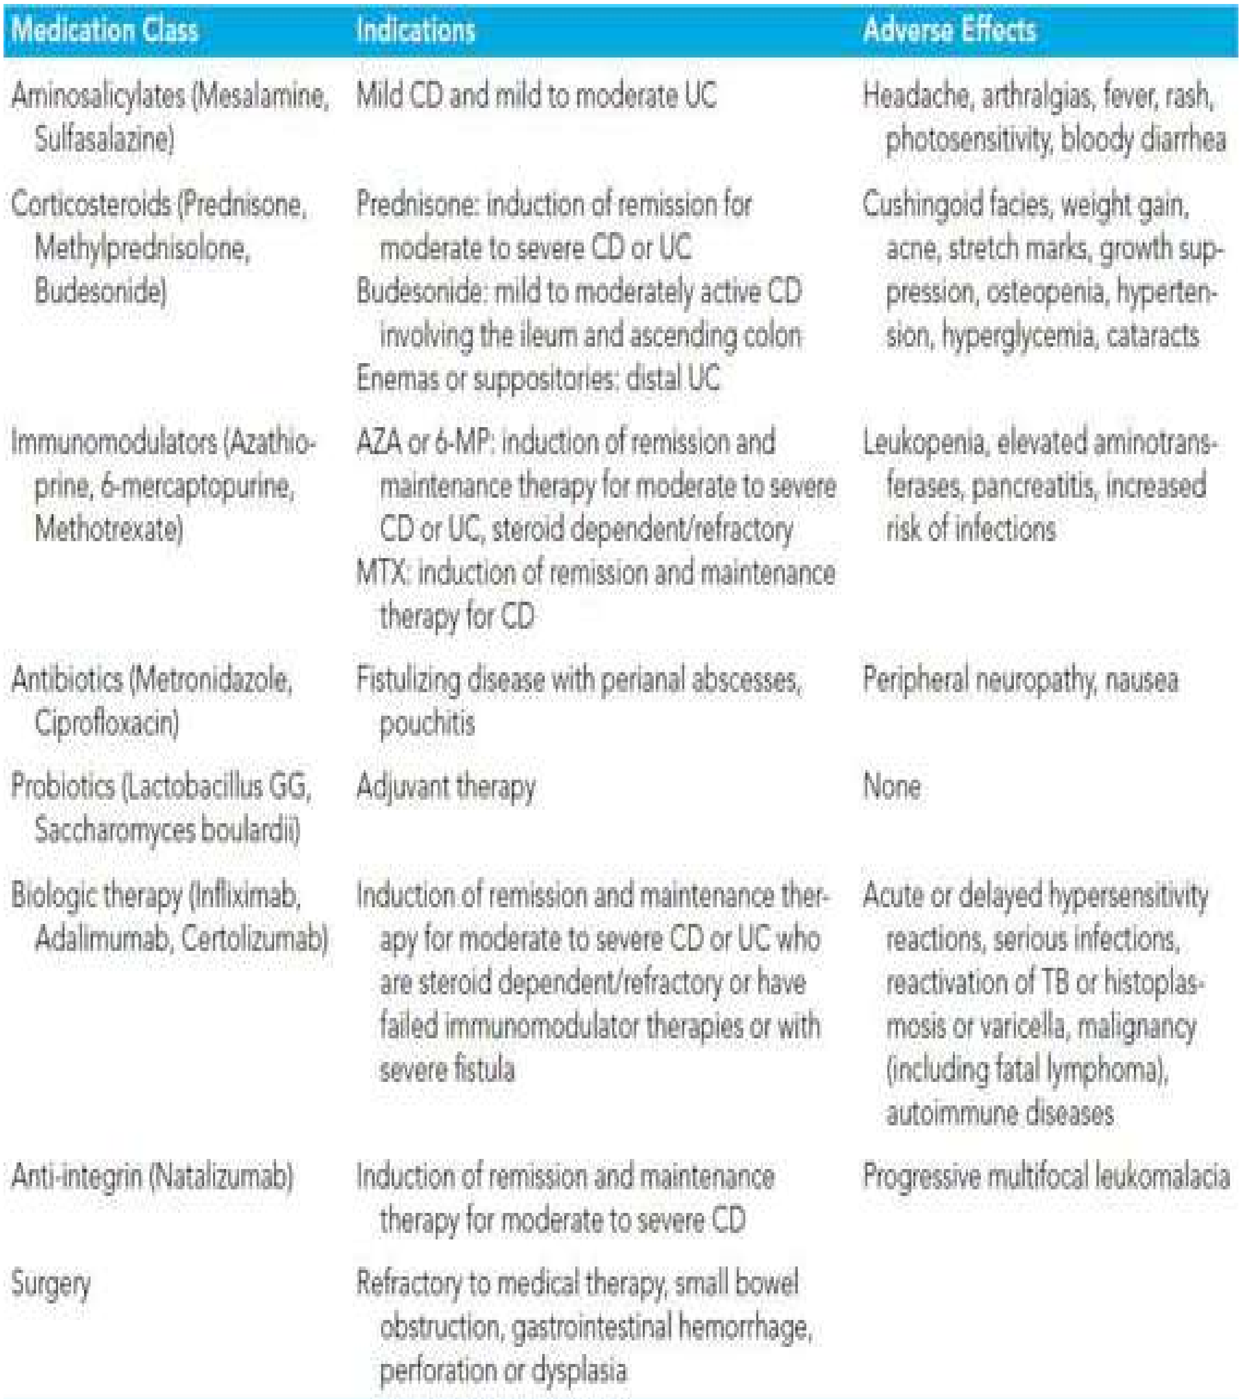
NONPHARMACOLOGIC

- Nutritional therapy is more effective in CD than UC, may consist of polymeric or elemental diets, and may result in remission of disease.[6]
- Nutritional fatigue and/or inability to sustain diet are common, often limiting the response of diet therapy alone.

MEDICATIONS

- Medications are chosen based on the disease severity and location.
- Classes of IBD medications include corticosteroids, 5-aminosalicylates (5-ASA), immunomodulators, biologic agents, antibiotics, and probiotics (**see Table 59-2**).

TABLE 59-2 Management of Inflammatory Bowel Disease



Medication Class	Indications	Adverse Effects
Aminosalicylates (Mesalamine, Sulfasalazine)	Mild CD and mild to moderate UC	Headache, arthralgias, fever, rash, photosensitivity, bloody diarrhea
Corticosteroids (Prednisone, Methylprednisolone, Budesonide)	Prednisone: induction of remission for moderate to severe CD or UC Budesonide: mild to moderately active CD involving the ileum and ascending colon Enemas or suppositories: distal UC	Cushingoid facies, weight gain, acne, stretch marks, growth suppression, osteopenia, hypertension, hyperglycemia, cataracts
Immunomodulators (Azathioprine, 6-mercaptopurine, Methotrexate)	AZA or 6-MP: induction of remission and maintenance therapy for moderate to severe CD or UC, steroid dependent/refractory MTX: induction of remission and maintenance therapy for CD	Leukopenia, elevated aminotransferases, pancreatitis, increased risk of infections
Antibiotics (Metronidazole, Ciprofloxacin)	Fistulizing disease with perianal abscesses, pouchitis	Peripheral neuropathy, nausea
Probiotics (Lactobacillus GG, Saccharomyces boulardii)	Adjuvant therapy	None
Biologic therapy (Infliximab, Adalimumab, Certolizumab)	Induction of remission and maintenance therapy for moderate to severe CD or UC who are steroid dependent/refractory or have failed immunomodulator therapies or with severe fistula	Acute or delayed hypersensitivity reactions, serious infections, reactivation of TB or histoplasmosis or varicella, malignancy (including fatal lymphoma), autoimmune diseases
Anti-integrin (Natalizumab)	Induction of remission and maintenance therapy for moderate to severe CD	Progressive multifocal leukomalacia
Surgery	Refractory to medical therapy, small bowel obstruction, gastrointestinal hemorrhage, perforation or dysplasia	

- In general, therapy for mild disease involves the use of 5-aminosalicylic acid (5-ASA) agents. SOR Ⓒ
- For patients with more severe disease or who do not respond to 5-ASA therapy, corticosteroids are typically added. These are usually effective in establishing remission but are not effective in maintaining remission.[7, 8] SOR Ⓐ

- Methotrexate may be useful in management especially if there are concurrent joint symptoms. SOR Ⓒ
- Immunomodulators, such as azathioprine, 6-mercaptopurine, and methotrexate are utilized for the treatment of steroid refractory disease and as maintenance therapy. SOR Ⓒ
- Antibiotics such as ciprofloxacin and metronidazole are often used in the management. Their precise mechanism of action and role in the management is not clear. SOR Ⓒ
- Monoclonal antibodies to tumor necrosis factor alpha, such as infliximab (given as intravenous infusions), have been shown to be highly effective in achieving clinical improvement and remission and are especially helpful in healing perianal and other fistulas.[9] SOR Ⓐ

SURGERY

- Indications for surgery for patients with IBD include the inability to control the inflammatory conditions despite optimal medical management, intestinal perforation, abscess, bowel obstruction, enterocutaneous fistula, or hemorrhage.[10]
- Surgery is not a cure for CD, but is aimed at providing relief from symptoms and treating disease complications.
- Unlike surgery for CD, surgery for UC may be curative and is used when optimal medical management fails or when there are complications of disease, such as bleeding, perforation, or toxic megacolon.

PREVENTION AND SCREENING

- Baseline bone density scan because of the risk of osteoporosis (especially with long term systemic steroids).
- Annual ophthalmology examination.

- IBD patients who are not on immunosuppressive therapy (steroids, immunomodulators, biologics) should follow routine vaccination schedule.
- Live vaccines (measles-mumps-rubella, varicella, oral polio vaccine, intra-nasal influenza) are contraindicated in immuno-compromised patients. Killed vaccines can be given according to recommended schedules.

PROGNOSIS

- 1/3 of patients may experience an IBD flare at 1 year and more than half at 2 years after initiation of therapy.
- Patients with IBD are at increased risk for colorectal cancer and the risk depends on the extent and duration of the disease.

FOLLOW-UP

- Routine surveillance colonoscopy to screen for dysplasia beginning 8 years after initial diagnosis and 1 to 2 years thereafter.

PATIENT EDUCATION

- Patients with manifestations of IBD require a careful and thorough evaluation by a gastroenterologist.
- Adherence to dietary and medical management is of paramount importance in achieving a sustained response.

60 CELIAC DISEASE

Jonathan Moses, MD
Tara Harwood, MS, RD, CSP, LD

PATIENT STORY

A 2-year-old male presents with weight loss. The mother states his pediatrician first noticed impaired growth around 12 months of age. The mother also noticed his abdomen looked more distended over the last few months and he is more irritable than usual. She describes a vague history of looser stools without overt hematochezia. Pediatric gastroenterology was consulted and sent blood work which was remarkable for mild anemia and positive anti-tissue transglutaminase immunoglobulin A antibodies (TTG IgA). The patient underwent an upper endoscopy with biopsies, which was visually remarkable for erythematous duodenal mucosa with scalloping of the intestinal folds (**Figures 60-1** and **60-2**).

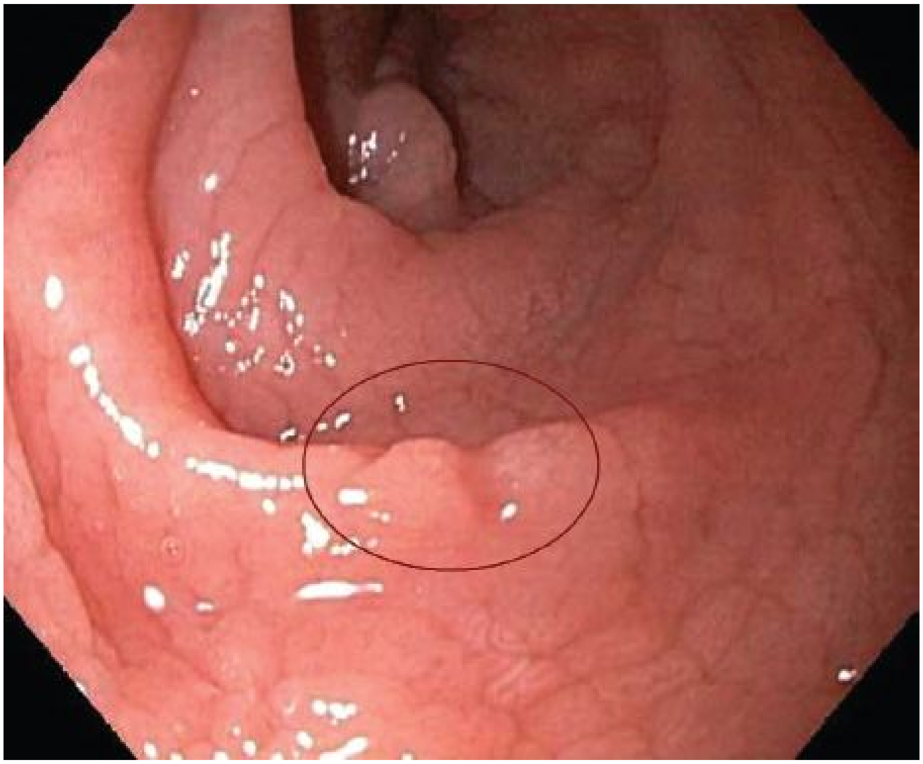

FIGURE 60-1 Endoscopic findings of scalloping in celiac disease. Note the notching of the mucosal folds (red circle). The mucosal surface also demonstrates a mosaic pattern found in celiac disease. (*Used with permission from Jonathan Moses, MD.*)

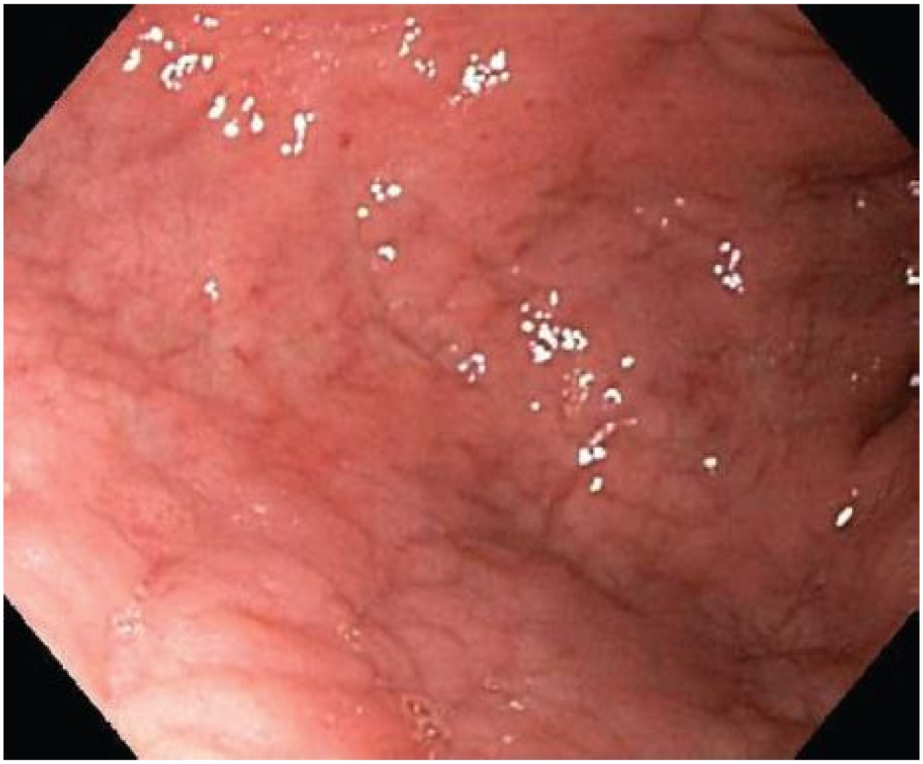

FIGURE 60-2 Endoscopic findings of nodularity in celiac disease. The duodenal mucosa shows a diffuse, nodular pattern which is an abnormality found in celiac disease. There is also significant erythema of the duodenal mucosa due to the inflammation. (*Used with permission from Jonathan Moses, MD.*)

Histology demonstrated increased intra-epithelial lymphocytes (IEL) with villous blunting, confirming the diagnosis of celiac disease (**Figure 60-3**). The patient was placed on a gluten free diet and has had improved growth and normalization of laboratory values.

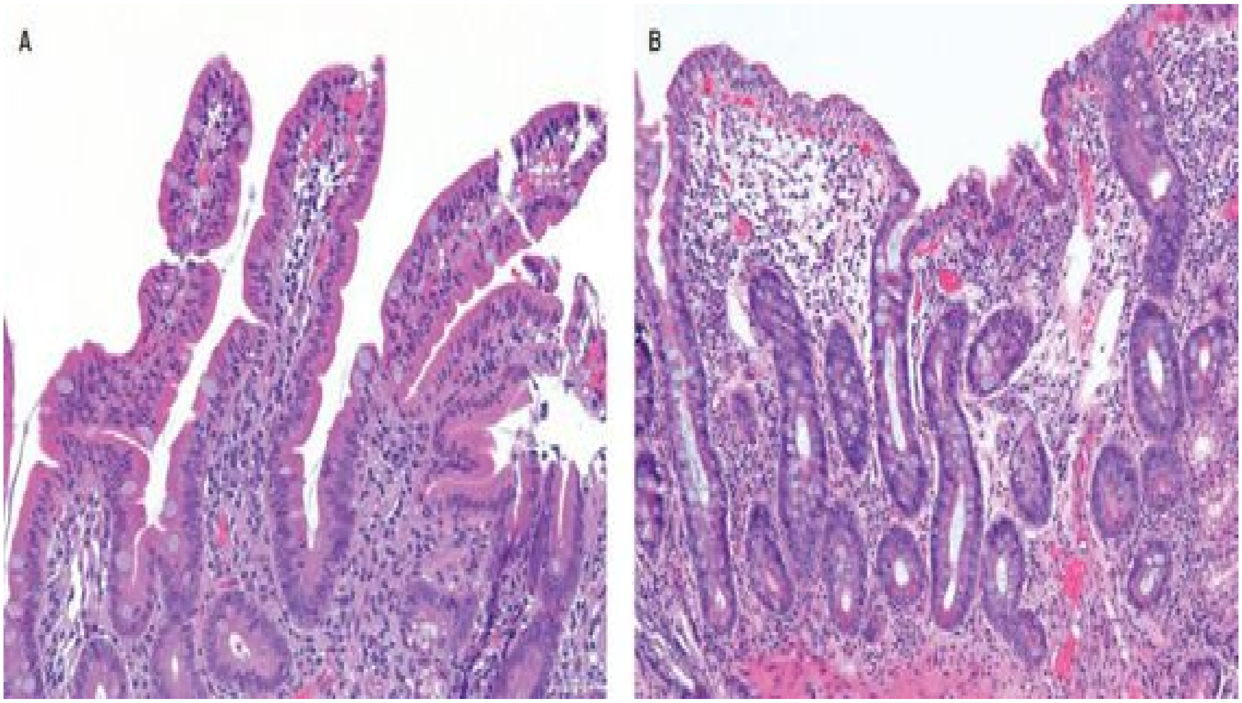

FIGURE 60-3 Histological findings in celiac disease. **A.** Marsh grade I changes with increased intraepithelial lymphocytes and intact villi. **B.** Marsh III changes with increased intraepithelial lymphocytes, crypt hyperplasia, and villous atrophy. (*Used with permission from Thomas Plesec, MD.*)

INTRODUCTION

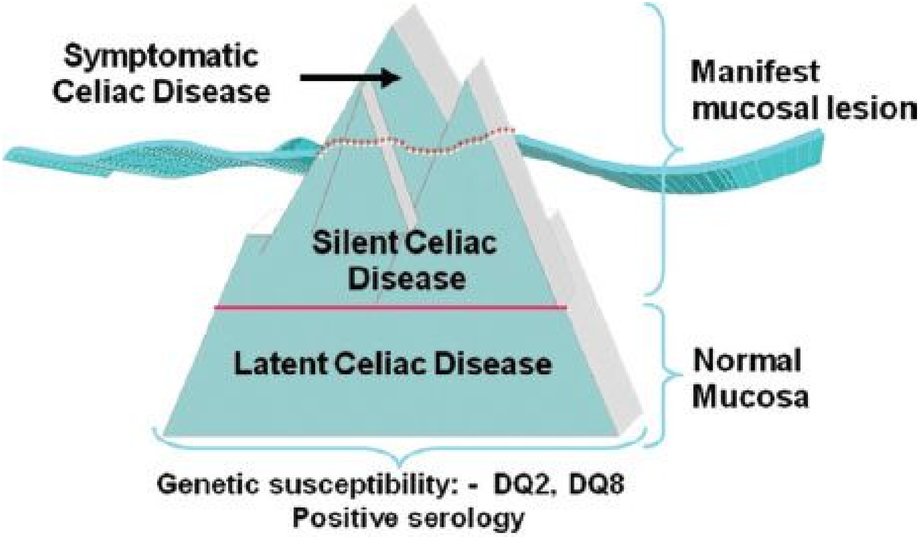
Celiac disease is an autoimmune disorder related to the ingestion of gluten containing foods in genetically susceptible individuals. If unrecognized and untreated celiac disease can result in gastrointestinal symptoms, growth disturbances, and potential long-term complications.

SYNONYMS

Celiac Sprue; Gluten Enteropathy; Gluten-sensitive Enteropathy; Nontropical Sprue.

EPIDEMIOLOGY

- Worldwide distribution has been demonstrated despite the incorrect historical view that celiac disease was limited to the Caucasian population.[1]
- Incidence of various countries:[2]
  - US—1:100 to 1:200.
  - Europe—1:88 to 1:262.
  - Middle East—1:87 to 1:166.
  - South America—1:67 to 1:681.
  - India—1:100 to 1:310.
- True incidence likely unknown given wide variation in presentation, as illustrated by the “celiac iceberg” (**Figure 60-4**).



Symptomatic Celiac Disease
Manifest mucosal lesion
Silent Celiac Disease
Latent Celiac Disease
Normal Mucosa
Genetic susceptibility: - DQ2, DQ8
Positive serology

FIGURE 60-4 The “celiac iceberg” as an illustration of the various manifestations of celiac disease. The top level represents symptomatic patients with typical mucosal lesions. The middle level represents asymptomatic patients with typical mucosal lesions. The bottom level represents asymptomatic patients with normal mucosa who will likely develop celiac disease at some point in their lifetime. The common denominator is the genetic predisposition of HLA-DQ2 and DQ8. (*Provided by The NASPGHAN Foundation for Children’s Digestive Health and*

Nutrition and the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition. www.naspghanfoundation.org and www.naspghan.org.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Celiac disease is an autoimmune disorder related to the ingestion of gluten containing foods (wheat, barley, and rye) in genetically susceptible individuals.[3,4]
- Genetic predisposition linked to human leukocyte antigen (HLA)-DQ2 and DQ8.[3,4]
    - More than 95 percent of patients with celiac disease have the HLA-DQ2 heterodimer, with the remainder positive for the HLA-DQ8.
    - Presence of the HLA-DQ2 molecules does not necessarily confer disease as 30 to 40 percent of the Caucasian population possesses this genetic background, without developing celiac disease.
- Upon ingestion of gluten containing foods, activation of the immune system occurs as follows:[5,6]
    - Deamidation of the gluten proteins by tissue transglutamine 2 (TG2) and formation of an antigen complex, which includes DQ2 and DQ8.
    - This antigen complex is presented to T cells, which become activated T cells and release antibodies to TG2 and gliadin peptides, along with pro-inflammatory cytokines.

RISK FACTORS

- The presence of other disorders places patients at-risk of developing of celiac disease.[3,7] These disorders with associated prevalence rates are:
    - Type I diabetes (8%).
    - Autoimmune thyroiditis (2%).
    - Down’s Syndrome (5 to 12%).

  - Turner Syndrome (4.1 to 8.1%).
  - Williams Syndrome (8.2%).
  - Selective IgA deficiency (1.7 to 7.7%).
- In a study by Fasano et al., the prevalence of celiac disease in a not at-risk population was 1:133 and increased to 1:22 in first degree relatives of patients with established celiac disease.[8]

DIAGNOSIS

CLINICAL FEATURES

- Classic presentation is a child between the ages of 6 to 24 months with growth issues, irritability, and diarrhea.[3] The clinical presentation of celiac disease has evolved over time as the diagnosis has become better recognized and testing more ubiquitous, with it being diagnosed across all ages.
- Gastrointestinal symptoms at presentation can include:[3]
  - Diarrhea.
  - Failure to thrive.
  - Abdominal pain.
  - Vomiting.
  - Constipation.
  - Anorexia.
  - Abdominal distention.
  - Malnutrition.
- Non-gastrointestinal symptoms at presentation can include:[3]
  - Dermatitis herpetiformis (**Figure 60-5**).

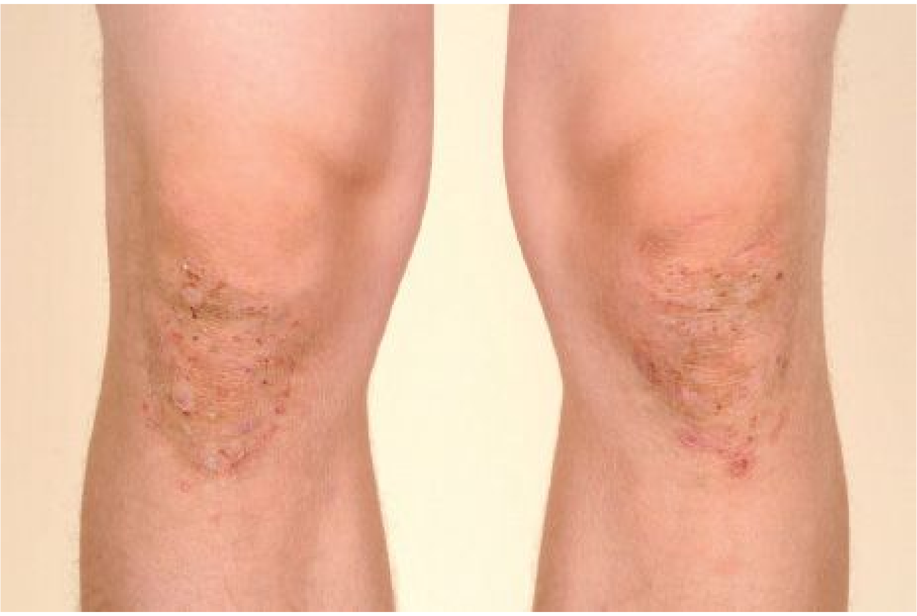


FIGURE 60-5 Dermatitis herpetiformis, an extraintestinal manifestation of celiac disease. This is characterized by a vesicular to pustular rash on an erythematous base. This lesion is symmetric and rarely asymptomatic, as patients present with severe pruritus. Correlates well with villous atrophy on endoscopy, but overt gastrointestinal symptoms may not be present. (*Used with permission from Janine Sot, Cleveland Clinic*.)

- Dental enamel hypoplasia of permanent teeth (**Figure 60-6**).

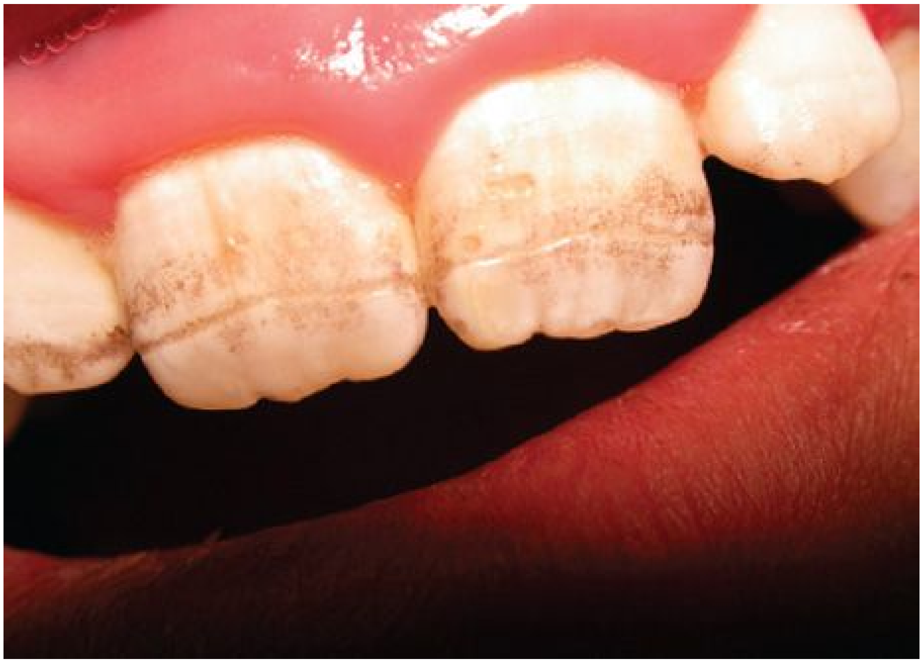

FIGURE 60-6 Dental enamel defects, another extraintestinal manifestation of celiac disease. This generally involves the secondary dentition and may be the only presenting sign of celiac disease. (*Provided by The NASPGHAN Foundation for Children's Digestive Health and Nutrition and the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition. www.naspghanfoundation.org and www.naspghan.org*.)

  - Osteopenia/osteoporosis.
  - Short stature.
  - Delayed puberty.
  - Iron deficiency anemia unresponsive to oral supplementation.
  - Hepatitis.
  - Arthritis.
  - Epilepsy with occipital calcifications.
- Asymptomatic patients are increasingly being recognized and generally fall into the at-risk population, along with first-degree relatives of patients with celiac disease.
- Celiac crisis is the rare presentation of severe diarrhea, metabolic and electrolyte abnormalities, and hypoproteinemia. It is considered a life-threatening syndrome.[1]

LABORATORY STUDIES

- Laboratory abnormalities can include iron deficiency anemia on complete blood count (CBC) and hypoalbuminemia on metabolic panel.
- First line testing should include a TTG IgA with a total IgA level. TTG IgA provides a high level and sensitivity (98%) and specificity (98%), which is ideal for screening purposes.[9]
- Additional celiac antibodies available include:
  - Anti-endomysium IgA and IgG antibodies (EMA IgA and IgG).
  - Anti-deamidated gliadin IgA and IgG antibodies (DGA IgA and IgG).
  - Anti-gliadin IgA and IgG antibodies (AGA IgA and AGA IgG).
- EMA IgA provides excellent specificity and have a role as confirmatory testing when the TTG IgA results are unclear.[1]

- In patients with IgA deficiency, IgG testing is indicated with DGA IgG performing the best.[1,9]
- AGA IgA and IgG do not provide adequate accuracy and are not recommended for screening purposes.[3]
- Genetic testing for HLA DQ2 and DQ8 status may play a role in cases of uncertain diagnosis. There may also be a role in at-risk populations to eliminate frequent screening, if both HLA DQ2 and DQ8 are negative.[3,4]

ENDOSCOPY

- The gold standard for diagnosis of celiac disease remains upper endoscopy with small bowel biopsies, specifically from the duodenum.
- Characteristic macroscopic findings include:
    - Scalloping (**Figure 60-1**).
    - Mosaicism (**Figure 60-1**).
    - Nodularity (**Figure 60-2**).
    - Erythematous mucosa (**Figure 60-2**).
    - Flattening of intestinal villi.
- Characteristic microscopic findings on biopsy include:
    - Presence of intraepithelial lymphocytes (**Figure 60-3**).
    - Villous atrophy (**Figure 60-3**).
    - Crypt hyperplasia (**Figure 60-3**).
- These histological findings are the basis of the Marsh criteria used to confirm the diagnosis of celiac disease.[10]

DIFFERENTIAL DIAGNOSIS

- Infectious diarrhea, commonly *Giardia lamblia*—may manifest with similar symptoms but can be ruled out with appropriate testing of stool and by microscopic examination of the small intestine (see Chapter 179, Gastrointestinal Infections (including diarrhea)).

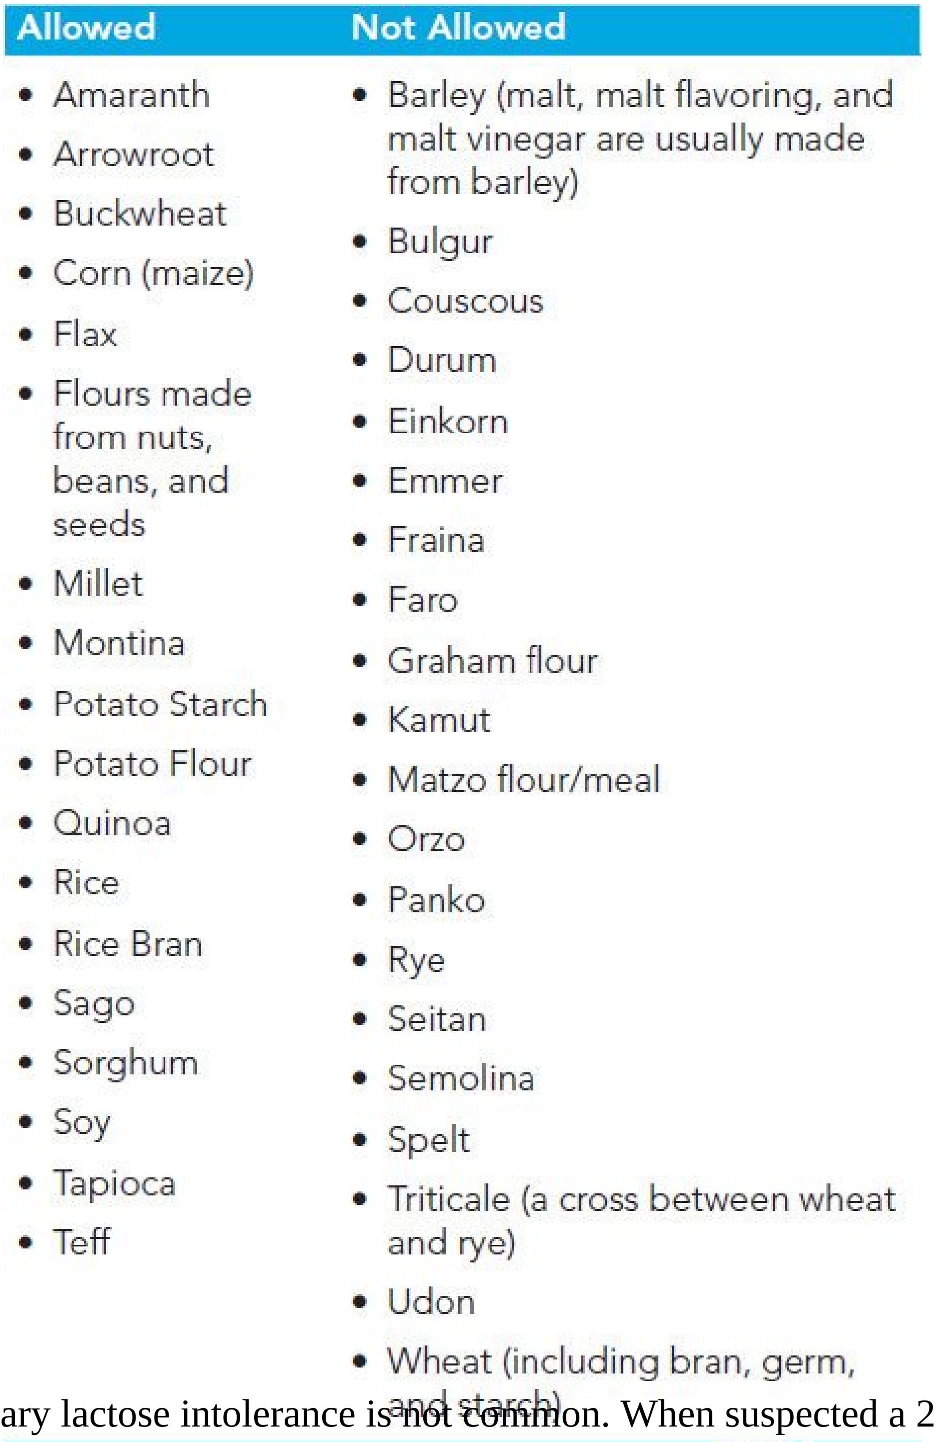
- Nonspecific diarrhea of childhood (toddler’s diarrhea)—Usually related to ingestion of large amounts of fluids and not associated with growth disturbances.
- Inflammatory bowel disease—Usually presents later in life and associated with more severe symptoms and possible extraintestinal manifestations (see Chapter 59, Inflammatory Bowel Disease).
- Autoimmune enteritis—Can be differentiated on histopathology of the small intestine.
- HIV enteropathy—Usually manifests with other signs of HIV such as lymphadenopathy and recurrent infections early in life.
- Non-steroidal anti-inflammatory drug-induced enteropathy—Can be differentiated by history, laboratory, and histopathology of celiac disease.
- Eosinophilic gastroenteritis—Usually manifests with peripheral eosinophilia and eosinophilia on histopathology of the small intestine (see Chapter 54, Esophageal Disorders).
- Food protein induced enterocolitis syndromes—Can be distinguished by appropriate laboratory and histopathologic work-up for celiac disease.
- Immunodeficiency—Usually associated with other findings such as recurrent infections.

MANAGEMENT

NONPHARMACOLOGIC

- Initiation of a gluten free diet remains the cornerstone for treatment of celiac disease.[3,11] SOR A
- Elimination of wheat, barley, and rye is advised. Elimination of oats is less clear due to concerns of gluten contamination during processing.[3]
- Acceptable dietary alternatives include rice and corn (maize), with a complete list in **Table 60-1**.[11]

TABLE 60-1 List of Grains Allowed and Not Allowed As Part of a Gluten Free Diet



Allowed	Not Allowed
• Amaranth • Arrowroot • Buckwheat • Corn (maize) • Flax • Flours made from nuts, beans, and seeds • Millet • Montina • Potato Starch • Potato Flour • Quinoa • Rice • Rice Bran • Sago • Sorghum • Soy • Tapioca • Teff	• Barley (malt, malt flavoring, and malt vinegar are usually made from barley) • Bulgur • Couscous • Durum • Einkorn • Emmer • Fraina • Faro • Graham flour • Kamut • Matzo flour/meal • Orzo • Panko • Rye • Seitan • Semolina • Spelt • Triticale (a cross between wheat and rye) • Udon • Wheat (including bran, germ, and starch)

- Secondary lactose intolerance is not common. When suspected a 2- to 4-week lactose elimination course could be instituted. SOR Ⓒ
- Commonly overlooked sources of gluten:[11]

  - Prescription and over-the-counter medications.
  - Lipstick.
  - Candy.
  - Communion wafers.
  - Beer and lagers.
  - Playdoh (proper hand washing advised, does not pass through skin).
  - Soy sauce.
  - Luncheon meats.
  - Gloss and balms.

REFERRAL

- Patients with typical gastrointestinal symptoms, non-gastrointestinal symptoms, in the at-risk groups, or with first degree relatives who have established celiac disease should be screened with a TTG IgA and total IgA level. If positive for TTG IgA with normal total IgA levels, clinical suspicion persists despite negative TTG IgA, or if IgA deficient, referral to a pediatric gastroenterologist is warranted.

SCREENING

- Patients in the at-risk group should be actively screened (**see Risk Factors**), along with first-degree relatives of patients with established celiac disease.

PROGNOSIS

- Patients who maintain a lifelong gluten free diet are expected to have a normal life expectancy.
- Untreated Celiac disease can lead to long term complications:
  - Osteoporosis.[1]
  - Increased risk of gastrointestinal malignancies.[12]

FOLLOW-UP

- Repeat TTG IgA at 6 months after institution of a gluten free diet.[3]
- Repeat TTG IgA for patients with continued symptoms and to monitor compliance with the gluten free diet.
- Once stable and developed good understanding of a gluten free diet without symptoms, follow-up is every 1 year with the pediatric gastroenterologist, which includes:
    - Assessment of growth.
    - Recheck TTG IgA.
    - Monitoring for associated conditions, such as osteoporosis or autoimmune thyroid disease.[1]

PATIENT EDUCATION

- Instructions should be given to the patient and family to continue their current diet and not implement a gluten free diet before consultation with the pediatric gastroenterologist. Initiation of a gluten free diet prior to diagnostic endoscopy can lead to false negative results on biopsy specimens.
- Newly diagnosed celiac patients should meet with a registered dietitian to review institution of a gluten free diet.

61 NEONATAL CHOLESTASIS

Katharine Eng, MD
Naim Alkhouri, MD

PATIENT STORY

A 4-week-old full-term female is seen for routine follow-up with her pediatrician. Her mother reports that she has been taking breast milk well with good weight gain. She has no specific concerns; however does report she noticed lighter colored stools recently. On physical exam, jaundice and scleral icterus are noted, along with dark urine in her diaper. The pediatrician orders labs drawn urgently and calls the pediatric gastroenterologist for immediate assistance. The work-up is expedited and she is found to have biliary atresia (**Figures 61-1** and **61-2**). The Kasai portoenterostomy procedure is performed to treat the cholestatic jaundice. This surgery involves exposing the porta hepatis and attaching part of the small intestine to the exposed liver surface to allow bile to drain out of the liver into the intestines.

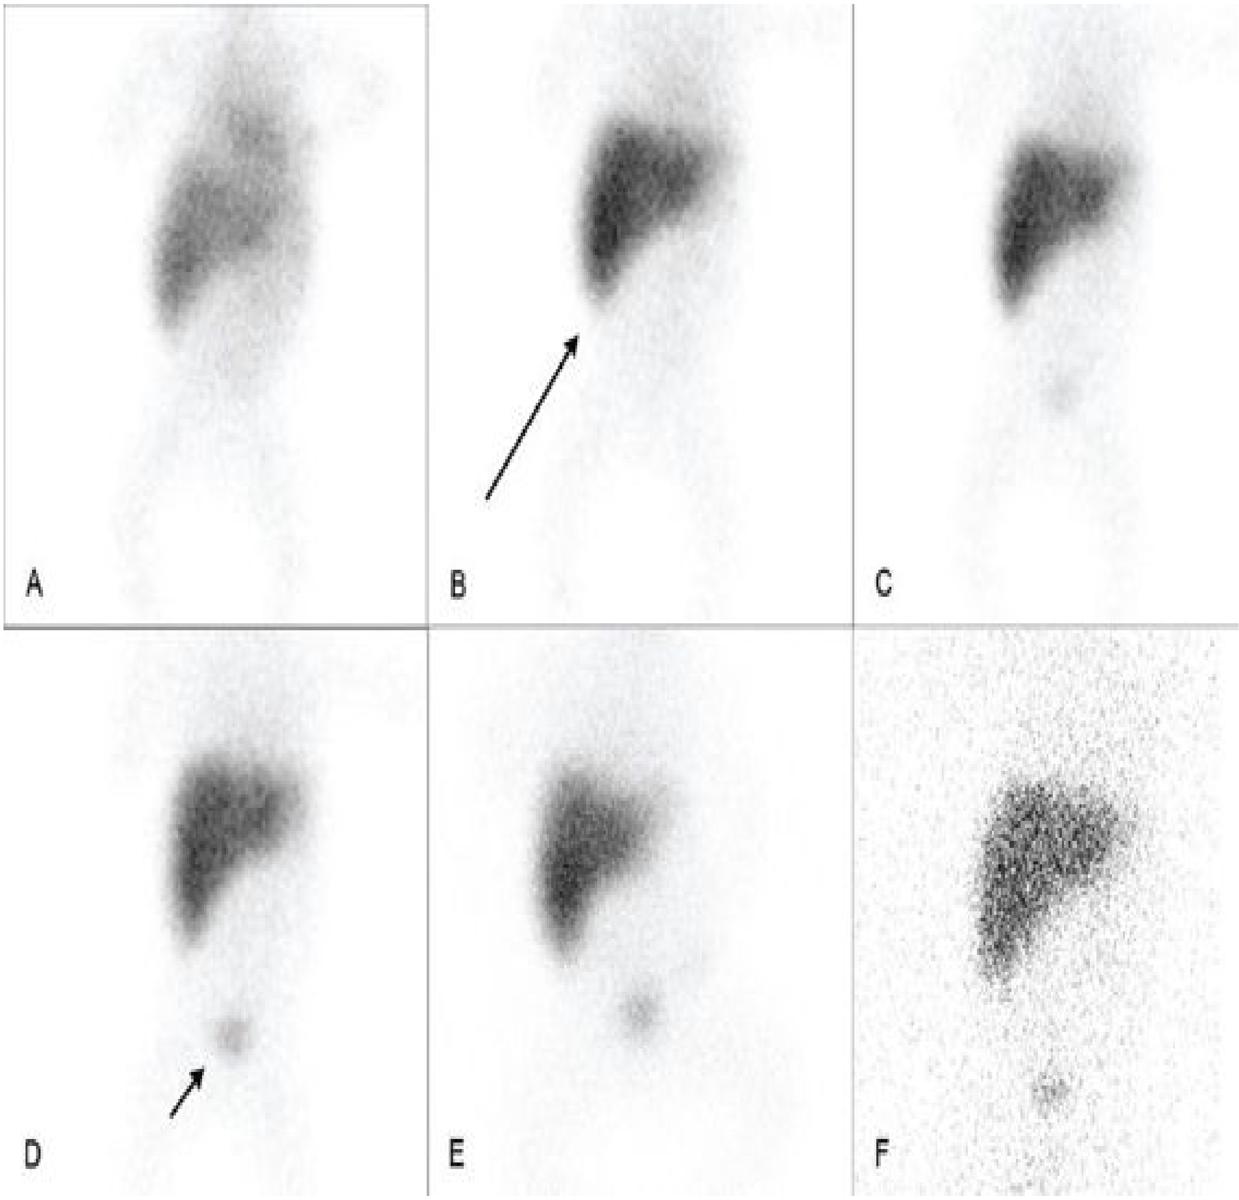

FIGURE 61-1 Biliary atresia on a hepatobiliary nuclear scintigram. Selected static images of the abdomen and pelvis seen here show good uptake of Tc-99m mebrofenin radiotracer in the liver (*large arrow*); however, there is no evidence of excretion into the biliary tree, gallbladder, or intestines. Images are taken at 1 min (**A**), 15 min (**B**), 30 min (**C**), 60 min (**D**), 4 hrs (**E**), and 24 hrs (**F**) after tracer injection. There is excretion into the bladder (*small arrow*) via the kidneys from backup of tracer in the blood

pool. Lack of bowel visualization on 24-hour images is suggestive of biliary atresia. (*Used with permission from Shyam Srinivas, MD.*)

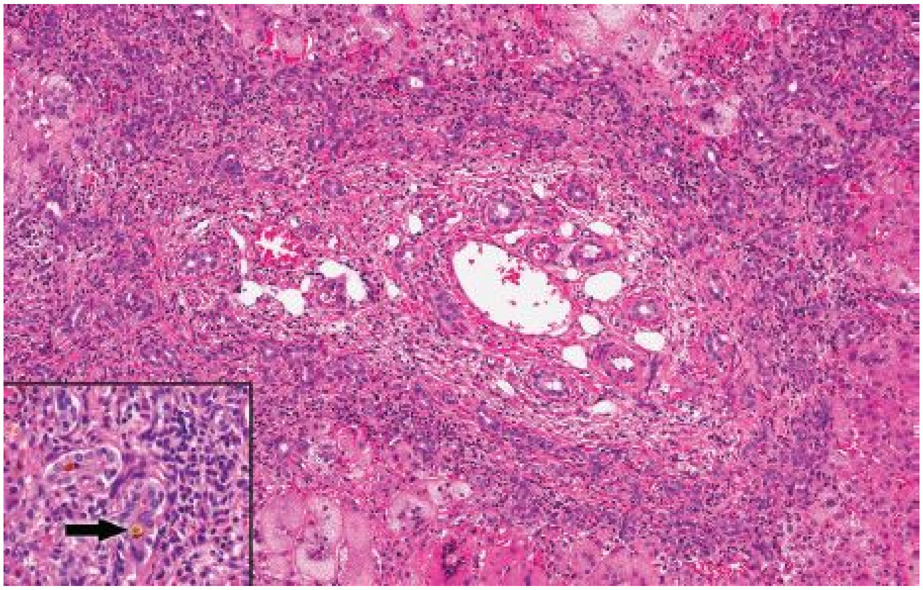

FIGURE 61-2 Biliary atresia on a liver biopsy. The typical changes seen on liver biopsy (hematoxylin and eosin stain) in a patient with biliary atresia. Note the characteristic portal edema, marked bile ductular proliferation, and chronic cholestatic changes to the periportal hepatocytes. In the inset, ductular cholestasis can be appreciated with bile duct plugging (*arrow*). (*Used with permission from Thomas Plesec, MD.*)

INTRODUCTION

- Neonatal jaundice can be a common finding in the first 2 weeks of life.
- Majority of cases are caused by *physiologic jaundice* and *breast milk jaundice*, characterized by *unconjugated hyperbilirubinemia*, which can spontaneously resolve.
- However, neonatal jaundice persisting after the 2nd week of life is concerning and requires urgent investigation to differentiate *unconjugated hyperbilirubinemia* from the less frequent, but pathological and more serious condition of *cholestatic jaundice*.

- *Cholestatic jaundice* is characterized by the *elevation of conjugated bilirubin*, indicating impaired hepatobiliary function.
- Conjugated hyperbilirubinemia has been defined as (1) direct bilirubin >1 mg/dL if total bilirubin is <5 mg/dL or (2) direct bilirubin >20 percent of the total bilirubin if the total bilirubin >5 mg/dL.[1]
- Neonatal cholestatic jaundice can be serious and requires early detection by the primary care physician with prompt referral to a pediatric gastroenterologist to ensure timely diagnosis and appropriate treatment for a favorable prognosis.
- Early intervention for underlying infectious or metabolic causes for cholestasis can be crucial, and in particular, timely surgical management of extra-hepatic biliary obstruction is of paramount importance.

SYNONYM

Neonatal cholestasis, neonatal conjugated hyperbilirubinemia.

EPIDEMIOLOGY

- Neonatal cholestasis is estimated to affect about 1 in every 2,500 infants.[2]
- There are many causes for neonatal cholestasis, with the most common cause being biliary atresia.
- The incidence of biliary atresia is estimated to be between 1 in 8,000 to 1 in 21,000 live births.[3]
- Neonatal cholestasis is caused by:
    - Biliary atresia in about 1/3 of cases.
    - Idiopathic neonatal hepatitis is estimated to comprise about 10 to 15 percent.
    - Alpha-1-antitrypsin deficiency about 10 percent.

  - Inborn errors of metabolism about 20 percent.
  - Various inherited forms of cholestasis 10 to 20 percent.
  - Congenital infections about 5 percent of cases.[3,4]

ETIOLOGY

- Cholestasis is a result of either reduced bile formation by hepatocytes or obstruction of bile flow through the intra- or extrahepatic biliary tree. This can lead to accumulation of biliary substances in the liver, extrahepatic tissue, and blood.

DIAGNOSIS

CLINICAL FEATURES

- Cholestasis may be recognized by findings of jaundice, scleral icterus (**Figure 61-3**), pale (or acholic) stools, and/or dark urine. Hepatomegaly can also be found on exam.

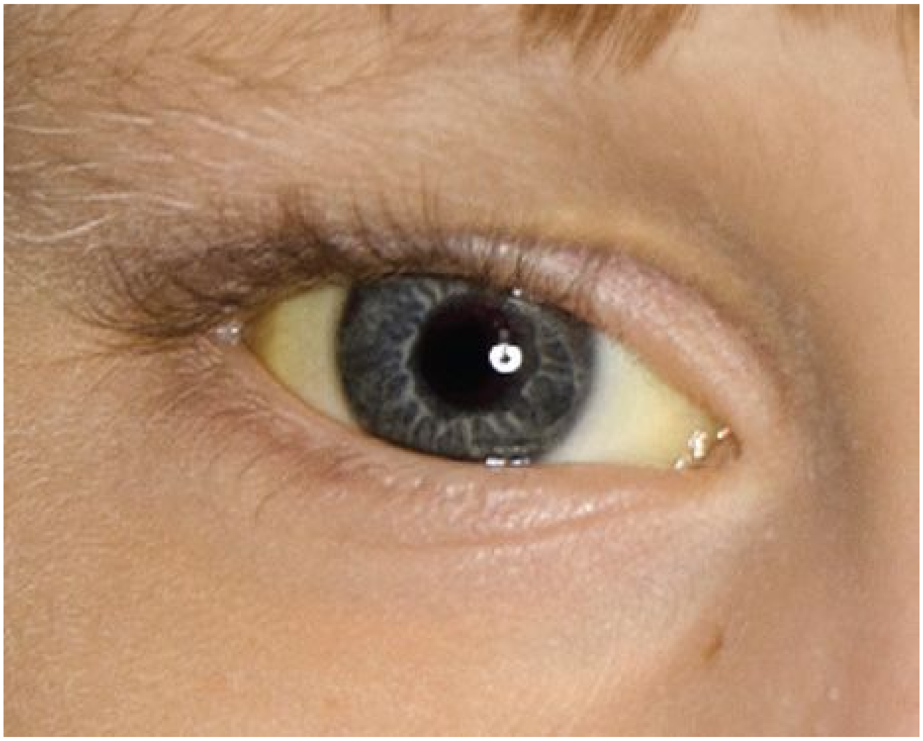

FIGURE 61-3 Scleral icterus, or yellowing of the conjunctiva of the eye, in a pediatric patient with hyperbilirubinemia. (*Used with permission from Naim Alkhouri, MD.*)

- Infants may sometimes initially present with gastrointestinal blood loss, intracranial hemorrhage, bleeding from umbilical stump, or bruising as a result of a coagulopathy from poor hepatic synthetic function and vitamin K deficiency.
- Ascites (**Figure 61-4**) and edema can also be seen in the setting of impaired hepatic function with advanced disease such as cirrhosis. Splenomegaly may be found in the setting of advanced disease, but can also be found in the presence of infection.

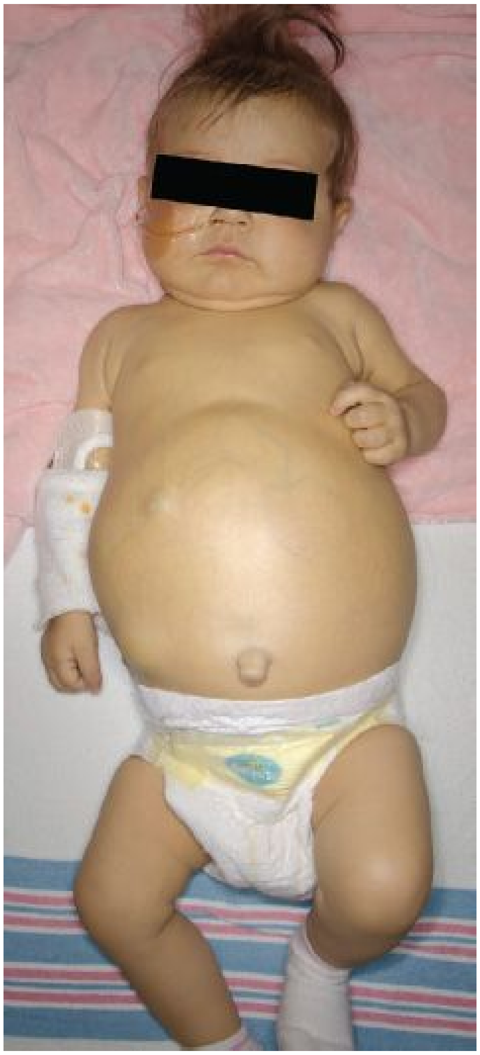

FIGURE 61-4 Ascites with abdominal distention is visible here in a 7-month-old female with history of biliary atresia, with a now failing Kasai portoenterostomy. A small incisional scar and incisional hernia are noted in the right upper quadrant region of her abdomen from her prior procedure. (*Used with permission from Naim Alkhouri, MD.*)

- The clinical presentation of neonatal cholestasis may vary depending on the underlying etiology.
- Infants with biliary atresia may present with jaundice, acholic stools, and/or dark urine, and they can often be healthy appearing and asymptomatic until later in their disease progression
- Poor feeding, irritability, lethargy, and vomiting may be seen in metabolic disorders such as galactosemia and tyrosinemia, but also may be a sign of

generalized infections causing cholestasis.

- Infants with cholestasis secondary to congenital infections may present with low birth weight, microcephaly, chorioretinitis, and purpura.
- Dysmorphic facial features (**Figure 61-5**), heart murmur, and anomalies of vertebrae, eyes, and kidneys may be found in Alagille syndrome.[5]

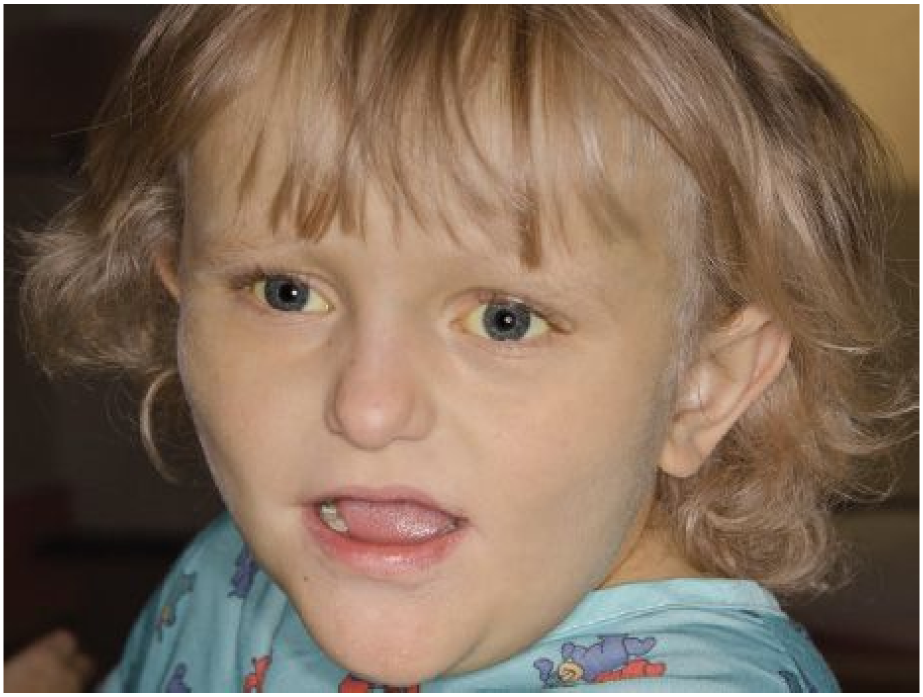

FIGURE 61-5 Alagille syndrome in a 3-year-old girl with the classic dysmorphic facial features. Note the prominent forehead, straight nose with flattened tip, deep-set eyes, and pointed chin. (*Used with permission from Naim Alkhouri, MD.*)

LABORATORY STUDIES[3]

▸ Initial laboratory studies

- Initial laboratory tests should always include a fractionated bilirubin to establish the presence of cholestasis, along with a total bilirubin.
- Tests of hepatic synthetic function: ammonia, albumin, serum glucose levels, or coagulation studies (partial thromboplastin time, prothrombin

time and INR, coagulation factor levels).

- Serum hepatic chemistry: ALT, AST, alkaline phosphatase, or gamma glutamyl transferase.
- Complete blood count.
- Blood and urine culture if indicated.

More specific laboratory studies to be considered based on the differential diagnosis:

- Serum alpha-1-antitrypsin level and phenotype.
- Sweat chloride analysis.
- Serology and culture for infection (TORCH, viral hepatitis, parvovirus, or HIV).
- Urine and serum bile acid analysis.
- Metabolic screen (urine reducing substances, urine and serum amino acids and organic acids, galactose-1-phosphate uridylyltransferase activity).
- Endocrinologic studies (TSH, free T4, or consider work-up for hypopituitarism).
- Genetic testing (Alagille syndrome, cystic fibrosis, or progressive familial intrahepatic cholestasis).

IMAGING

- Ultrasound—Can be useful to identify structural causes of cholestasis, such as the presence of gallstones, sludge in biliary tree or gallbladder, or choledochal cyst. A small or absent gallbladder would be suggestive (but not diagnostic) of biliary atresia, however, the presence of the gallbladder does not exclude biliary atresia.
- Hepatobiliary scintigraphy—Can be useful to differentiate biliary atresia from nonobstructive causes of cholestasis. While hepatobiliary scintigraphy has a high sensitivity for biliary atresia, it is important to note that the specificity is low, thus diagnosis should not be made solely on this test (**Figure 61-1**).[6]

INVASIVE TESTS

- Percutaneous liver biopsy—Thought to be the most reliable diagnostic procedure in the evaluation of neonatal cholestasis (**Figures 61-2** and **61-6**).[6]

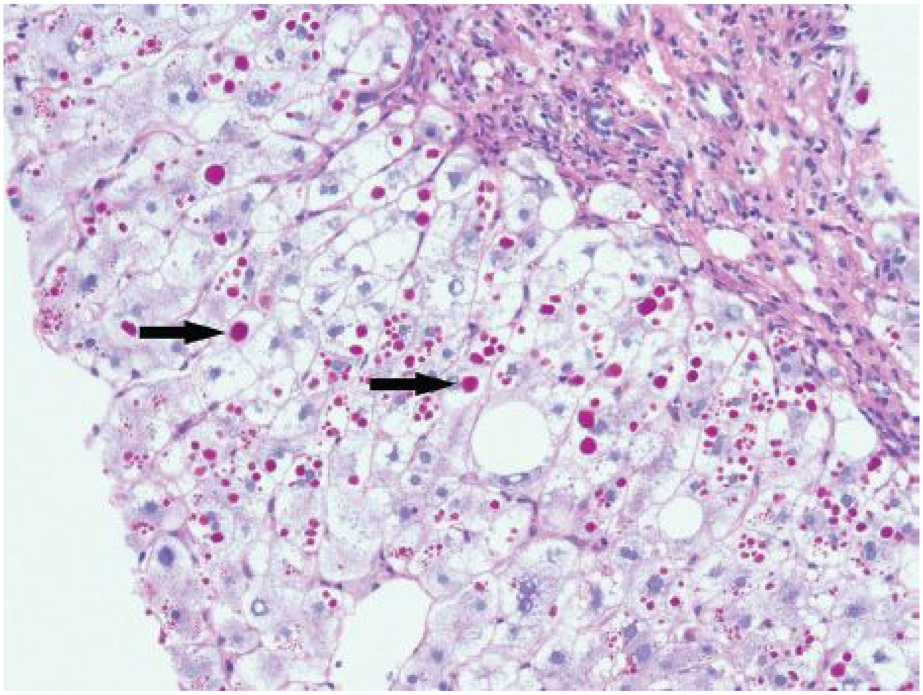

FIGURE 61-6 Alpha-1-antitrypsin on a liver biopsy. A PAS with diastase stain has been performed on this liver biopsy specimen in a patient with alpha-1-antitrypsin deficiency. Note the presence of PAS-positive diastase-resistant pink periportal intracytoplasmic globules (*arrows*), which is characteristic of this disease. (*Used with permission from Thomas Plesec, MD.*)

- If biliary atresia cannot be excluded from initial studies, an exploratory laparotomy and intra-operative cholangiography should be performed.

DIFFERENTIAL DIAGNOSIS

OBSTRUCTIVE CHOLESTASIS

- Biliary atresia—Most common cause of neonatal cholestasis and critical to identify as early as possible.
- Choledochal cyst—A rare congenital bile duct anomaly that may manifest with cholestasis and diagnosed with imaging.
- Alagille syndrome—An autosomal dominant genetic disorder with variable expression is associated with abnormalities in liver, heart, skeleton, eye, kidneys, and with distinct facial features (**Figure 61-5**).
- Cholelithiasis or biliary sludge—Rarely presents early in life.
- Cystic fibrosis—Cholestasis may be a result of abnormally viscous bile resulting in obstruction of bile ducts (see Chapter 51, Cystic Fibrosis).
- Congenital hepatic fibrosis—May be associated with other congenital defects; more frequently associated with polycystic kidney disease (see Chapter 66, Polycystic Kidneys).

HEPATOCELLULAR CHOLESTASIS

- Idiopathic neonatal hepatitis—Features of hepatocellular cholestasis but without a specific etiology found.
- Genetic/metabolic disorders.
  - Alpha-1-antitrypsin deficiency—Most common hereditary cause of liver disease in children.
  - Disorders of bile acid secretion and metabolism—Related to deficiency in enzymes necessary for bile acid synthesis/metabolism or defects in biliary epithelial transporters.
  - Cystic fibrosis—See the preceding discussion.
  - Galactosemia—A rare metabolic disorder that affects the ability to metabolize the sugar galactose appropriately; cholestasis may be the initial manifestation.
  - Tyrosinemia—An inherited metabolic disorder in which the body lacks the enzyme to metabolize tyrosine, an amino acid found in most proteins.

  - Hereditary fructosemi—A metabolic disorder that affects the ability to metabolize the sugar fructose appropriately; key identifying feature is the appearance of symptoms following the introduction of fructose into the diet.
  - Other inborn errors of metabolism.
- Endocrine disorders—Cholestasis may be the initial manifestation of hypothyroidism or hypopituitarism.
- Infectious—Cholestasis and hepatitis is a common manifestation of any infection in the neonate and always warrant consideration because the manifestations of these infections are nonspecific:
  - Viral infection (cytomegalovirus, HIV, herpesvirus, coxsackie virus, echovirus, rubella, or parvovirus).
  - Bacterial infection (urinary tract infection, sepsis, or syphilis).
  - Toxoplasmosis.
- Vascular disorders.
  - Budd-Chiari—Occlusion of the hepatic veins or outflow of blood from the liver.
  - Cardiac insufficiency—May compromise blood flow to the liver and biliary tract.
  - Shock, hypoperfusion—May compromise blood flow to the liver and biliary tract.
- Toxic/secondary.
  - Parenteral nutrition-associated cholestasis—In neonates who are in the neonatal intensive care unit receiving parenteral nutrition for various reasons.
  - Drugs (maternal or used in intensive care)—Hepatotoxic drugs or medications used by the mother or the infant.

MANAGEMENT

- Recognition of neonatal cholestasis by the primary care physician is critical, and prompt referral to a pediatric gastroenterologist for further work-up is necessary.

- It is important to address medical and surgical emergencies immediately when evaluating a neonate with cholestasis.
- Specific management of neonatal cholestasis is often dependent on the underlying diagnosis, and it is important to identify those diseases that are amenable to early surgical intervention (e.g., biliary atresia, choledochal cyst) or specific medical therapy (e.g., hypothyroidism, galactosemia, infections).
- Early diagnosis of biliary atresia is crucial to a good outcome. Observational evidence and expert recommendations suggest that infants referred for Kasai portoenterostomy before 45 to 60 days of age have the greatest likelihood of re-establishing bile flow and longer term survival of their native liver.[1,7 8 9–10] SOR A Some studies do suggest that there is no contraindication to performing a Kasai portoenterostomy for biliary atresia in children over 75 days of age and up to 100 days.[11,12] One study by Wong et al. showed performing the Kasai portoenterostomy between the age of 60 and 100 days was not associated with a worse outcome.[12]
- In addition to treating specific disorders, general management for neonatal cholestasis is mainly supportive, working towards optimal nutrition and growth, correcting fat soluble vitamin deficiencies if present, and treating complications such as hypercholesterolemia, pruritus, portal hypertension, cirrhosis, and liver failure.[4]

REFERRAL

- Cholestasis in the pediatric population requires evaluation by a pediatric gastroenterologist.
- Further referral may be required depending on the specific etiology of the cholestasis.

PROGNOSIS

- The specific prognosis depends on the etiology for the cholestasis.
- The preponderance of the evidence shows that infants with biliary atresia who undergo portoenterostomy prior to 60 days of age have a better prognosis than those diagnosed after this time period.[7–10]

FOLLOW-UP

- The need for and specific timing for follow-up depends on the specific diagnosis and should be directed by the appropriate subspecialists.

PATIENT EDUCATION

- Parents should be educated regarding the possible etiologies and work-up for cholestasis.
- Once the specific etiology is found, support for the family can be provided, as many of the causes of cholestasis are chronic in nature.

62 ANAL AND RECTAL DISORDERS

Federico G. Seifarth, MD
Gavin A. Falk, MD

It is important to recognize the various anal and rectal disorders in infants and children. In this chapter, the following disorders are discussed in succession:

1. Hirschprung disease
2. Imperforate anus
3. Rectal prolapse
4. Anal fissure
5. Anal abscess and Fistula in ano

HIRSCHSPRUNG DISEASE

PATIENT STORY

An 8-week-old girl is brought to your office with abdominal distention and constipation. On digital examination of her anus she has an episode of explosive diarrhea and flatus. A plain radiograph shows stool impaction and a contrast enema reveals a transition zone in the sigmoid colon (**Figure 62-1**). A suction biopsy confirms the diagnosis of Hirschsprung disease. An enema regimen was started and 3 weeks later she underwent a primary pull through operation.

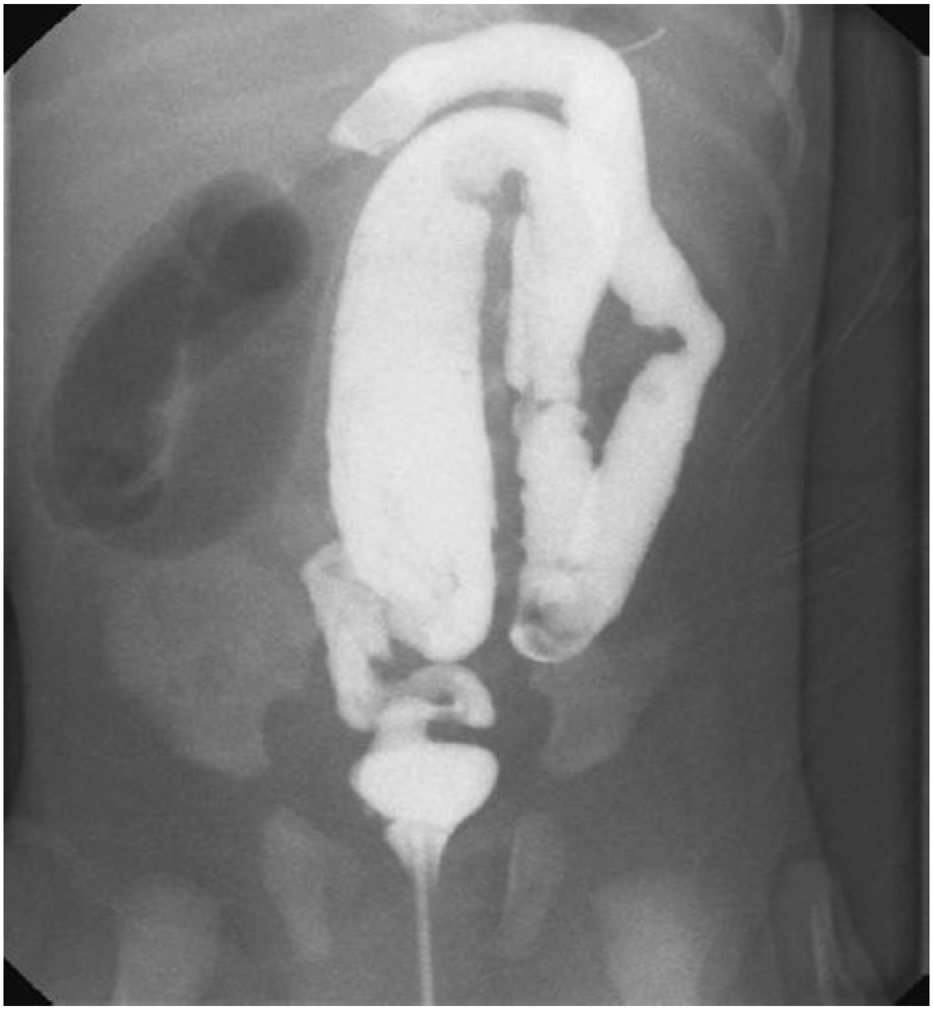

FIGURE 62-1 Hirschprung disease on a water-soluble contrast enema demonstrating a transition zone at the splenic flexure. (*Used with permission from Oliver S. Soldes, MD.*)

INTRODUCTION

Hirschsprung disease is a developmental disorder of the enteric nervous system characterized by absence of ganglion nerve cells in the myenteric and submucosal plexuses of the distal intestine.

SYNONYMS

Hirschsprung disease; partial or total aganglionosis; congenital megacolon.

EPIDEMIOLOGY

- US: 1 case per 5400 to 7200 newborns.
- Worldwide: 1 case per 1500 to 7000 newborns.[1]
- Most cases are diagnosed by 2 years of age.

ETIOLOGY AND PATHOPHYSIOLOGY

- Congenital aganglionosis of the distal bowel leads to impaired bowel peristalsis with constipation. The aganglionosis usually begins in the anus and continues proximally for a variable distance.
- There are two theories for the aganglionosis: The incomplete migration of ganglion cells from the neural crest to the distal bowel or the dysfunctional maturation or apoptosis of primitive nerve cells. There is increasing evidence that mutations in a variety of genes, including the RET proto-oncogene, may play a key role in the etiology.[2,3]

RISK FACTORS

- Race: No racial predilection.
- Sex: Male to Female ratio 4:1.
- About 10 percent of patients have a positive family history.

- Trisomy 21.

DIAGNOSIS

HISTORY

- Neonatal period.
  - Consider the diagnosis in any newborn with delayed passage of first meconium. beyond the first 24 hours, abdominal distention, and repeated vomiting.
  - Signs of intestinal obstruction with bilious vomiting, poor feeding, and failure to thrive.
- Children.
  - Chronic constipation, abdominal distension since birth.
  - Soiling and overflow incontinence.
- Enterocolitis.
  - Ten percent of all patients present with fever, abdominal distension, and diarrhea caused by enterocolitis, which can progress to colonic perforation and life-threatening sepsis.

CLINICAL FEATURES

- Physical examination may reveal a distended abdomen and/or a hypertonic anus with empty rectum.
- Digital rectal examination may result in explosive expulsion of stool.

RECTAL BIOPSY

- Definitive diagnosis is made by histologic evaluation of a rectal biopsy.

- A *suction* rectal biopsy that samples rectal mucosa and submucosa is routinely used in neonates and small children and can be performed at the bedside.
- Alternatively, full-thickness rectal biopsies are taken under general anesthesia in the OR.

LABORATORY TESTING

- White blood cell count and C-reactive protein may be elevated in children with enterocolitis.
- Chemistry panel: Electrolytes are usually normal. Children with diarrhea may have findings consistent with dehydration.

IMAGING

- Plain abdominal radiographs may show distended bowel without air in the rectum.
- Contrast enema—A narrowed distal colon representing the pathologic segment with proximal dilation of the normal bowel is the classic finding (**Figure 62-1**).

ANORECTAL MANOMETRY

- Demonstrates decreased relaxation of the diseased segment.
- May not be available in all facilities and is not routinely used for neonates.
- Most useful in the evaluation of an older child with chronic constipation to rule out Hirschsprung disease.

DIFFERENTIAL DIAGNOSIS

- Functional constipation—Usually not associated with systemic symptoms, failure to thrive and bilious vomiting.
- Cystic fibrosis—Can present with meconium ileus early in life (see Chapter 51, Cystic Fibrosis).
- Hypothyroidism—Constipation is often a manifestation along with other systemic findings.
- Intestinal obstruction—May present with similar symptoms and may need to rely to imaging studies to determine the location of the obstruction.
- Ileus—Usually more acute and does not present with systemic manifestations such as failure to thrive.
- Neonatal sepsis—Always need to be considered in the newborn, but signs other than constipation usually evident (see Chapter 187, Congenital and Perinatal Infections).
- Intestinal Motility Disorders—May present with symptoms similar to Hirschsprung but without the systemic manifestations.
- Low imperforate anus with large perineal fistula opening—Usually can be seen on physical examination.

MANAGEMENT

- Definitive treatment is surgical—To remove the aganglionic portion of bowel, which can be performed semielectively.[4,5] SOR Ⓐ
- Preoperative considerations include treatment of complications of unrecognized or untreated disease until reconstructive surgery can be performed:
  - Constipation—Rectal stimulation, enemas, laxatives.
  - Dehydration—Resuscitation with intravenous fluids.
  - Bowel obstruction—Naso-/orogastric tube decompression.
  - Enterocolitis—Colonic irrigations, broad-spectrum antibiotics.

MEDICATIONS

- Antimicrobial therapy—Perioperatively and in cases of enterocolitis. SOR Ⓒ
- Laxatives. SOR Ⓒ

SURGERY

- Surgical treatment options:
    - Primary pull-through procedure without diverting colostomy.
    - Diverting colostomy with secondary definitive repair.
- Contraindications to a one-stage procedure include very distended proximal bowel, enterocolitis, bowel perforation, and malnutrition.

REFERRAL

- Pediatric surgeon.
- Pediatric gastroenterologist.
- Geneticist if associated with a syndrome.

PREVENTION AND SCREENING

- Hirschsprung disease can be associated with different syndromes, including trisomy 21.[6]

PROGNOSIS

- Left untreated, Hirschsprung disease results in a high rate of mortality.

- Common postoperative problems include obstructive symptoms, fecal soiling, and enterocolitis.[7]
- Constipation can be caused by mechanical obstruction, residual aganglionosis, motility disorder, or habitual stool-holding behavior.
- The long-term outcome after definitive pull-through procedure is good.[4,5] SOR B
- Most adolescents and adults with Hirschsprung disease report normal sexual function.

FOLLOW-UP

- Despite proper corrective surgery patients remain at high risk of developing constipation, soiling, and enterocolitis.[7]

PATIENT RESOURCES

ANORECTAL MALFORMATIONS—IMPERFORATE ANUS

PATIENT STORY

A newborn boy is found to have noticeably flat buttocks and no anal opening on his first physical examination (**Figure 62-2**). The pediatric surgeon is consulted and the child is given nothing by mouth (NPO). The following day fecal particles are noted in his urine. A cross-table radiograph shows a rectal stump above the coccyx (**Figure 62-3**). A high rectourethral fistula is suspected and the surgeon takes the neonate to the operating room for colostomy formation. Three months later the child undergoes definitive imperforate anus repair and later colostomy takedown.

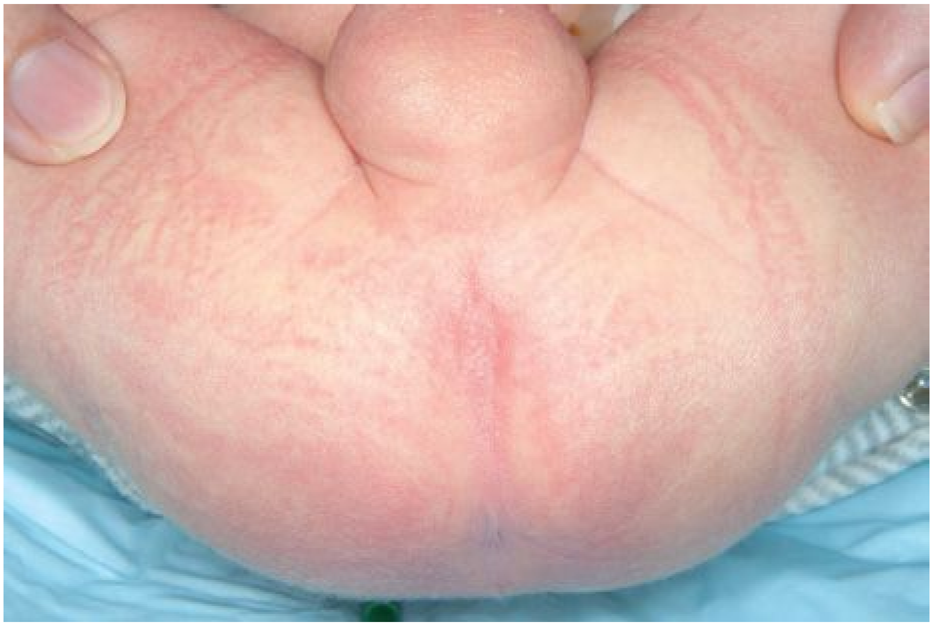

FIGURE 62-2 Newborn boy with imperforate anus and rectourethral fistula. (*Used with permission from Federico Seifarth, MD.*)

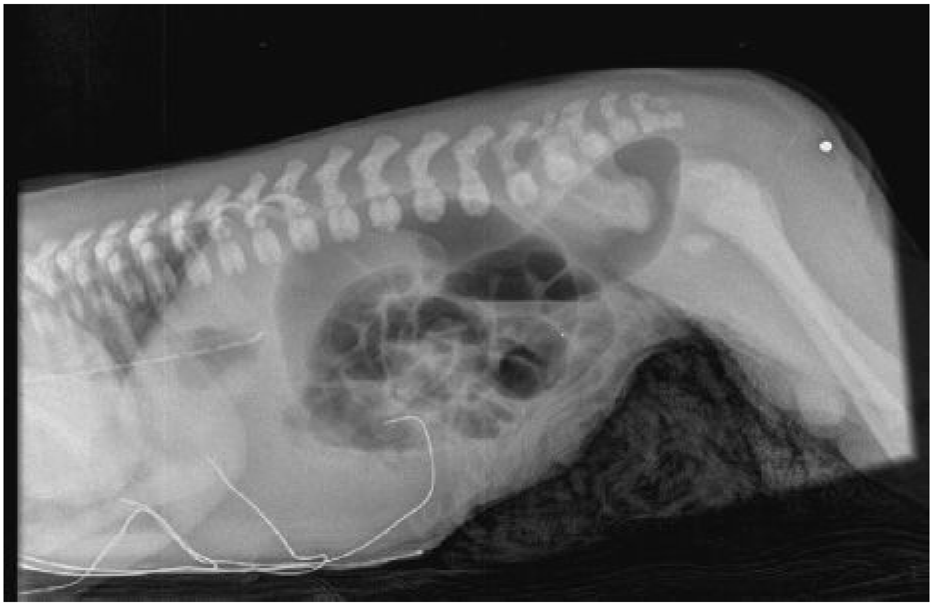

FIGURE 62-3 Cross-table lateral radiograph showing a high rectal stump. The radiopaque pellet marks the imperforate anal skin. (*Used with permission from Federico Seifarth, MD.*)

INTRODUCTION

Imperforate anus is a congenital anomaly in which the natural anal opening is absent. The presentation is highly variable with inconsistent findings of fistulas to skin or the urogenital tract. The term “anorectal malformations” integrates various forms of imperforate anus.

EPIDEMIOLOGY

- Approximately 1 newborn per 5000 live births.[8]
- Slight male preponderance.

ETIOLOGY AND PATHOPHYSIOLOGY

- Defects in the early urogenital and anorectal development, normally completed by 9 weeks gestation, account for the described abnormalities of imperforate anus.[9]

RISK FACTORS

- There are no known risk factors.
- Most cases are sporadic, but geographic clustering and families with cases in succeeding generations have been described.

DIAGNOSIS

- Usually identified at first physical examination in newborn age. More subtle cases of imperforate anus with large perineal fistulas may be missed and manifest later with chronic constipation.

CLINICAL FEATURES

- Usually discovered within 24 hours—At first physical exam or when the neonate develops abdominal distention and fails to pass meconium.
- May present with flat buttocks, malformed sacrum, perineal fistula opening, or no visible signs of meconium filled fistula tract.[10]
- Lesions are classified as *low* or *high* based on the termination of the rectum in relation to the levator muscles or more recently according to clinical relevance and fistula anatomy.

LABORATORY TESTING

- Urinalysis.

IMAGING

- Directed to identify associated anomalies: cardiac, gastrointestinal, spinal/sacral/vertebral, or urogenital.[11]
    - Babygram—Vertebral anomalies.
    - Sacral radiography—Sacral defects.
    - Abdominal ultrasonography—Genitourinary tract anomalies.
    - Spinal ultrasonography—Spinal malformations.
    - Echocardiogram—Cardiac defects.
    - Cross-table lateral radiograph—Elevated, prone lateral radiograph to determine level of sacral pouch if no fistula is evident on second day of life (**Figure 62-3**).

MANAGEMENT

- Assessment of type of malformation, level of rectal pouch, and identification of rectal fistula, which is present in the majority of cases.
- Naso-/orogastric tube decompression and NPO.
- Workup for associated malformations.
- Planning of surgical management according to the level of the rectal pouch: *high* versus *low*.

MEDICATIONS

- Newborns with imperforate anus should not be fed and need intravenous hydration. SOR B

SURGERY

- Primary repair versus colostomy and definitive repair in a staged fashion.[12] SOR Ⓑ
  - High lesions (high position of rectal pouch and urogenital fistulas) may require initial colostomy (**Figure 62-4**).

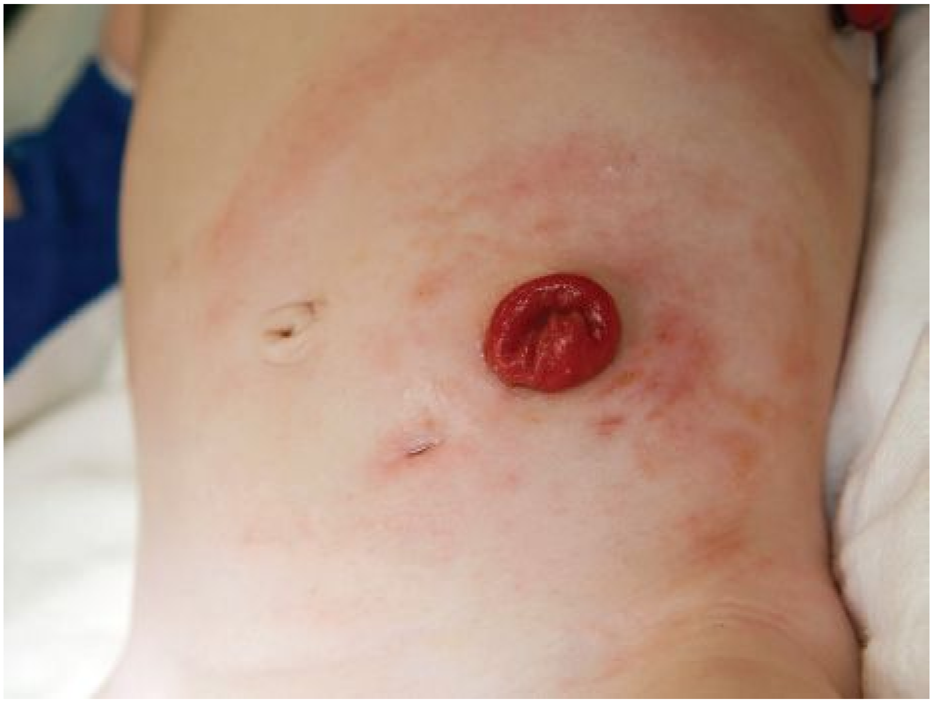

FIGURE 62-4 Descending sigmoid colostomy with distal mucous fistula in a patient with an imperforate anus/recto-bladder neck fistula. (*Used with permission from Federico Seifarth, MD.*)

-
  - Low lesions with visible fistulas at skin level may be primarily repaired.
- The preferred surgical approach for anal reconstruction is the posterior sagittal anorectoplasty (PSARP; **Figure 62-5**).[12] SOR Ⓑ

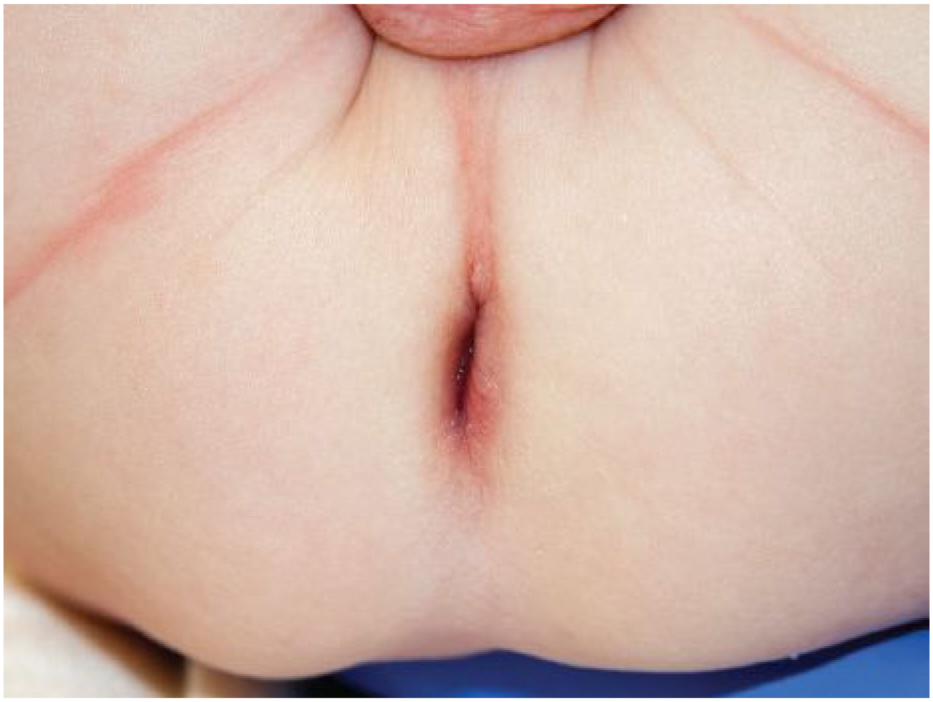

FIGURE 62-5 New functional anus after operative reconstruction of an imperforate anus/recto-bladder neck fistula. (*Used with permission from Federico Seifarth, MD.*)

REFERRAL

- Immediate consultation of Pediatric surgeon.
- Neurosurgeon, if a tethered spinal cord is present (25% of all cases).

PROGNOSIS

- Patients with anorectal malformations may suffer from long-term sequelae like constipation and fecal soiling.

FOLLOW-UP

- Long-term close follow-up is required to early identify and treat complications such as soiling and constipation. Some patients need lifelong bowel management and dietary modifications.[13]

PATIENT RESOURCES

RECTAL PROLAPSE

PATIENT STORY

A 3-year-old boy is brought to your office. He was recently potty trained and has been complaining of anal pain after defecation for the last two days. His mother noted a mass protruding from his anus after bowel movements (**Figure 62-6**). On further discussion, the mother reports that her son has an aversion to using the potty. Potty training was delayed, and the mother was educated on importance of a high fiber/fluid diet to promote regular, soft bowel movements. On follow up, the prolapse had resolved.

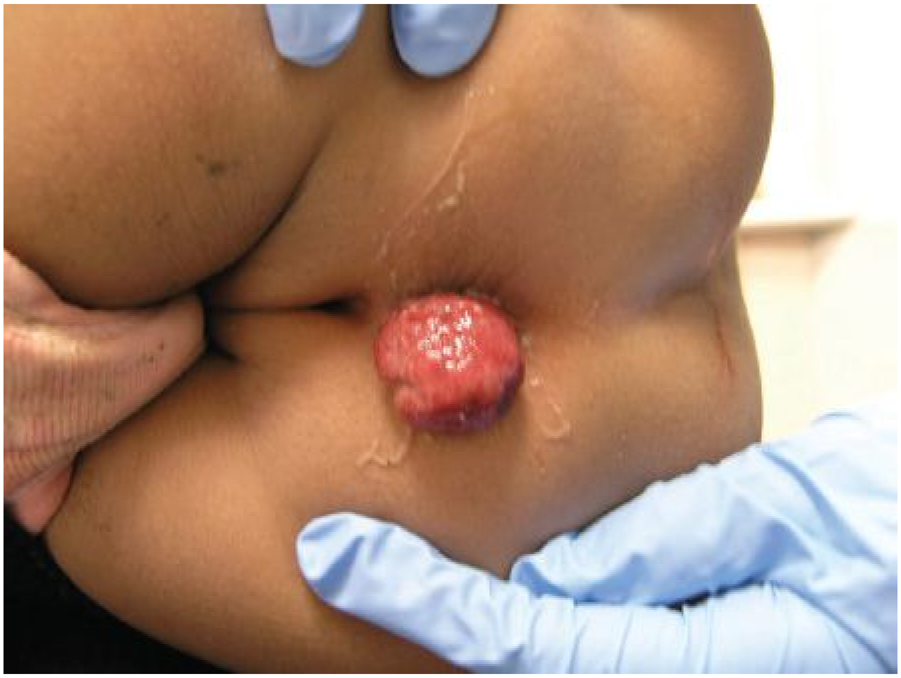

FIGURE 62-6 Mucosal rectal prolapse in a child. (*Used with permission from Thomas J Abramo, MD, From Figure 72-7 Pediatric Emergency Medicine, 3rd edition. www.accessemergency medicine.com*.)

INTRODUCTION

Rectal prolapse in a child is relatively common and the vast majority of patients do not have any predisposing factors. It may involve only a small ring of mucosa or all layers of the rectum (full thickness prolapse).

EPIDEMIOLOGY

- Relatively common with peak incidence between 1 to 3 years of age.

ETIOLOGY AND PATHOPHYSIOLOGY

- Idiopathic.
- Postoperative—Mucosal rectal prolapse is common after imperforate anus repair (PSARP).
- Predisposing conditions:
    - Constipation—Controversial. Only 3 percent of patients with chronic constipation have rectal prolapse.[14]
    - Cystic fibrosis (CF)—More than 20 percent of CF patients suffer from rectal prolapse.
    - Myelomeningocele—Dysfunctional levator ani complex.
    - Connective tissue disorders—Ehler-Danlos.
    - Behavioral disorders—Withholding stool with subsequent increased intraabdominal pressure.
    - Rectal polyps may act as leading point.

RISK FACTORS

- See Etiology.

DIAGNOSIS

- Usually noticed by parents shortly after or during defecation.

CLINICAL FEATURES

- A rosette of rectal mucosa is seen after defecation and usually reduces spontaneously.
- Radial folds of mucosa are suggestive of mucosal prolapse.

- Concentric circles of mucosa are seen with full-thickness prolapse (**Figure 62-7**).

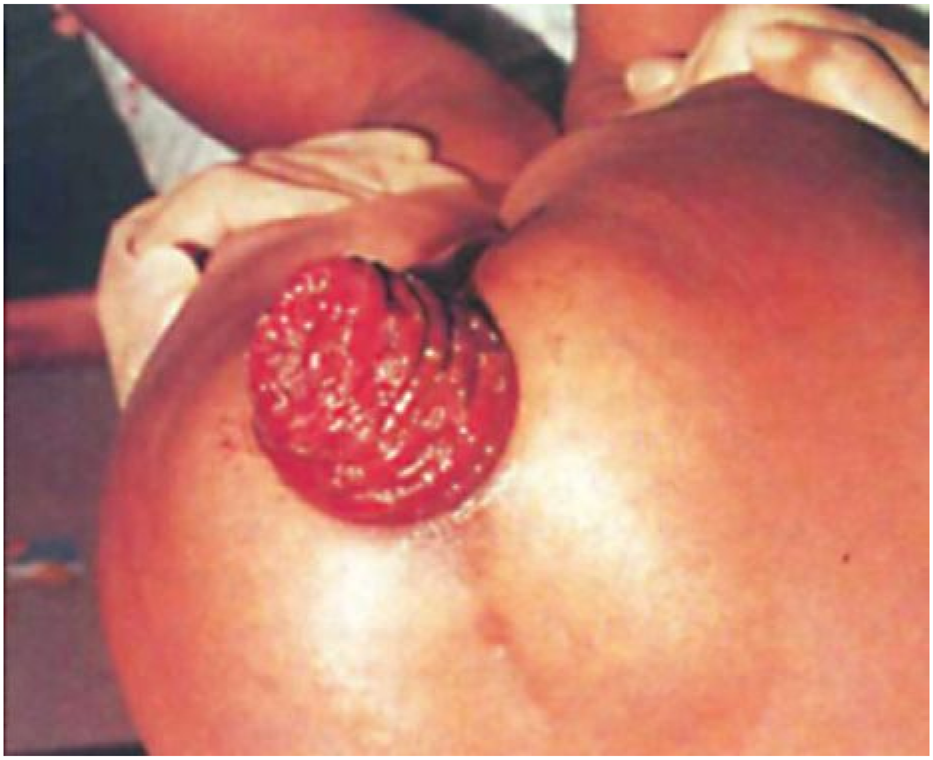

FIGURE 62-7 Full thickness rectal prolapse with concentric rings. The concentric rings in the prolapsed mucosa are a sign of a full thickness rectal prolapse. (*Used with permission from Rudolph Textbook of Pediatrics, 22nd edition. Figure 416-1. www.accesspediatrics.com*.)

- Easy manual reduction.

DIFFERENTIAL DIAGNOSIS

- Prolapsing rectal polyp—Can usually be differentiated by appearance of the tissue.
- Hemorrhoids—Unusual in the pediatric population. Can usually be differentiated by the characteristic appearance.

- Intussusception—Usually associated with abdominal pain and bloody/mucus stools (see Chapter 58, Intussusception).
- Proctitis—Usually associated with systemic manifestations.

MANAGEMENT

- Nonoperative management—Prompt manual reduction.

NONPHARMACOLOGIC

- Biofeedback in patients with chronic straining or paradoxical contractions of the anal sphincters. SOR Ⓒ
- Behavioral modification.

MEDICATIONS

- Treat diarrhea or constipation if present.

SURGERY

- Reserved for chronic prolapse in children older than 4 years of age or for complicated cases with recurrent, painful, ulcerated, or bleeding prolapse. SOR Ⓒ
- Surgical options include transanal treatments such as sclerotherapy, thermocauterization, or excision of redundant mucosa. SOR Ⓑ
- Laparoscopic suspension of the rectum to anterior sacrum or resection of the sigmoid colon may be rarely necessary.[15] SOR Ⓑ

REFERRAL

- Pediatric surgeon—Gastroenterologist.

PREVENTION AND SCREENING

- Screen for Cystic fibrosis.[16]
- Proctosigmoidoscopy to rule out rectal polyps or other lesions.

PROGNOSIS

- High rate of spontaneous resolution.[17] SOR Ⓑ
- Patients older than 4 years of age require surgery much more frequently than younger children.[18] SOR Ⓑ
- Low recurrence rate for patients who require surgery.[19] SOR Ⓑ

FOLLOW-UP

- Routine well child visits by primary care physician.

PATIENT EDUCATION

- Parents need to be educated regarding the role of constipation in the etiology of rectal prolapse.

PATIENT RESOURCES

- **www.livestrong.com/article/220449-rectal-prolapse-in-children**.

PROVIDER RESOURCES

- **www.patient.co.uk/doctor/Rectal-Prolapse.htm**.

ANAL FISSURE

PATIENT STORY

An 11-month-old baby boy presents with blood in his diaper. Examination of his anal region reveals longitudinal skin lesions (**Figure 62-8**). The differential is discussed with the parents and sitz baths were recommended. Dietary changes are advised in order to promote regular, soft bowel movements. Three weeks later at follow-up, the child's anal fissure has healed.

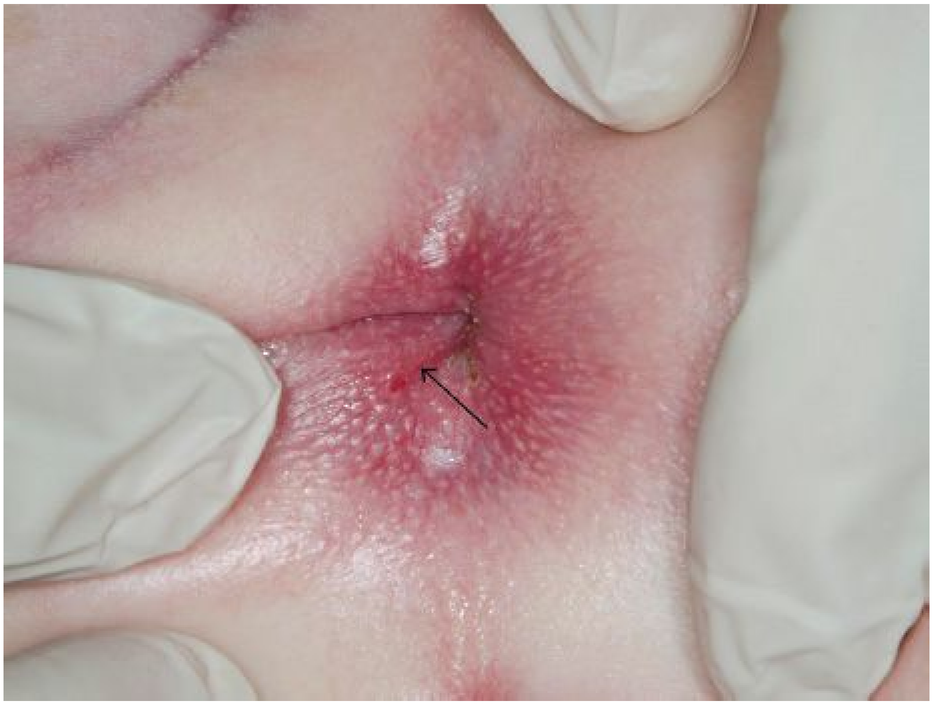

FIGURE 62-8 Anal fissure in an 11-month-old boy who presented with diarrhea and streaks of blood in his stool. (*Used with permission from Federico Seifarth, MD.*)

INTRODUCTION

An anal fissure is a longitudinal tear in the distal anal canal epithelium that extends from the dentate line to the anal verge. It is the most common cause of rectal bleeding in childhood and a frequent cause of anal pain.

EPIDEMIOLOGY

- Anal fissures may occur at any age but most commonly occur in children aged 12 to 24 months.

ETIOLOGY AND PATHOPHYSIOLOGY

- The pathogenesis of anal fissures is not completely understood.
- A mechanical tear caused by hard stools is the suspected etiology in children.
- Avoidance of painful defecation can worsen the fissure and prevent healing.
- May become infected and develop into a chronic ulcer.

RISK FACTORS

- Constipation.
- Habitual stool withholding.

DIAGNOSIS

HISTORY

- Painful bowel movements, with bright red blood on stool, diaper or toilet paper.
- Diagnosis is made by inspection.

CLINICAL FEATURES

- Gentle retraction of the perianal skin reveals a longitudinal tear usually in the posterior midline.
- Digital examination should be avoided as it will cause pain and sphincter spasm.
- Usually posterior midline (90%) but may be seen in the anterior midline or lateral.
- A classic sentinel skin tag in the posterior midline can develop from a healed fissure. This is due to epithelialized granulation tissue from chronic inflammation.

IMAGING

- Abdominal flat radiograph to evaluate grade of constipation may be obtained.

DIFFERENTIAL DIAGNOSIS

- Pruritus ani–Usually differentiated based on history of pruritis and evidence of more widespread irritation.
- Inflammatory bowel disease–Usually more chronic or recurrent and associated with systemic manifestations (see Chapter 59, Inflammatory Bowel Disease).
- Immunologic disorders–Usually involved other mucosal surfaces and other manifestations usually present, such as failure to thrive and recurrent infections (see Chapter 221, Combined B and T cell Immunodeficiencies).
- Sexual abuse–Should be suspected based on the history and extent of the involvement (see Chapter 9, Child Sexual Abuse).

MANAGEMENT

NONPHARMACOLOGIC

- Nonsurgical management includes dietary modification, stool softeners, sitz baths, and increasing fluid consumption and fiber intake. SOR Ⓒ

MEDICATIONS

- Botulinum toxin injections into the anal sphincter muscles to reduce pressure for chronic fissures.[20] SOR Ⓐ

SURGERY

- Surgical therapies are rarely necessary.

- Reported surgical options for chronic anal fissure in children include fissurectomy, anal dilatation, and lateral internal sphincterotomy.[21] SOR A

PREVENTION AND SCREENING

- Adequate hydration, high fiber diet, and avoid constipation and straining. SOR B

PROGNOSIS

- Symptoms usually resolve in 10 to 14 days with medical management.[22]
- In 50 percent of cases, idiopathic fissures heal in 6 to 8 weeks with conservative management, and 25 percent of these will have a recurrence in 5 years.[23] SOR B

FOLLOW-UP

- Dietary modifications, stool softeners, and sitz baths should be continued for several weeks after operative treatment.
- A follow-up visit is scheduled for 2 to 3 weeks after the procedure.

PATIENT EDUCATION

- Parents should be educated regarding the importance of adequate hydration and avoidance of constipation.

- Reassurance should be provided to the parents that anal fissures are usually benign and resolve with adequate attention to prevent dehydration and constipation.

PATIENT RESOURCES

- **www.patient.co.uk/health/Anal-Fissure.htm**.

PROVIDER RESOURCES

- **www.cpnonline.org/CRS/CRS/pa_analfis_hhg.htm**.

PERIANAL ABSCESS AND FISTULA IN ANO

PATIENT STORY

A 5-month-old boy presents with an area of cellulitis and obvious fluctuance in his perianal region (**Figure 62-9)**. He undergoes and incision and drainage under general anesthesia (**Figures 62-10** and **62-11**). Two months later, he still suffers from recurrent drainage from the abscess site. He is taken back to the operating room and a fistula in ano is diagnosed and unroofed. At follow-up 4 weeks later, no evidence of the previous fistula tract can be found.

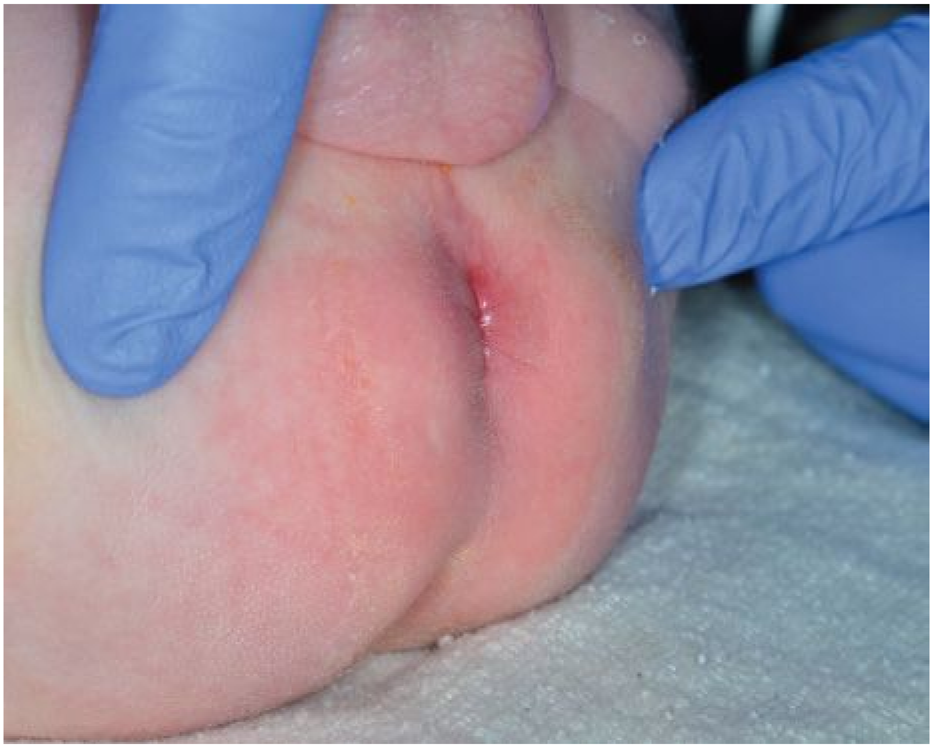

FIGURE 62-9 Perianal abscess at 9 o’clock position in lithotomy position. Note the induration at the site. (*Used with permission from Federico Seifarth, MD.*)

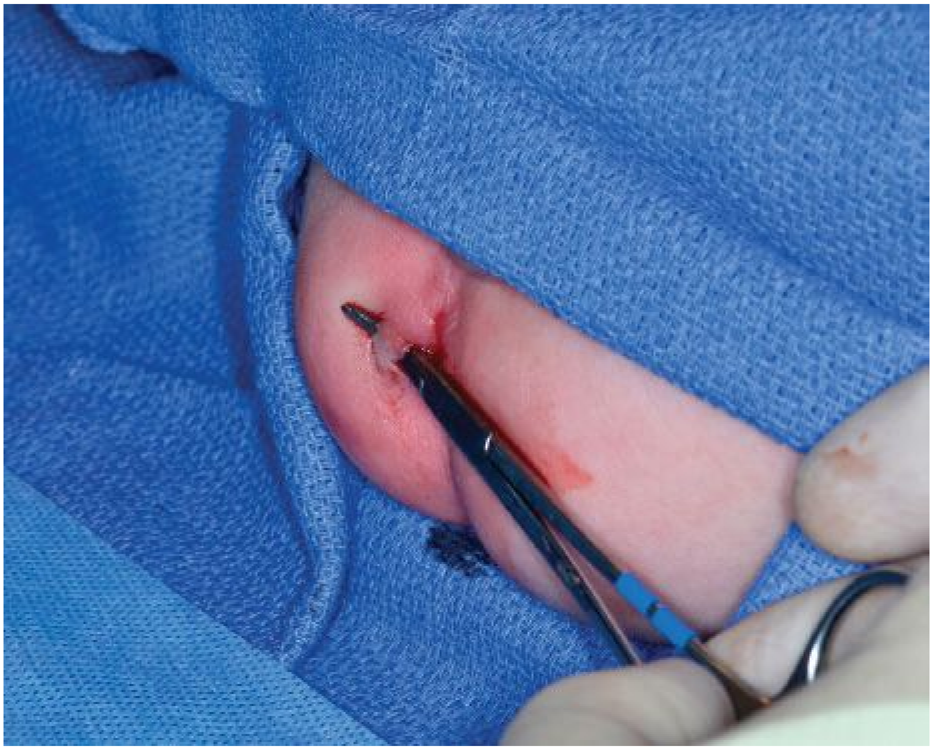

FIGURE 62-10 Incision and counterincision of perianal abscess. (*Used with permission from Federico Seifarth, MD.*)

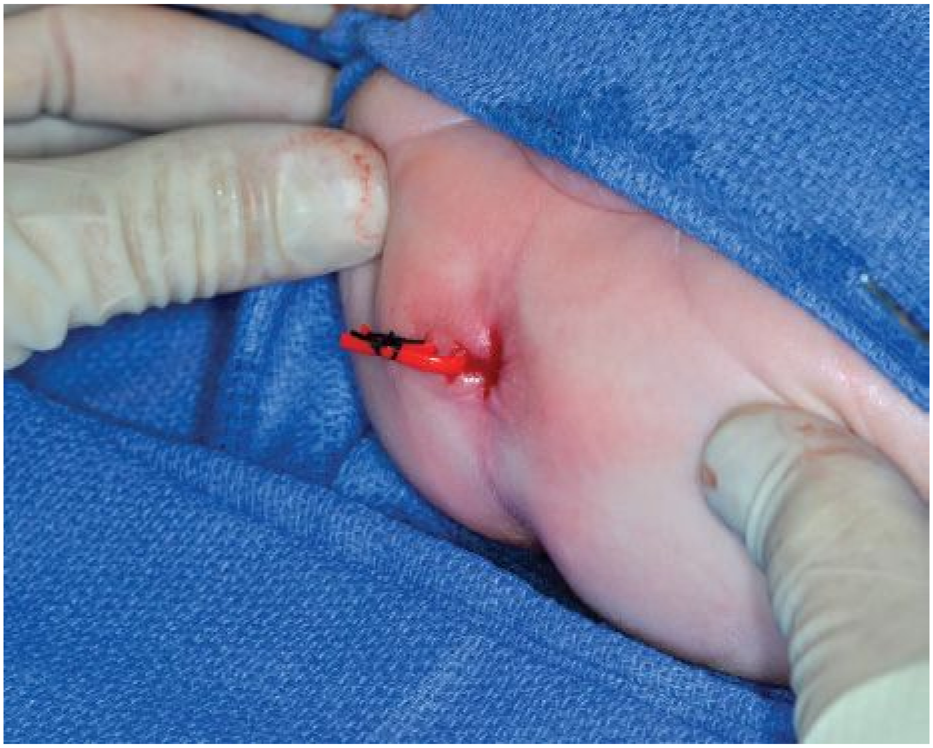

FIGURE 62-11 Perianal abscess with red vessel loop drain in place. (*Used with permission from Federico Seifarth, MD.*)

INTRODUCTION

Perianal abscesses are common and typically present between 6 and 12 months of age. After spontaneous rupture or incision and drainage, the condition may progress to a fistula in ano in 10 to 20 percent of patients.[24]

EPIDEMIOLOGY

- More common in males.

ETIOLOGY AND PATHOPHYSIOLOGY

- Perianal abscesses are caused by infected anal crypts.
- Epithelization of draining abscesses can lead to development of anal fistulas. They traverse from the affected crypt through the subcutaneous external sphincter to the perianal skin.
- A congenital etiology has been suggested for infant anal fistulas.[25]
- A proposed relationship to androgens resulting in congenital deep, epithelialized crypts may explain the predominant occurrence in male infants.[26]

RISK FACTORS

- Male gender.

DIAGNOSIS

A careful physical examination of the perianal region is the key to the diagnosis.

CLINICAL FEATURES

- Abscess–Tender erythematous perianal swelling with or without spontaneous drainage.
- Anal fistula–Draining fistulous tract opening or perianal pustule (**Figure 62-12**). The tract is typically subcutaneous, extrasphincteric, and straight.

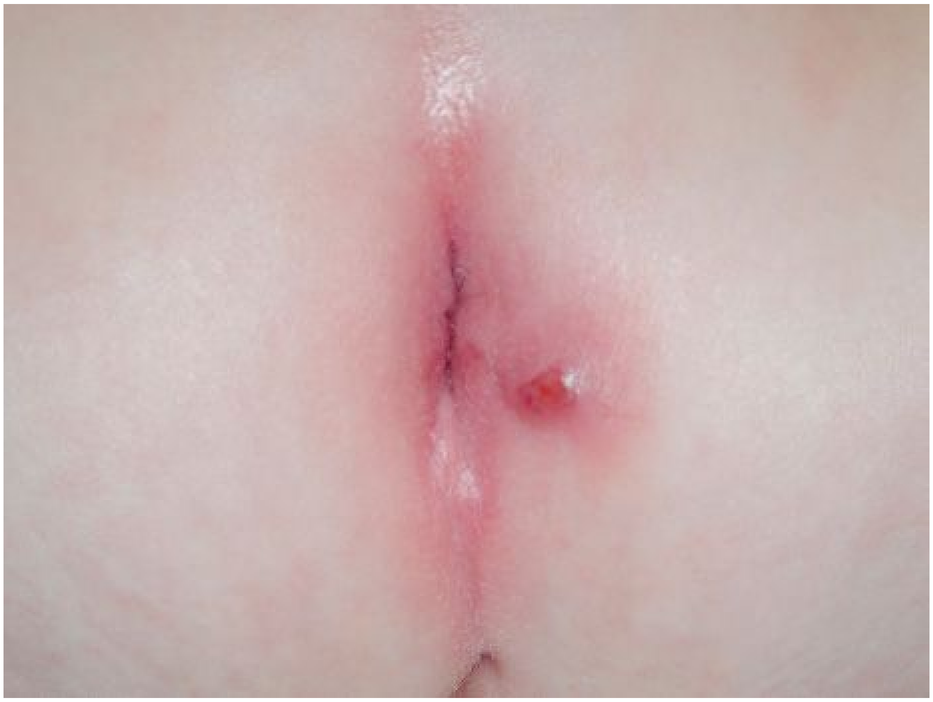

FIGURE 62-12 Fistula in ano following a perianal abscess. This infant presented with a recurrent pustule at the site of the previously drained abscess. (*Used with permission from Federico Seifarth, MD.*)

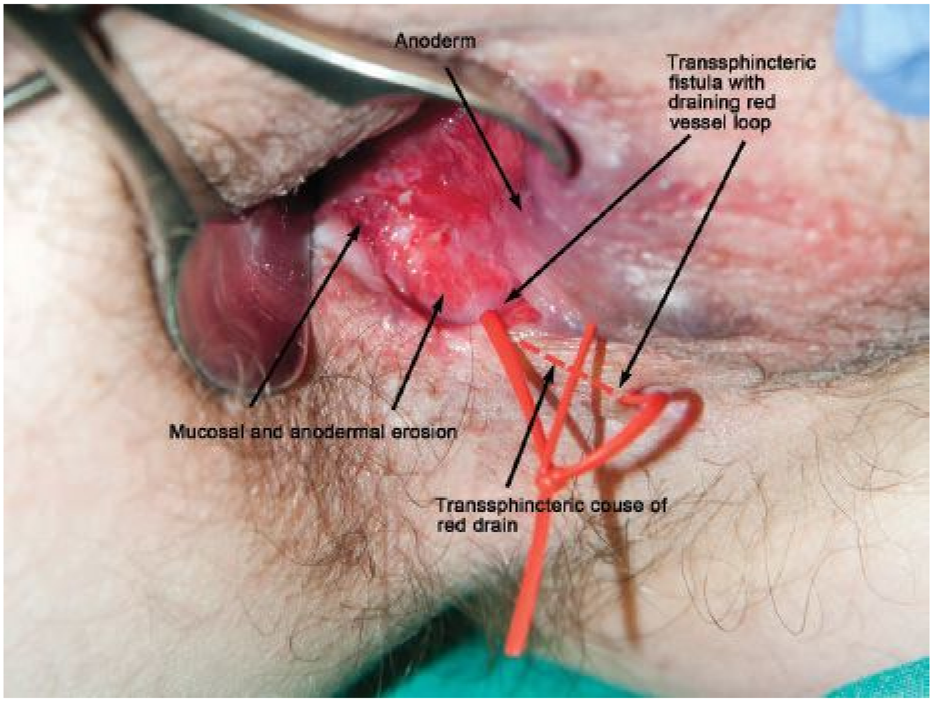
DISTRIBUTION

- The fistulas are usually distributed evenly around the anal circumference.
- Multiple lesions occur in 15 to 20 percent of cases.[27]

DIFFERENTIAL DIAGNOSIS

- Anal fissure–see previous discussion.
- Diaper rash and dermatitis, fungal infection–Usually more widespread involvement (see Chapter 121, Candidiasis).
- Sexual abuse–Should be suspected based on the history and other findings (see Chapter 9, Child Sexual Abuse).

- Inflammatory bowel disease in older children (**Figure 62-13**) (see Chapter 59, Inflammatory Bowel Disease).



Anoderm
Transsphincteric fistula with draining red vessel loop
Mucosal and anodermal erosion
Transsphincteric couse of red drain

FIGURE 62-13 Transsphincteric anal fistula in a patient with Crohn disease. (*Used with permission from David K. Magnuson, MD.*)

MANAGEMENT

- Initially nonsurgical therapy: SOR C
    - Sitz baths.
    - Warm packs.
    - Frequent diaper changes and hygienic measures.
    - Expression of pus collections.

MEDICATIONS

- Antibiotic therapy Definitive choice of agent can be guided by culture and susceptibility information obtained at the time of surgical drainage.

SURGERY

- Perianal abscess–Incision and drainage (**Figures 62-10** and **62-11**) vs. antibiotic therapy alone.[24]
- Anal fistula–Deroofing of the fistula tract and fistulotomy (**Figure 62-14**).

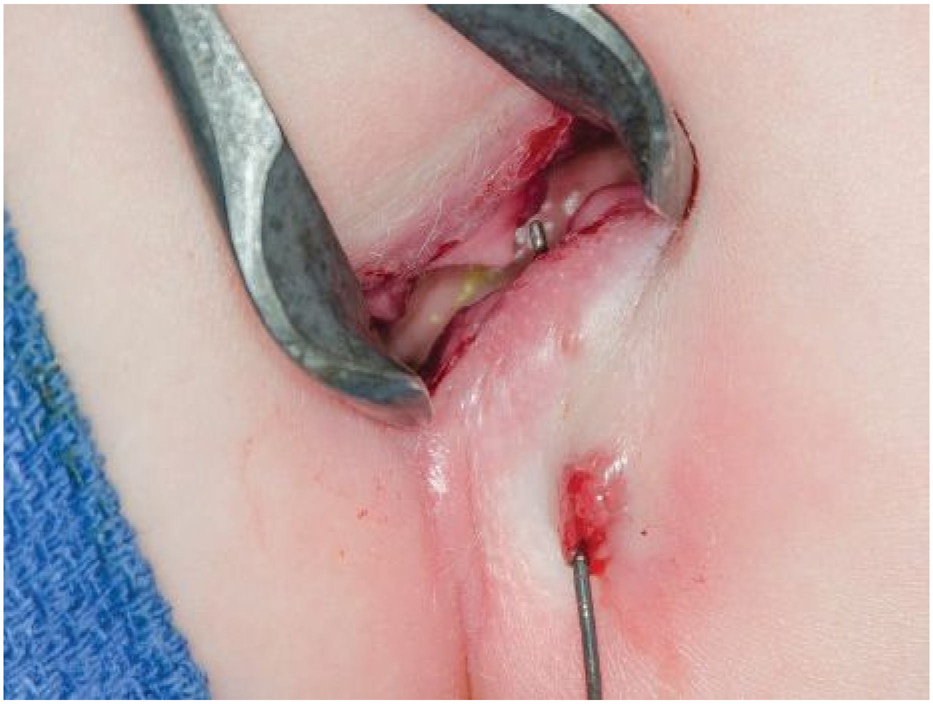


FIGURE 62-14 Fistula in ano in the same infant as in Figure 62-12, as seen with metal probing at the time of surgical excision. Note the fistulous tract extending from the perianal skin to inner opening at the anal crypt. (*Used with permission from Federico Seifarth, MD.*)

- Recent reports have advocated expectant treatment for asymptomatic anal fistulas.[28]
- Treatment of adolescent anal fistulae is similar to adults. The fistulous tract is incised and left open to granulate or excised with primary closure.

PREVENTION AND SCREENING

- Crohn’s disease should be ruled out in all children who present outside the typical age groups.

PROGNOSIS

- Most fistulas heal within 12 to 24 months without further sequelae.
- Surgery–Recurrent fistulas are seen in 10 to 20 percent of cases.

FOLLOW-UP

- By primary care physician and pediatric surgeon.

PATIENT EDUCATION

- The expected course and management options should be reviewed with the parents.

PATIENT RESOURCES

- **www.pedsurg.ucsf.edu/conditions-procedures/perirectal-abscessfistula.aspx**.

63 NUTRITIONAL DISORDERS IN CHILDREN

Victor E. Uko, MD
Lori A. Mahajan, MD

PATIENT STORY

An 18-month-old female was brought in for evaluation of a pale appearance. She was described as an active toddler with no recent fatigue, melena, or hematochezia. She was described as a picky eater and has averaged 30 to 40 ounces of milk intake per day for the past 6 months. Family history and past medical histories were noncontributory. On exam, height and weight were at the 50th percentile. Examination was normal except for a pale appearance, spooning of her nails (**Figure 63-1**), mild tachycardia, and a grade II/VI systolic ejection murmur heard best over the left lower sternal border. Labs were significant for the following: Hgb 7.0 g/dl, Hct 21.0 percent, MCV 52 fL, RDW 18 percent, reticulocyte count 1.9 percent, total iron 10 ug/dL (30 to 140 ug/dL), transferrin saturation 9 percent (11 to 46%), and ferritin 16 ng/mL (18–300 ng/mL). Peripheral smear showed microcytosis, hypochromia, mild anisocytosis, and polychromasia.

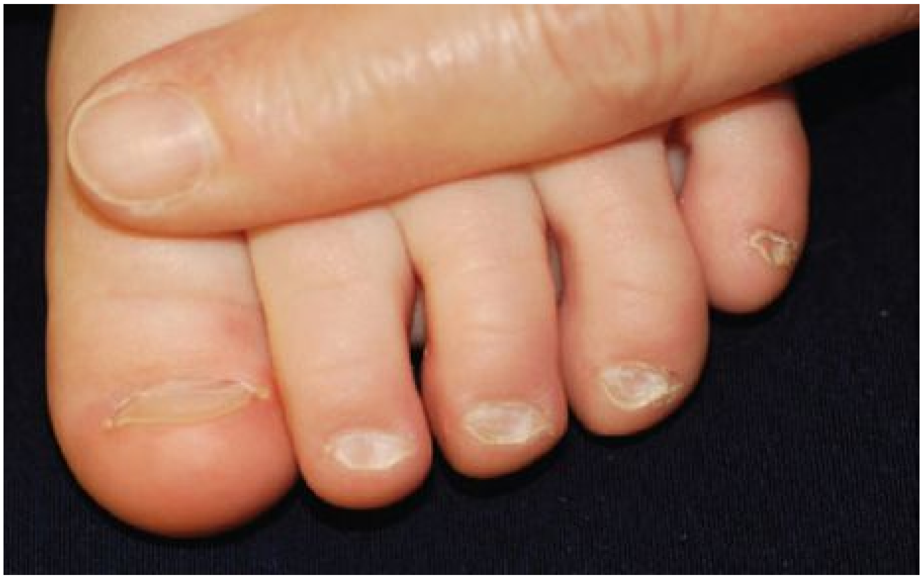

FIGURE 63-1 Koilonychia due to iron deficiency. (*Used with permission from Rudolph CD, Rudolph AM, Lister GE, First LR, Gershon AA: Rudolph's Pediatrics, 22nd edition: www.accesspediatrics.com*.)

She was diagnosed with iron deficiency anemia and started on oral iron with concomitant reductions in her daily consumption of milk to no more than 18 to 20 ounces a day. At follow-up appointment one month later, she looked well and her appetite had improved with consumption of a wider variety of foods. Repeat Hgb was 9.5 g/dL and her MCV 69 fL. Three months later, her hemoglobin had completely normalized.

INTRODUCTION

Nutritional disorders in children include both deficiency and excess states. Protein energy malnutrition remains one of the leading causes of death in children in underdeveloped countries. Obesity has emerged as one of the most common nutritional disorders in children worldwide. Children who have a body mass index (BMI) in the 85th to 94th sex- and age-specific percentile are considered overweight. Those with a BMI at or above the 95th percentile are considered obese.

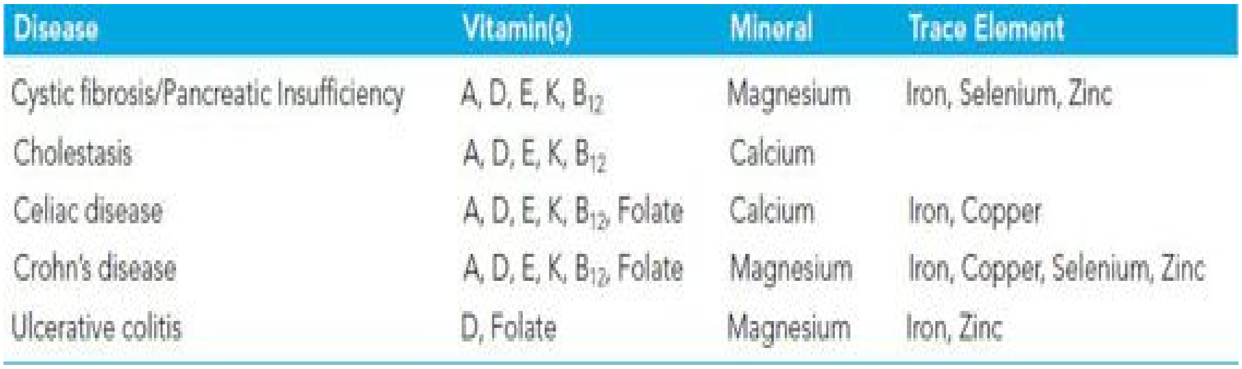
EPIDEMIOLOGY

- Severe protein-energy malnutrition is uncommon in the US and other developed countries.
- Childhood obesity rates have risen steadily, with current global estimates at approximately 17 percent, disproportionately affecting minority youth. Overweight and obesity are now on the rise in low- and middle-income countries, particularly in urban settings. Almost 35 million overweight children live in developing countries and 8 million in developed countries.
- Overweight and obesity are linked to more deaths worldwide than malnutrition.

ETIOLOGY AND PATHOPHYSIOLOGY

- Nutritional deficiency states may occur as a result of poor dietary intake, increased nutrient loss, or increased nutrient and energy requirements as seen in patients with chronic illness.
- The small intestine is the predominant site of absorption of nutrients from the gastrointestinal tract. Any disease that interrupts bile flow, digestive enzyme excretion, or small bowel mucosal integrity, may result in a variety of nutritional deficiencies (**Table 63-1**).

TABLE 63-1 Possible Nutritional Deficiencies in Gastrointestinal Disease



Disease	Vitamin(s)	Mineral	Trace Element
Cystic fibrosis/Pancreatic Insufficiency	A, D, E, K, B_{12}	Magnesium	Iron, Selenium, Zinc
Cholestasis	A, D, E, K, B_{12}	Calcium	
Celiac disease	A, D, E, K, B_{12}, Folate	Calcium	Iron, Copper
Crohn's disease	A, D, E, K, B_{12}, Folate	Magnesium	Iron, Copper, Selenium, Zinc
Ulcerative colitis	D, Folate	Magnesium	Iron, Zinc

- Deficiencies in fat soluble vitamins (A, D, E, and K) can be seen in patients with poor oral intake and diseases that cause malabsorption including pancreatic disorders and cholestatic liver disease. Vitamin D deficiency can also result from lack of sun exposure.[1]
- Iron deficiency is the most common nutritional deficiency in childhood. It can be seen secondary to poor oral intake, poor absorption, and in cases of chronic blood loss.
- Vitamin B_1 (thiamin) is found in milk, meats, eggs, legumes, and fruits. Deficiency results from inadequate intake or poor absorption due to intestinal or liver disease.
- Vitamin B_2 (riboflavin) deficiency is seen in patients on long term barbiturates, disorders of intestinal malabsorption, and in patients who avoid dairy products which are a good source of this vitamin.
- Vitamin B_3 (niacin) deficiency is seen in patients with carcinoid syndrome and Hartnup disease (autosomal recessive disorder of tryptophan metabolism). It is also seen with prolonged use of certain medications such as isoniazid, azathioprine, and phenobarbital.[2]
- Vitamin B_6 (pyridoxine) deficiency is uncommon. Low levels of pyridoxal phosphate can be seen in patients with chronic illnesses such as diabetes, asthma, and sickle cell anemia.
- Vitamin B_9 (folic acid) is essential to numerous bodily functions including DNA synthesis and repair as well as to act as a cofactor in certain biological reactions. It is especially important in aiding rapid cell division and growth, and is required to produce healthy red blood cells and prevent anemia. Lack of adequate intake leads to folate deficiency, which is now uncommon.
- Vitamin B_{12} is bound to intrinsic factor in the stomach and is absorbed primarily in the terminal ileum. Deficiency typically results from inadequate intake (vegan mothers and in their breast fed infants), surgery involving the stomach or terminal ileum, or lack of excretion of intrinsic factor in the stomach (pernicious anemia).
- Vitamin C (ascorbic acid) deficiency occurs in severely malnourished patients and in those who consume a diet devoid of fruits and vegetables.

Deficiency leads to impaired collagen and chondroitin sulfate formation. The tendency to hemorrhage, presence of defective tooth dentin, and loosening of teeth caused by deficient collagen is known as scurvy.

- Copper deficiency can be seen in patients after gastric bypass surgery and also in those with malabsorption such as patients with untreated celiac disease. Premature infants receiving milk without adequate copper supplementation and those on long-term total parenteral nutrition (TPN) can also develop copper deficiency.
- Zinc deficiency can occur in patients with pancreatic insufficiency (pancreatic enzymes are needed for the release of dietary zinc), chronic inflammatory diseases and those on long term total parenteral nutrition (TPN). Acrodermatitis enteropathica results in zinc deficiency due to malabsorption.[3]
- Selenium deficiency is rare, but can occur in patients receiving long-term parenteral nutrition without supplementation.[4]
- Nutrient toxicity states are more commonly seen with fat soluble vitamins as well as minerals and are due to excess ingestion or administration.
- The causes of obesity can be attributed to both genetic and environmental factors.[5] The most common cause is overconsumption of calories as compared to amount of calories used.

RISK FACTORS FOR NUTRITIONAL DEFICIENCY STATES

- Poor nutritional intake.
- Low socioeconomic status.
- Patients on long-term TPN.
- Malabsorption syndromes and chronic disorders (**Table 63-1**).

RISK FACTORS FOR NUTRITIONAL TOXICITY STATES AND OBESITY

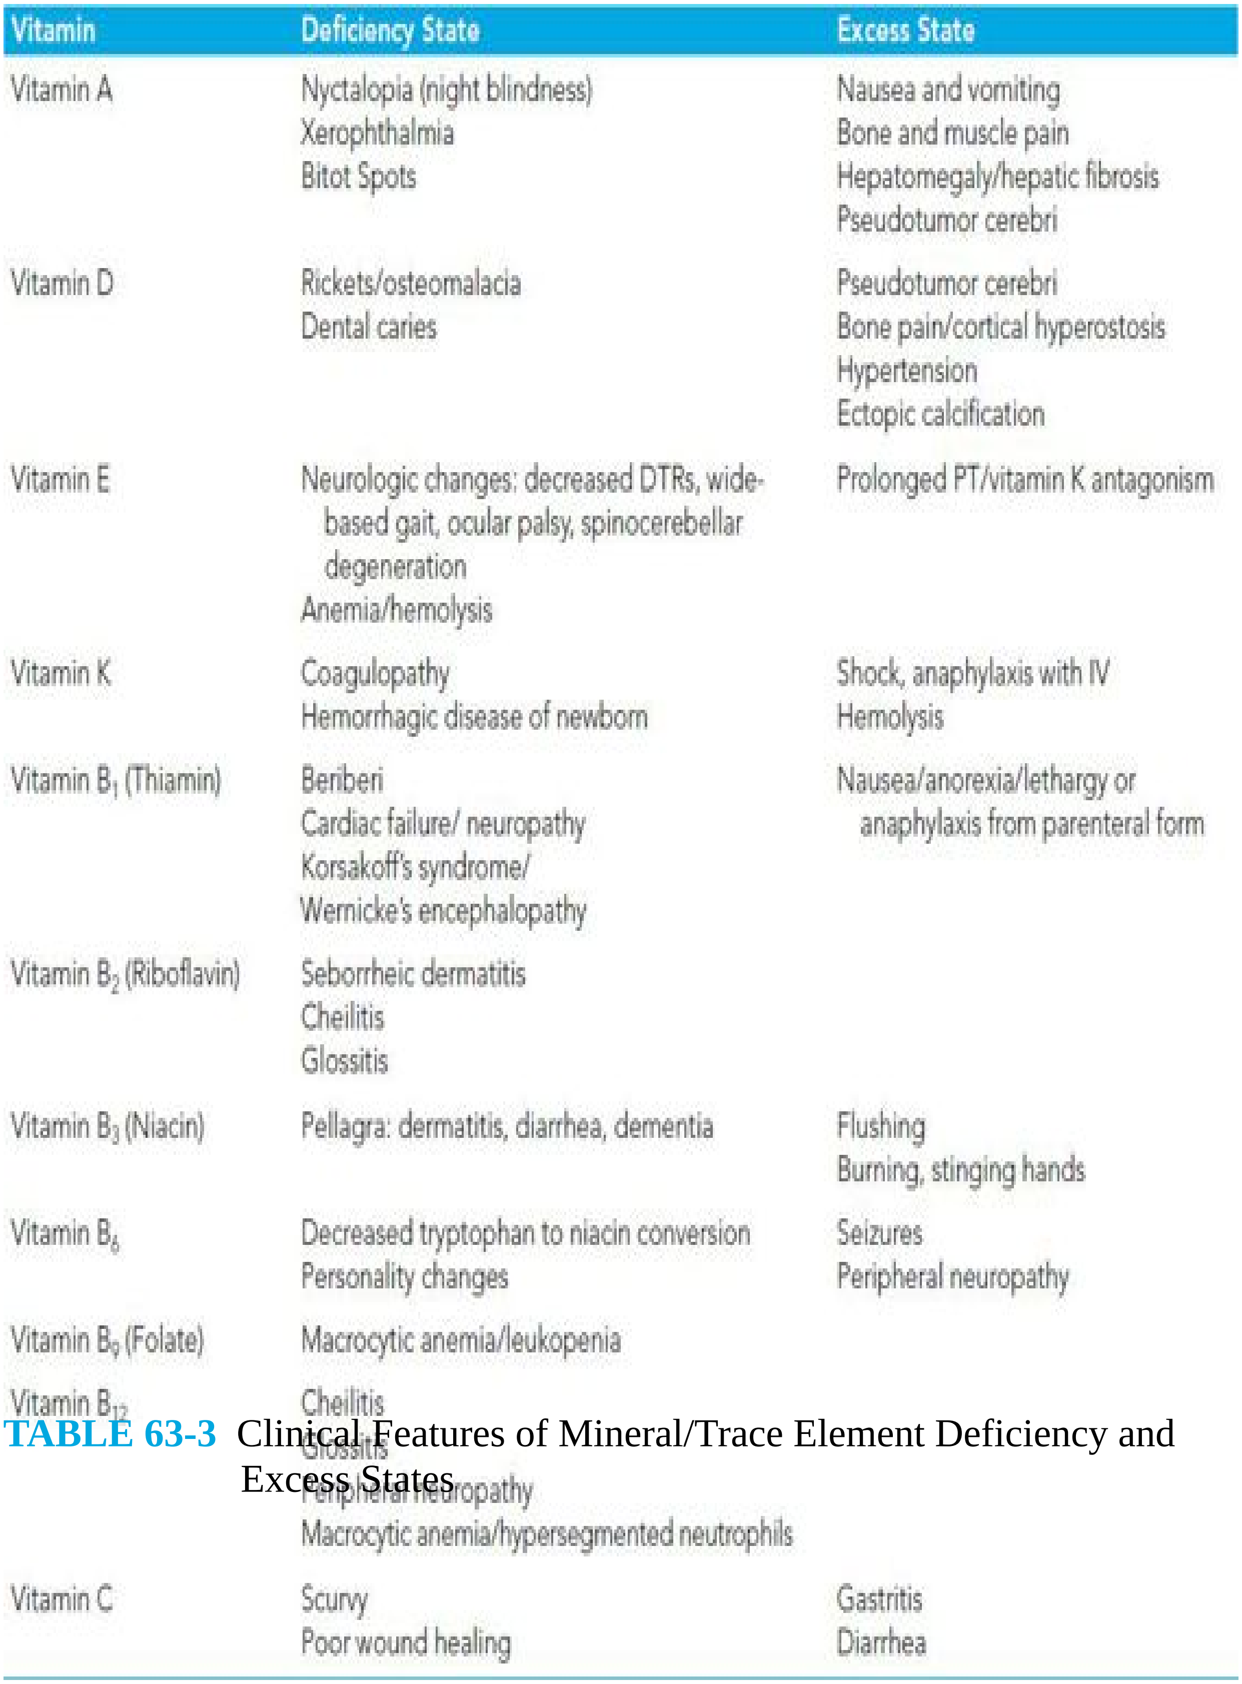
- Excessive intake.
- Sedentary lifestyle.

DIAGNOSIS

CLINICAL FEATURES

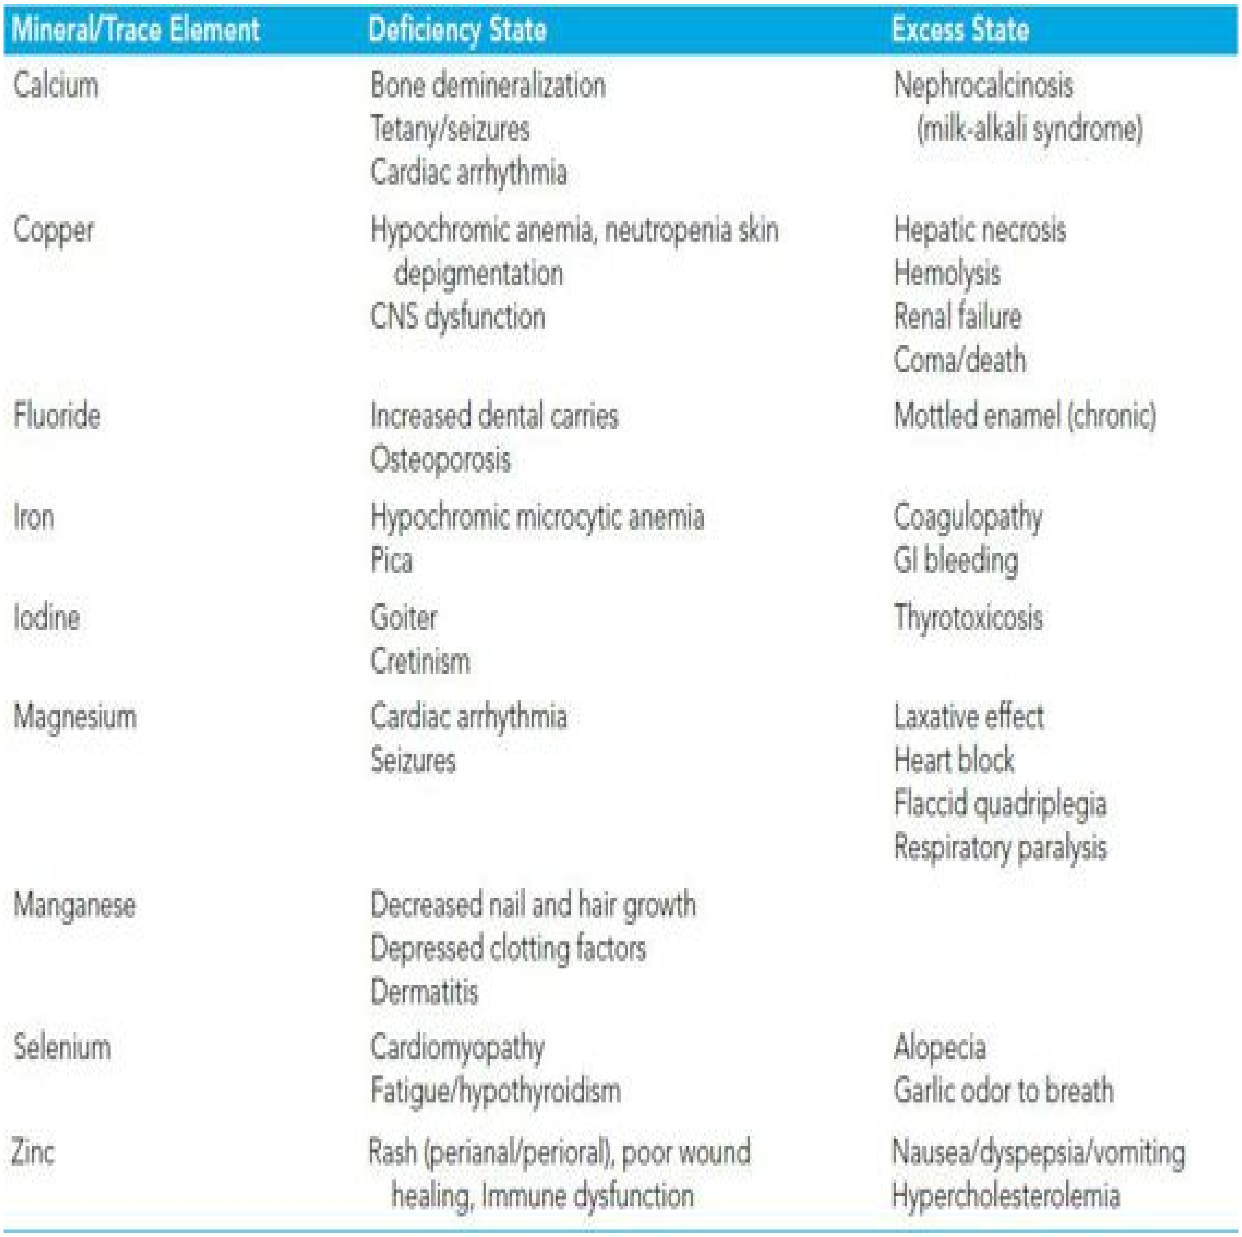
- The clinical manifestations of malnutrition and overweight/obesity can be assessed using anthropometric measurements (standardized growth charts), specific physical examination findings, and confirmatory laboratory measurements.
- Common clinical features of nutrient deficiency and excess states are listed in **Tables 63-2** and **63-3**.

TABLE 63-2 Clinical Features of Vitamin Deficiency and Excess States



Vitamin	Deficiency State	Excess State
Vitamin A	Nyctalopia (night blindness) Xerophthalmia Bitot Spots	Nausea and vomiting Bone and muscle pain Hepatomegaly/hepatic fibrosis Pseudotumor cerebri
Vitamin D	Rickets/osteomalacia Dental caries	Pseudotumor cerebri Bone pain/cortical hyperostosis Hypertension Ectopic calcification
Vitamin E	Neurologic changes: decreased DTRs, wide-based gait, ocular palsy, spinocerebellar degeneration Anemia/hemolysis	Prolonged PT/vitamin K antagonism
Vitamin K	Coagulopathy Hemorrhagic disease of newborn	Shock, anaphylaxis with IV Hemolysis
Vitamin B_1 (Thiamin)	Beriberi Cardiac failure/ neuropathy Korsakoff's syndrome/ Wernicke's encephalopathy	Nausea/anorexia/lethargy or anaphylaxis from parenteral form
Vitamin B_2 (Riboflavin)	Seborrheic dermatitis Cheilitis Glossitis	
Vitamin B_3 (Niacin)	Pellagra: dermatitis, diarrhea, dementia	Flushing Burning, stinging hands
Vitamin B_6	Decreased tryptophan to niacin conversion Personality changes	Seizures Peripheral neuropathy
Vitamin B_9 (Folate)	Macrocytic anemia/leukopenia	
Vitamin B_{12}	Cheilitis Glossitis Peripheral neuropathy Macrocytic anemia/hypersegmented neutrophils	
Vitamin C	Scurvy Poor wound healing	Gastritis Diarrhea

TABLE 63-3 Clinical Features of Mineral/Trace Element Deficiency and Excess States



Mineral/Trace Element	Deficiency State	Excess State
Calcium	Bone demineralization Tetany/seizures Cardiac arrhythmia	Nephrocalcinosis (milk-alkali syndrome)
Copper	Hypochromic anemia, neutropenia skin depigmentation CNS dysfunction	Hepatic necrosis Hemolysis Renal failure Coma/death
Fluoride	Increased dental carries Osteoporosis	Mottled enamel (chronic)
Iron	Hypochromic microcytic anemia Pica	Coagulopathy GI bleeding
Iodine	Goiter Cretinism	Thyrotoxicosis
Magnesium	Cardiac arrhythmia Seizures	Laxative effect Heart block Flaccid quadriplegia Respiratory paralysis
Manganese	Decreased nail and hair growth Depressed clotting factors Dermatitis	
Selenium	Cardiomyopathy Fatigue/hypothyroidism	Alopecia Garlic odor to breath
Zinc	Rash (perianal/perioral), poor wound healing, Immune dysfunction	Nausea/dyspepsia/vomiting Hypercholesterolemia

- Iron deficiency leading to anemia is the most prevalent mineral deficiency in children. Chronic deficiency may lead to spooning and pallor of the nail beds (**Figure 63-1**).
- Vitamin A deficiency presents with night blindness (earliest symptom), xerosis (dry eyes), and the development of Bitot’s spot—triangular areas

of abnormal squamous cell proliferation and keratinization of the conjunctiva (**Figure 63-2**).[6]

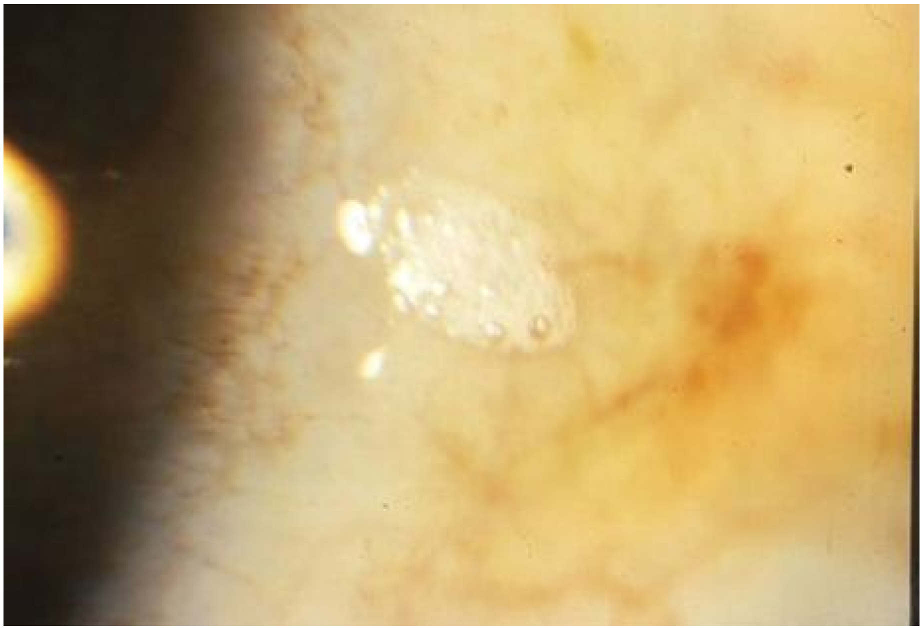


FIGURE 63-2 Bitot’s spot on the conjunctiva due to vitamin A deficiency. It is associated with conjunctival xerosis. (*Used with permission from Lueder GT: Pediatric Practice Ophthalmology* *www.accesspediatrics.com*.)

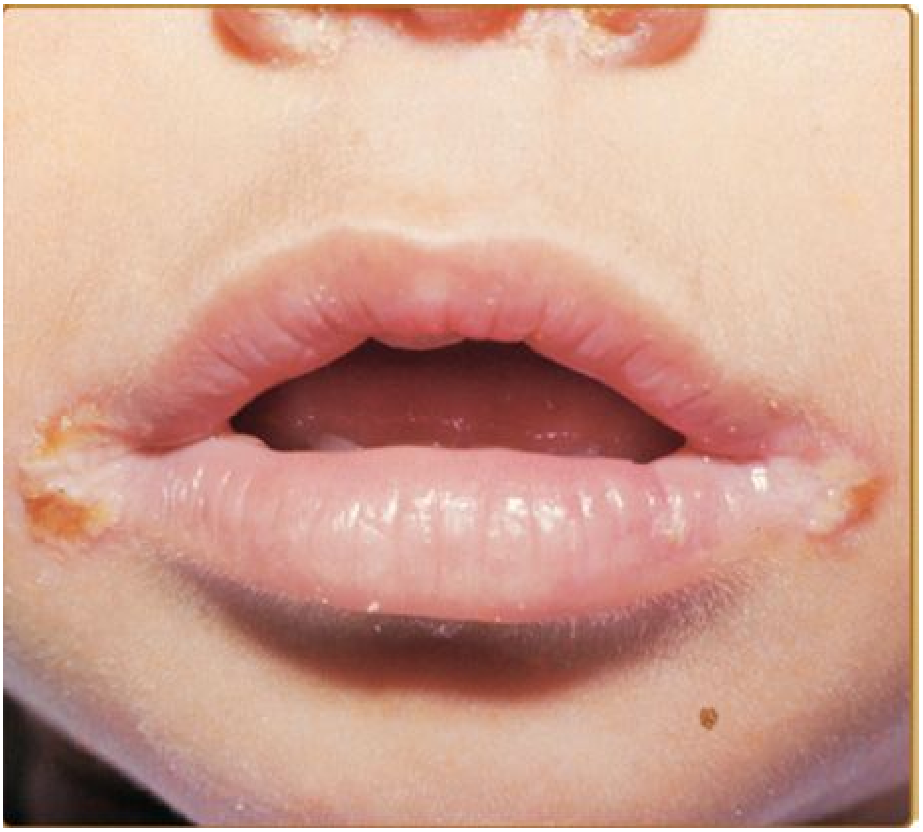

FIGURE 63-3 Angular Stomatitis due to vitamin B2 (riboflavin) deficiency. (*Used with permission from Goldsmith LA, Katz SI, Gilchrest BA, Paller AS, Leffell DJ, Wolff K: Fitzpatrick's Dermatology in General Medicine, 8th edition: www.accessmedicine.com*.)

- Vitamin B_1 (Thiamin) is classically associated with symptoms of cardiac dysfunction (cardiomyopathy) along with neurological symptoms, which may include polyneuropathy and seizures. Wernicke-Korsakoff syndrome (characterized by a triad of nystagmus, ophthalmoplegia, and ataxia) is only rarely seen in the pediatric age group.
- Vitamin B_2 (Riboflavin) deficiency is characterized by angular stomatitis, glossitis and seborrheic dermatitis (**Figure 63-3**).
- Zinc deficiency is characterized by perioral and perianal dermatitis (**Figure 63-4**). Other clinical manifestations include an increased susceptibility to infections, diarrhea, and growth failure.

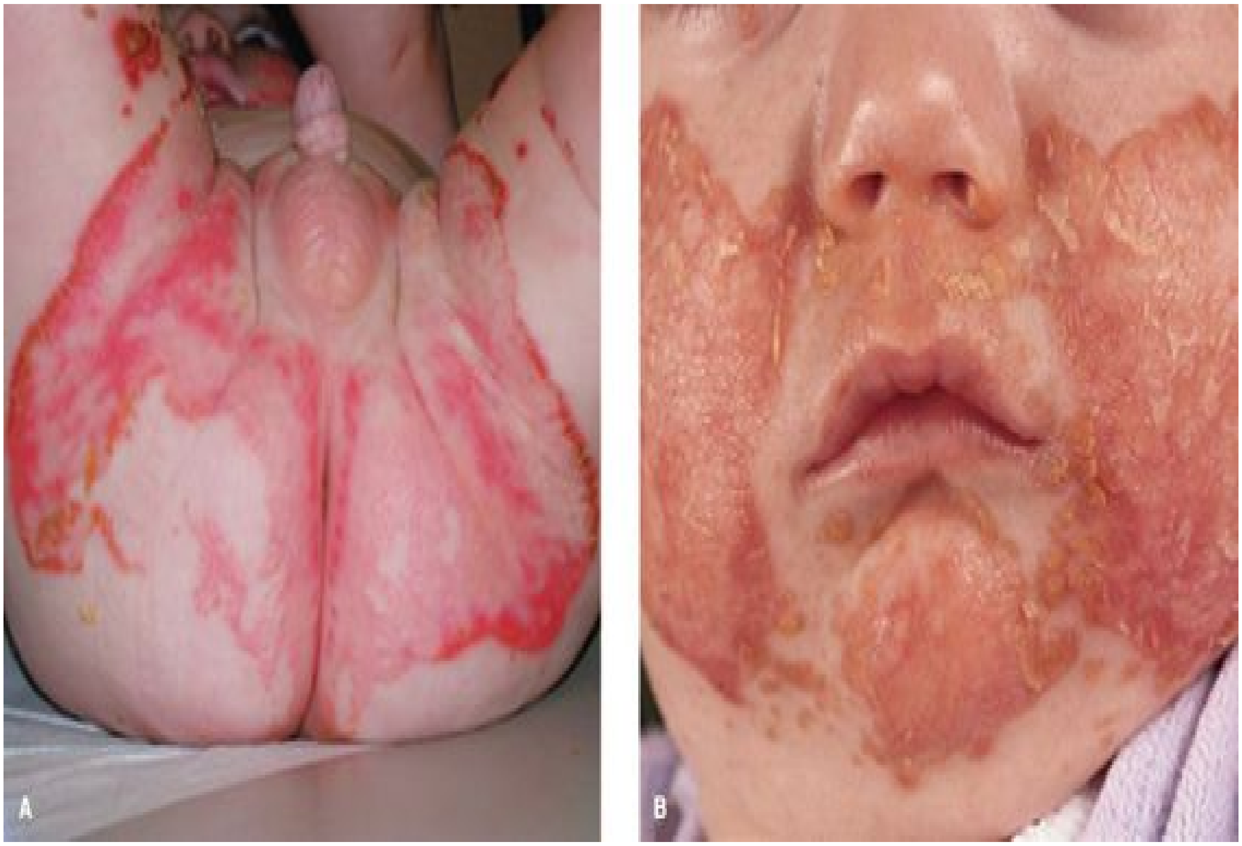

FIGURE 63-4 Perianal (**A**) and perioral (**B**) dermatitis due to zinc deficiency. Known as acrodermatitis enteropathica. (*Used with permission from Goldsmith LA, Katz SI, Gilchrest BA, Paller AS, Leffell DJ, Wolff K: Fitzpatrick's Dermatology in General Medicine*, 8th *edition: www.accessmedicine.com*.)

- Obese children should be carefully evaluated for hypertension. Other commonly associated signs include hepatomegaly from fatty liver disease and acanthosis nigricans (associated with insulin resistance). Signs of possible reversible causes of obesity should also be sought including deep purple striae and the "buffalo hump" of Cushing's syndrome (a rare secondary cause of obesity).

LABORATORY TESTING

- Should be tailored based on clinical history and physical exam findings.
- Fat-soluble vitamins (A and E) are measured directly in the serum.

- Vitamin D—Evaluated by measuring 25-dihydroxyl vitamin D (25 OH Vit D) levels in serum.
- Vitamin K—Evaluated by measuring prothrombin time and international normalized ratio (INR) in the serum.
- B group of vitamins—Laboratory tests are specific for each vitamin in this group.
- Most trace elements can be measured directly in the serum. Twenty-four hour urine collection for copper is preferred to copper analysis test in Wilson's disease. Low alkaline phosphatase levels are seen in patients with zinc deficiency.
- Laboratory testing recommended for children with a body mass index between the 85th and 94th percentiles but who have no obesity-related illnesses (hypertension, known dyslipidemia, increased blood pressure) include a fasting lipid profile should be done. Children with a BMI between the 85th and 94th percentiles and risk factors should have a fasting lipid profile, and measurement of alanine transaminase and aspartate transaminase levels (to detect fatty liver disease) and fasting blood glucose (to detect type 2 diabetes).[7] Children whose BMI is above the 95th percentile should have the same tests plus measurement of blood urea nitrogen and creatinine to detect impaired renal function (which may develop from long-standing hypertension or diabetes).
- Karyotype (with fluorescence in situ hybridization [FISH] for Prader-Willi [15q-]), only when indicated by clinical history and physical examination (**Figure 63-5**).

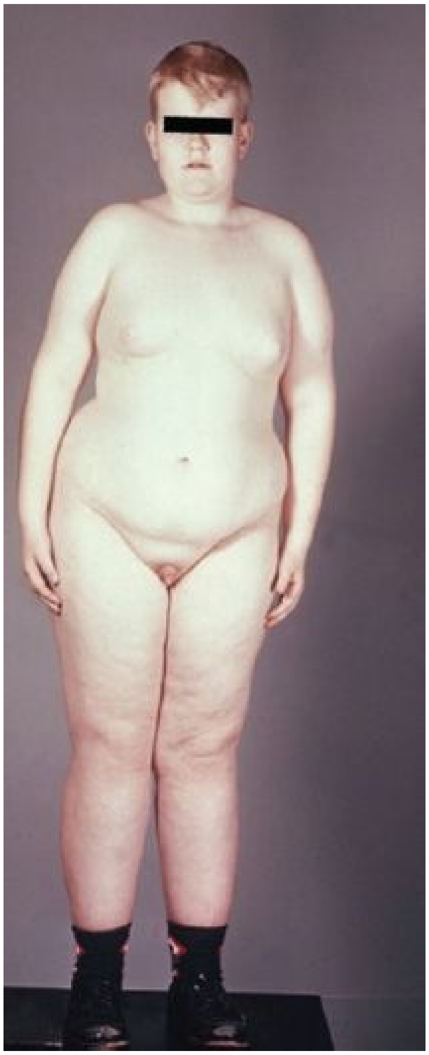

FIGURE 63-5 Prader Willi Syndrome in an 11-year-old boy. (*Used with permission from Cleveland Clinic Children’s Hospital Photo File*.)

DIFFERENTIAL DIAGNOSIS

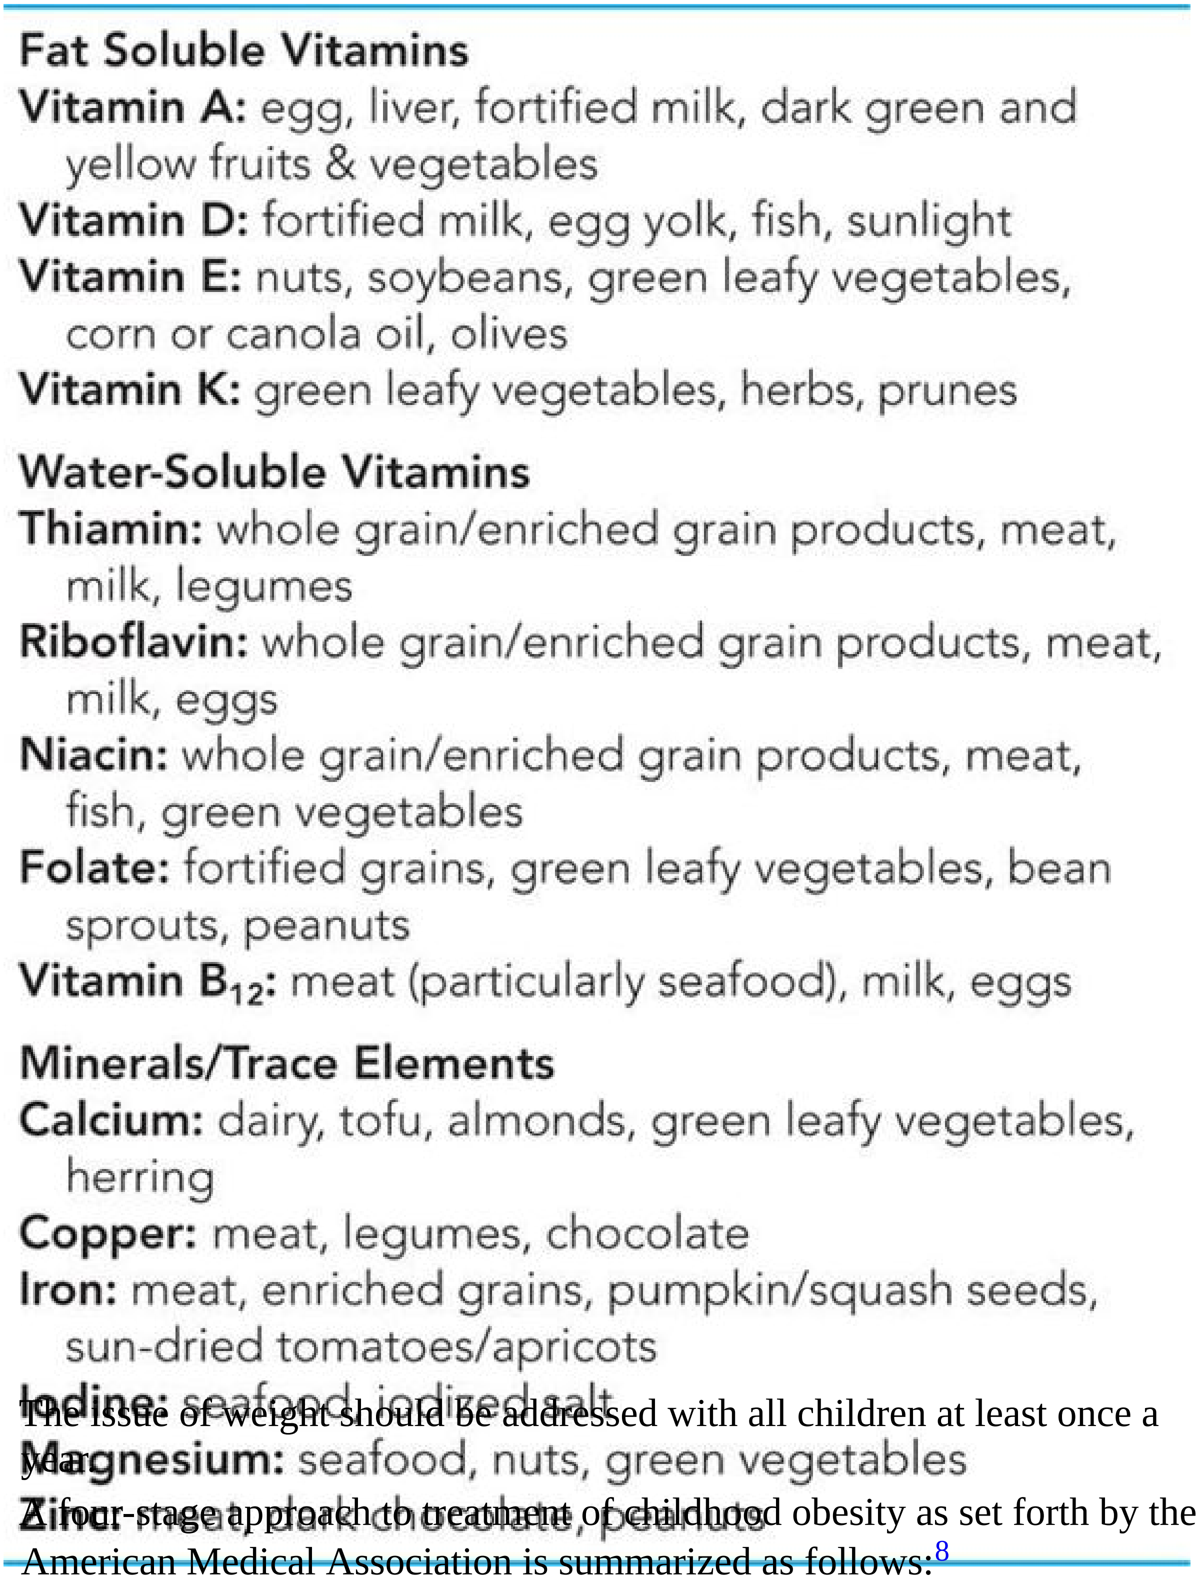
- Potential causes of nutritional deficiencies are many with the most common cause being poor oral intake. Other important considerations are listed in **Tables 63-1** to **63-3**.

MANAGEMENT

NONPHARMACOLOGIC

- Appropriate dietary counseling (recommend intake or avoidance depending on deficiency or excess state; see **Table 63-4**).

TABLE 63-4 Dietary Sources Rich in Nutrients



Fat Soluble Vitamins

Vitamin A: egg, liver, fortified milk, dark green and yellow fruits & vegetables

Vitamin D: fortified milk, egg yolk, fish, sunlight

Vitamin E: nuts, soybeans, green leafy vegetables, corn or canola oil, olives

Vitamin K: green leafy vegetables, herbs, prunes

Water-Soluble Vitamins

Thiamin: whole grain/enriched grain products, meat, milk, legumes

Riboflavin: whole grain/enriched grain products, meat, milk, eggs

Niacin: whole grain/enriched grain products, meat, fish, green vegetables

Folate: fortified grains, green leafy vegetables, bean sprouts, peanuts

Vitamin B_{12}: meat (particularly seafood), milk, eggs

Minerals/Trace Elements

Calcium: dairy, tofu, almonds, green leafy vegetables, herring

Copper: meat, legumes, chocolate

Iron: meat, enriched grains, pumpkin/squash seeds, sun-dried tomatoes/apricots

Iodine: seafood, iodized salt

Magnesium: seafood, nuts, green vegetables

Zinc: meat, dark chocolate, peanuts

- The issue of weight should be addressed with all children at least once a year.
- A four-stage approach to treatment of childhood obesity as set forth by the American Medical Association is summarized as follows:[8]

Stage 1 (Prevention-plus protocol)

- Eat ≥5 servings of fruits and vegetables daily.
- Use television and computer £2 hours per day.
- No television in child’s bedroom.
- ≥60 minutes of moderate to vigorous physical activity per day.
- No sugar-sweetened beverages.
- Eat breakfast daily.
- Limit meals outside the home.
- Family meals ≥ five times per week.
- Allow child to self-regulate food intake and avoid food restriction (e.g., a child should be permitted to eat portions of food until satiated, no more, or less).

Stage 2 (Structured weight-management protocol)

- A more structured plan that includes structured meals, supervised physical activity of at least 60 minutes daily, one hour or less screen time per day, and increased self-monitoring of these behaviors through log completion. If no improvement in BMI takes place after three to six months, Stage 3 is appropriate.

Stage 3 Comprehensive, Multidisciplinary Intervention

Stage 4 Tertiary-Care Intervention

MEDICATIONS

- Replacement of the deficient micronutrient or mineral should be instituted.
- Treatment should be instituted for any underlying disorder that has led to the nutritional deficient state.

SURGERY

- Patients with nutritional deficiencies and/or underlying disease may require surgical procedures for placement of feeding tubes or central venous lines for parenteral nutrition. SOR Ⓒ
- Weight loss surgery (gastric banding, bypass procedures) should be considered for adolescents with extreme obesity (BMI ≥40) and other comorbidities associated with long-term risks who are unresponsive to dietary and lifestyle modification. SOR Ⓒ

REFERRAL

- Consultation with a pediatric dietitian to provide appropriate dietary counseling.
- Consultation with a pediatric gastroenterologist to address any underlying gastrointestinal causes for nutritional deficiencies.
- The overweight or obese patient should have a multidisciplinary team assembled as indicated (dietitian, gastroenterologist, endocrinologist, counselor, trainer, etc.).

PREVENTION AND SCREENING

- Supplementation of fat soluble vitamins (A,D,E,K) is required for patients with cholestatic disease or fat malabsorption. They should also be periodically screened for insufficient levels of these vitamins even though supplemented.
- To prevent vitamin D deficiency, adequate sun exposure (30 minutes per week for infants clothed in diapers or 2 hours per week when fully clothed) is recommended. Dark-skinned infants require at least threefold longer periods of sunlight exposure.
- Daily vitamin D intake of 400 units/day for exclusively breast fed infants and those consuming less than 1 liter of infant formula each day is recommended.[9]

- Vitamin K administration to infants at or around the time of birth is recommended to prevent hemorrhagic disease of the newborn.
- Vitamin B_{12} supplementation is required for pregnant women who are strict vegans especially those who intend to exclusively breast feed their babies.
- Breast fed babies should start iron supplementation at 4 months of age. Infants (6 months and older) should have at least 2 iron fortified cereal feeds each day along with at least one feeding per day of vitamin C rich foods such as citrus fruits, dark green vegetables, tomatoes.
- Children aged 1 to 5 years should not consume more than 600 mL (20 ounces) of milk per day.
- Universal screening for iron deficiency is recommended for all children at 9 to 12 months of age.
- Additional iron screening at 15 to 18 months and also at 5 to 8 years of age for high-risk patients (premature infants, children with chronic inflammatory disease, children with recurrent/chronic infections and those on restricted diets).
- Children should be screened for overweight/obesity states at least annually. Parents should be counseled at initial well child checks regarding healthy foods, healthy habits, setting a good example themselves, and living an active lifestyle.

PROGNOSIS

- This is dependent on the underlying cause for the nutritional deficiency state.
- Nutritional deficiencies due to poor intake have an excellent prognosis with successful replacement of the deficient nutrient.
- Treatment of obesity at any age is a challenge. Obese children are at high risk of becoming obese adults. Approximately 80 percent of children who are obese at 10 to 15 years of age remain obese as adults.

FOLLOW-UP

- Close follow-up is required after pharmacological or dietary interventions are instituted in patients with nutritional deficiencies or excesses.

64 URINARY SEDIMENT/URINARY TRACT INFECTIONS

Mindy A. Smith, MD, MS
Richard P. Usatine, MD

PATIENT STORY

A 10-year-old boy presented to the office with a 2-day history of "tea-colored" urine. Two weeks prior to this presentation, he had an upper respiratory infection that resolved without treatment. Two years ago, he had a similar episode of gross hematuria that developed after a viral infection, and at that time the diagnosis of IgA nephropathy was entertained. His urine now reveals hematuria (**Figure 64-1**) but no proteinuria.

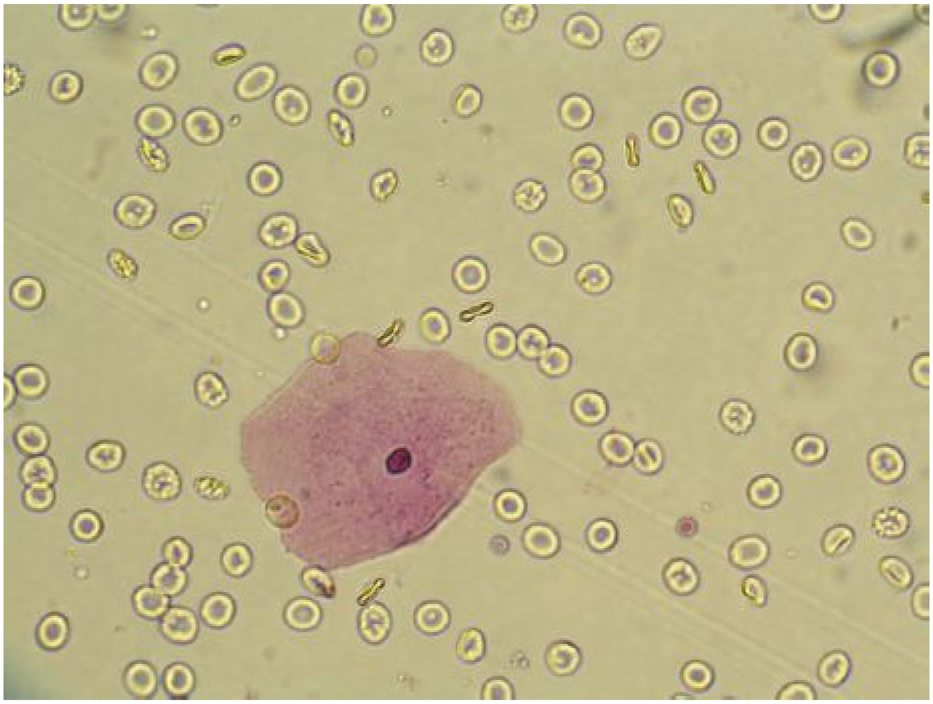

FIGURE 64-1 Red blood cells (RBCs) seen in the urine. Some of the RBCs are crenated and there is one epithelial cell visible. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Examination of the urinary sediment is a test frequently done for evaluation of patients with suspected genetic/intrinsic (e.g., systemic lupus nephritis, sickle cell disease, glomerulonephritis, interstitial nephritis), anatomic (e.g., arteriovenous malformation), obstructive (e.g., posterior urethral valves, kidney stones), infectious, metabolic (e.g., coagulopathy), traumatic, or neoplastic disease of the urinary tract. Potential findings of red or white blood cells, casts, bacteria, or neoplastic cells help in directing further evaluation of a patient's problem.

EPIDEMIOLOGY

- Although there is no consensus on the definition of microscopic hematuria in children, 5 to 10 RBCs/HPF are considered significant.[1]
- Based on an older study (N = 8,954 unselected children ages 8 to 15 years), the incidence of microscopic hematuria found in one or more of four urine specimens was 4.1 percent; the incidence was 1.1 percent for hematuria present in two or more specimens.[2]
- Macroscopic (visible) or gross hematuria among children has an estimated incidence of 1.3/1000.[3]
- Isolated pyuria (>2 to 10 white blood cells per high-power field [WBCs/HPF]) is not uncommon in sick neonates and febrile children.
    - In a study of 110 consecutive infants admitted to a neonatal intensive care unit in Karachi, 35 had pyuria, of who 71.4 percent had no growth in urine cultures.[4]

  - In a case series of children with Kawasaki disease (KD; N = 210), 29.5 percent (N = 62) had pyuria including 34 with sterile pyuria and eight with bacterial pyuria.[5]
  - In another case series of children with acute KD compared to children with other febrile illnesses, 79.8 percent of KD and 54.0 percent of febrile children without KD had pyuria.[6] The median number of white blood cells in the urine was higher for children with KD (42 WBC/microL vs. 12 WBC/microL in febrile children).

- Urinary tract infections (UTIs) are common in children (8% of girls and 2% of boys by age 7 years) and WBCs on microscopy have 73 percent sensitivity and 81 percent specificity for the diagnosis.[7]
  - About 60 percent of children who have a febrile UTI are found to have defects on renal cortical scintigraphy (RCS) indicating acute pyelonephritis; of these, 10 to 40 percent will have permanent renal scarring.[8]

- In a laboratory study of greater than 11,000 urinalyses from 88 institutions, 62.5 percent of the tests received a manual microscopic evaluation of the urinary sediment, usually triggered by an abnormal urinalysis.[9] New information was obtained 65 percent of the time as a result of the manual examination.

ETIOLOGY AND PATHOPHYSIOLOGY

- Hematuria (**Figure 64-1**) has many causes including:[1]
  - Idiopathic.
  - Glomerular disease (e.g., immunoglobulin [Ig]A nephropathy, post-streptococcal glomerulonephritis, membranoproliferative glomerulonephritis [MPGN]).
  - Interstitial and tubular disease (e.g., acute pyelonephritis, tuberculosis, hematologic disorders such as sickle cell, or thrombocytopenia).
  - Structural or congenital abnormalities (e.g., polycystic kidney disease).

  - Urinary tract (collecting system, ureters, bladder, or urethra) disease (e.g., bladder infection [*Escherichia coli* in about 85%],[7] stone, trauma [including recent catheterization], tumors, or exercise).
  - Metabolic abnormalities including hypercalcemia and hyperuricemia.
  - Medications (e.g., aminoglycosides, anticonvulsants, or aspirin).
  - Toxins (e.g., lead, turpentine).
  - Contamination (menstruation or bloody diarrhea).
  - The most common causes of hematuria in children are idiopathic, benign familial, idiopathic hypercalciuria, IgA nephropathy, and sickle cell trait or anemia.[1] In the Vehaskari et al. study, of 28 children with hematuria (6 or more RBC/0.9 mm^3 or more than 100,000 RBC/hour) on two occasions who underwent renal biopsy, 12 children had normal biopsies, two children were diagnosed with IgA-IgG nephropathy, one with focal segmental sclerosis, one with extracapillary glomerulonephritis, and one with possible hereditary nephritis.[2]
  - The source of bleeding in children is most commonly glomerular (vs. urinary tract); RBCs cross the glomerular endothelial-epithelial barrier entering the capillary lumen through discontinuities in the capillary wall.[1]
  - A family history of hematuria, hypertension, renal disease (e.g., kidney stones, cystic disease), sickle cell, hemophilia, and dialysis or transplant can be helpful.[1] In one study of 500 children with beta-thalassemia major requiring transfusion, 10.6 percent had hematuria.[10]
- Hematuria with dysmorphic RBCs or RBC casts (**Figure 64-2**) and excess protein excretion (>500 mg/dL) suggests glomerulonephritis.

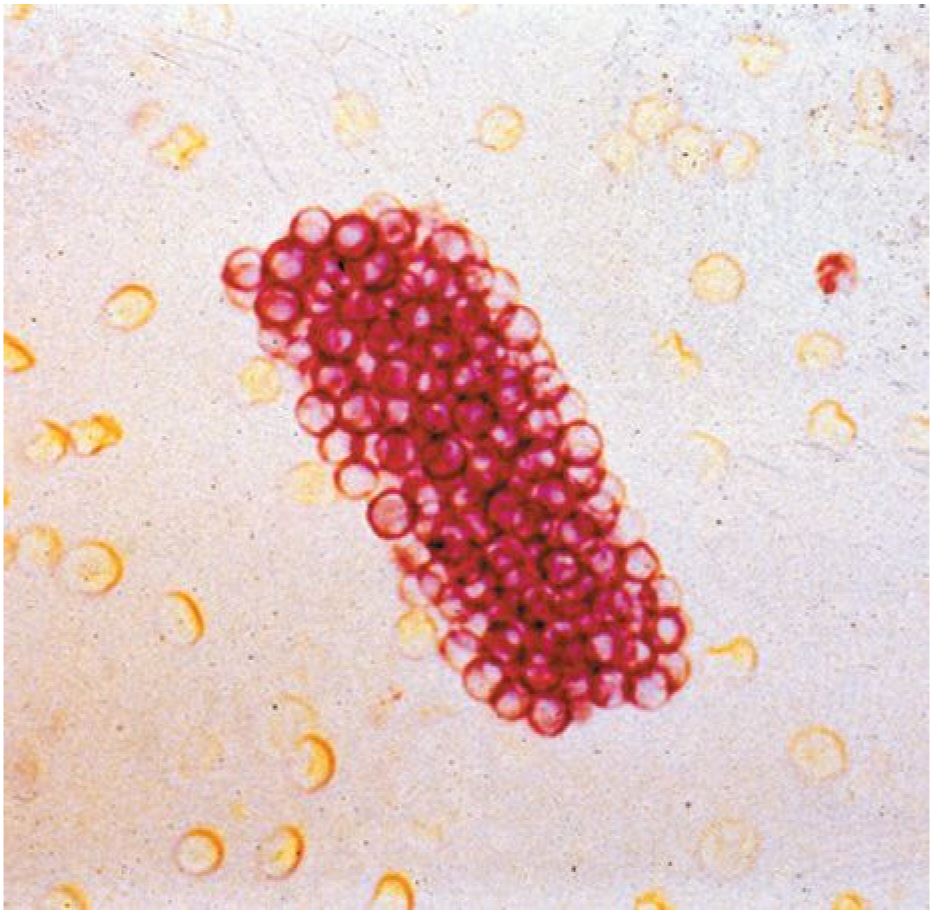

FIGURE 64-2 A RBC cast caused by bleeding into the tubule from the glomerulus. These casts are seen in glomerulonephritis, IgA nephropathy, lupus nephritis, Goodpasture syndrome, and Wegener granulomatosis. RBC casts are always pathologic.

- Gross hematuria suggests a postrenal source in the collecting system, although recurrent episodes of gross hematuria occur in 10 to 20 percent of patients with MPGN.[11]
    - Bright red urine and/or visible clots with normal appearing RBCs on microscopy suggest bleeding from the urinary tract.[1]
    - Brownish-colored urine (described as tea or cola-colored) with RBC casts and dysmorphic RBCs suggest glomerular bleeding.[1]
- Pyuria (**Figure 64-3**) is often the result of urinary tract infection.

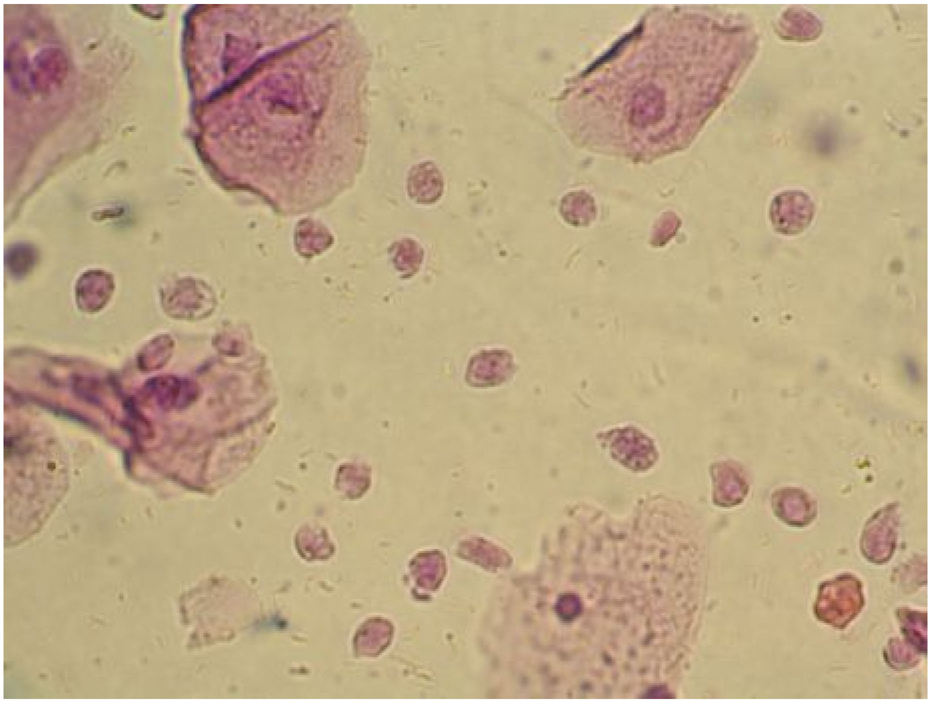

FIGURE 64-3 Pyuria and bacteriuria in a patient with a urinary tract infection. A simple stain was added to the wet mount of spun urine. Although there are epithelial cells present, the culture demonstrated a true urinary tract infection (UTI) and not merely contaminated urine. (*Used with permission from Richard P. Usatine, MD.*)

- The presence of bacteria (>10^2 organisms per mL or >10^5 using a midstream urine specimen in older children and adults) suggests infection. A urinalysis with 10 bacteria per HPF is highly suggestive (specificity 99%) of infection (positive likelihood ratio [LR+] 85).[12]
- Asymptomatic bacteruria is found in 4 to 15 percent of pregnant women, usually *Escherichia coli*.
- The presence of WBC casts (**Figure 64-4**) with bacteria indicates pyelonephritis.

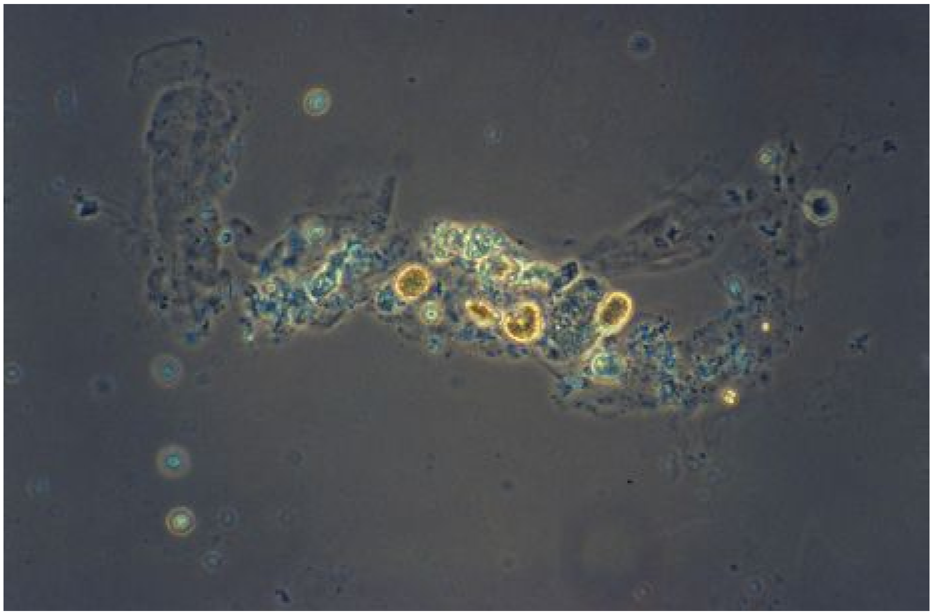

FIGURE 64-4 WBC casts seen in pyelonephritis. These can be differentiated from a clump of WBCs by their cylindrical shape and the presence of a hyaline matrix.

- As previously noted, isolated (sterile) pyuria can also been seen in children with KD or tuberculosis.[5,6,13]
- WBCs and/or WBC casts can be seen in tubulointerstitial processes like interstitial nephritis, systemic lupus erythematosus, or transplant rejection.
- Urinary casts are formed only in the distal convoluted tubule (DCT) or in the collecting duct (distal nephron).
- Hyaline casts are formed from mucoprotein secreted by the tubular epithelial cells within the nephrons. These translucent casts are the most common type of cast and can be seen in normal persons after vigorous exercise or with dehydration. Low urine flow and concentrated urine from dehydration can contribute to the formation of hyaline casts (**Figure 64-5**).

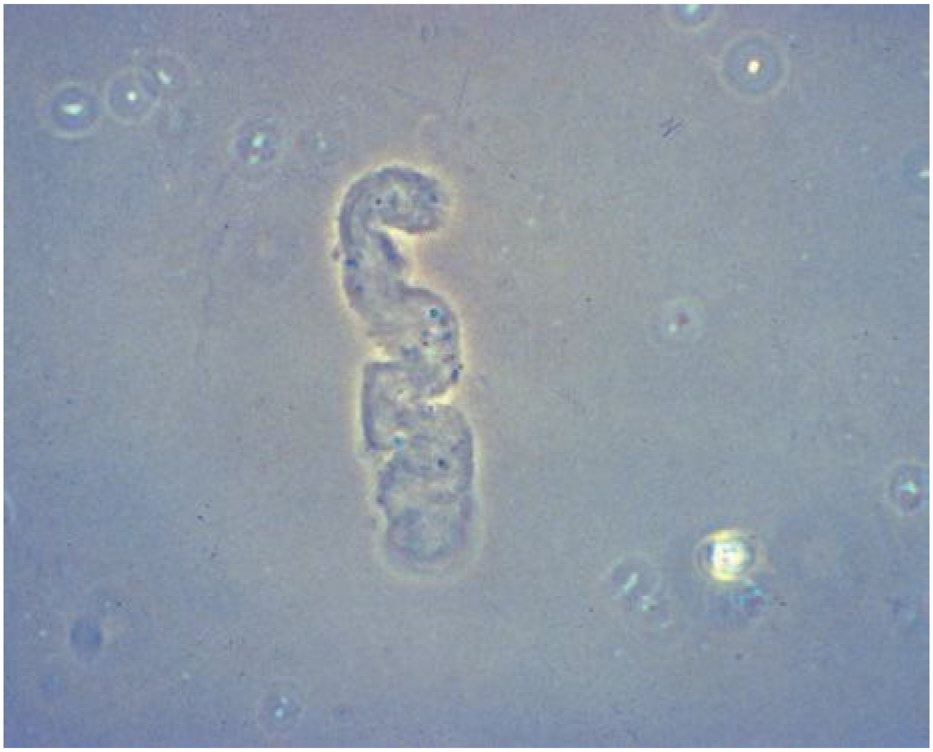

FIGURE 64-5 Hyaline casts are translucent and proteinaceous. These are the most common casts found in the urine and can be seen in normal individuals. Concentrated urine with low flow, usually caused by dehydration, exercise, and/or diuretics, can lead to hyaline cast formation.

- Granular casts are the second most common type of cast seen (**Figure 64-6**). These casts can result from the breakdown of cellular casts or the inclusion of aggregates of albumin or immunoglobulin light chains. They can be classified as fine or coarse based on the size of the inclusions. There is no diagnostic significance to the classification of fine or coarse.

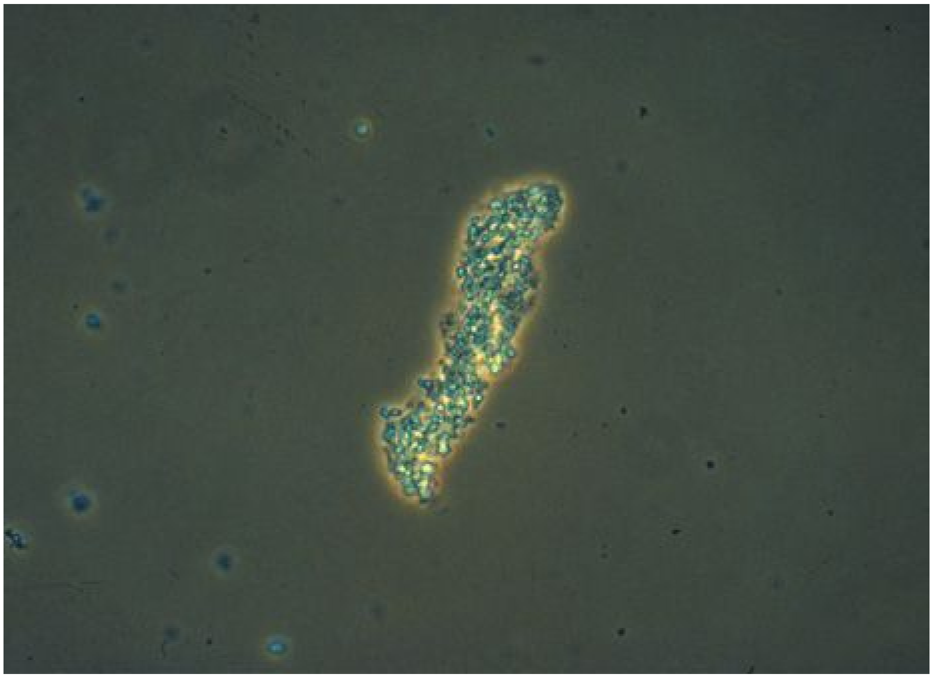

FIGURE 64-6 Coarse granular cast. All granular casts indicate underlying renal disease. These are nonspecific and may be seen in diverse renal conditions.

RISK FACTORS

- Constipation (for UTI in children).
- Clinical factors associated with urinary tract infection in febrile children in one study were:[14]
  - Uncircumcised male (OR 10.4; 95% CI 4.7 to 31.4).
  - Temperature of > or = 39 degrees C (OR 2.4 per degree C; 95% CI 1.5 to 3.6).

DIAGNOSIS

CLINICAL FEATURES

- Hematuria is often asymptomatic in patients with glomerular disease or metabolic abnormalities.
    - Important aspects of the history include prior or current infection (urinary tract, diarrhea, or strep throat), strenuous exercise, menstruation, tropical exposures, trauma, pain (bladder, flank, or joint), rash, or symptoms of UTI (frequency or dysuria).[1,18] Inquire about changes in urine volume. Also examine for foreign body insertion and occult trauma, including sexual abuse (e.g., genital bleeding).
    - Family history of sickle cell disease or hemophilia, stone disease, hearing loss, and familial renal disease, hematuria, and hypertension can be helpful.[18]
    - Signs and symptoms of glomerular disease include various degrees of renal failure, edema, oliguria, hypertension, and anemia out of proportion to the degree of renal failure. Ask about sore throat or skin infection within the last 4 weeks, suggesting post-infectious disease. Patients with MPGN present with one of the following patterns: nephrotic syndrome (40 to 70%); acute nephritic syndrome (20 to 30%); asymptomatic proteinuria and hematuria detected on routine urinalysis (20 to 30%); or recurrent episodes of gross hematuria (10 to 20%).[15] Hypertension is detected in 1/3 of patients with MPGN.[15]
    - In a case series of children with Henoch-Schönlein purpura (N = 223), nephritis occurred in 46 percent, most within 1 month of diagnosis.[16] Nephritis presented as isolated hematuria in 14 percent, isolated proteinuria in 9 percent, both hematuria and proteinuria in 56 percent, nephrotic-range proteinuria in 20 percent, and nephrotic-nephritic syndrome in 1 percent.
    - Renal stones can cause pain in the ipsilateral flank and/or abdomen with radiation to the ipsilateral groin, testicle, or vulva or irritative symptoms of frequency, urgency, and dysuria, if located in the bladder.
    - An abdominal mass may be caused by a tumor, hydronephrosis, multicystic dysplastic kidney, or polycystic kidney disease.[1]
    - Rash and/or arthritis can occur in patients with Henoch-Schönlein purpura or systemic lupus erythematosus.

- UTI in children is more likely in the presence of pain (abdominal pain [LR+ 6.3; 95% CI, 2.5 to 16.0] or back pain [LR+ 3.6; 95% CI, 2.1 to 6.1]) in addition to dysuria, frequency, or both (LR+ 2.2 to 2.8); new-onset urinary incontinence (LR+ 4.6; 95% CI, 2.8 to 7.6) also increases the likelihood of a UTI.[17]
    - In infants, findings of previous UTI (LR+ 2.3 to 2.9), fever higher than 40°C (104°F) (LR+ 3.2 to 3.3), and suprapubic tenderness (LR+ 4.4) were the findings most useful for identifying UTI.
- Symptoms of pyelonephritis include chills and rigor, fever, nausea and vomiting, and flank pain; positive likelihood ratios, however, are low (1.5 to 2.5).

LABORATORY TESTING AND IMAGING

- The work-up for microscopic hematuria in a child includes urinary sediment looking for dysmorphic cells or RBC casts (**Figure 64-2**) and a test for proteinuria (>2+ by dipstick).
    - If positive, suspect glomerular disease and consider a basic metabolic panel, complete blood count and platelet count, complement, albumin, streptozyme, and antibody testing (antistreptolysin O, antiglomerular basement membrane antibody, antineutrophil cytoplasmic antibody); a renal biopsy may be indicated.[1] Work-up for patients with suspected MPGN is covered elsewhere.[11]
    - If negative and the sediment contains WBCs (**Figure 64-3**) or WBC casts (**Figure 64-4**), suspect infection and obtain a urine culture and susceptibility test if pyelonephritis is suspected; *E. coli* is the most common organism.
    - If negative and no WBCs or symptoms, obtain a urinalysis (UA) from family members looking for hematuria (if positive, the diagnosis of benign familial hematuria is likely) or signs of glomerular disease, and a urine for calcium/creatinine ratio; if the diagnosis remains unclear, consider a 24-hour urine collection for protein, creatinine and calcium.[1] If these tests are also negative and hematuria persists, consider a hearing test, renal ultrasound, and hemoglobin electrophoresis.[1]

  - For a child with isolated hematuria, the American College of Radiology (ACR) recommends an ultrasound of the kidneys and bladder.[18] If the child has painful, nontraumatic hematuria, ACR recommends a computed tomography (CT) scan without contrast to evaluate for stones and an ultrasound of the kidneys and bladder. An x-ray of the abdomen and pelvis can also be considered.

- For a child with macroscopic hematuria, look for signs of glomerulonephritis (e.g., edema, hypertension, proteinuria, or RBC casts) and if present, consider tests previously noted for microscopic hematuria suspicious for glomerulonephritis.
  - If there is no trauma involved, obtain a urine culture and renal and bladder ultrasound.[1]
  - If the hematuria was caused by trauma, ACR recommends obtaining a CT of the abdomen and pelvis with contrast.[18] x-ray retrograde urography is considered in cases where blood is present at the urethral meatus or if there are pelvic fractures.[18]
  - For painful hematuria that is not infectious, a CT of the abdomen and pelvis without contrast and/or an ultrasound of the kidneys and bladder is most appropriate looking for stones or urologic conditions (e.g., tumor).[18]
  - Cystoscopic evaluation is helpful if bladder pathology is suspected or to localize bleeding during an episode of active bleeding.
  - If the preceding evaluation is negative, consider periodic follow-up.

- If RBC casts (**Figure 64-2**) are seen on UA in addition to proteinuria, also consider nephrotic syndrome caused by diabetes or amyloidosis (see Chapter 67, Nephrotic Syndrome).

- Note that RBC casts are fragile and are best seen in a fresh urine specimen (**Figure 64-2**).

- Based on older data, for a child with a suspected UTI, microscopy positive for pyuria and bacteruria (pooled LR+ 37.0; 95% CI 11.0 to 125.9) or a dipstick positive for both leukocyte esterase (LE) and nitrite (pooled LR+ 28.2; 95% CI: 17.3 to 46.0) are best for ruling in UTI.[19] Microscopy negative for both (pooled LR–0.11; 95% CI: 0.05 to 0.23) or a dipstick negative for both LE and nitrite (pooled LR–0.20, 95% CI, 0.16 to 0.26) can be used to rule out UTI.[11]

  - If the child is 3 years of age or younger, a urine sample for microscopy and culture is recommended; pyuria and positive bacteruria (at least 50,000 colonies per mL of a single uropathogenic organism in an appropriately collected specimen of urine) defines UTI.[20] Positive likelihood ratios are lower for dipstick testing in infants (LR+ 7.62; 95% CI 0.95 to 51.85).[21] For febrile infants, the urine specimen should be obtained before an antimicrobial agent is administered and through catheterization or suprapubic aspiration.[20]
  - For older children with a positive LE and nitrite, treatment can be initiated empirically and a urine culture obtained for confirmation and susceptibility testing. If only one of the dipstick tests is positive, a urine sample for microscopy and culture is indicated with treatment based on clinical and lab findings.[7]

- Following a UTI, imaging is recommended by ACR in the following cases:[22]
  - Age <2 months, febrile urinary tract infection—Ultrasound of kidneys and bladder with consideration of x-ray voiding cystourethrogram in boys and in the presence of an ultrasound abnormality.
  - Age >2 months and ≤3 years, febrile urinary tract infection with good response to treatment—Ultrasound of kidneys and bladder. The yield of this test decreases with increasing age and clinical judgement is needed for older children.
  - Atypical (poor response to antibiotics within 48 hours, sepsis, urinary retention, poor urine stream, raised creatinine, non-*E. coli* UTI), or recurrent febrile UTI—ultrasound of kidneys and bladder, x-ray voiding cystourethrogram (VCUG), and consideration of radionuclide cystography in girls.
- VCUG is also indicated for children if renal and bladder ultrasonography reveals hydronephrosis, scarring, or other findings that would suggest either high-grade VUR or obstructive uropathy.[20]

MANAGEMENT

Treatment will depend on the underlying etiology:

- If the child has glomerulonephritis, hyperkalemia or azotemia, stone disease, or a family history of renal failure, referral to a nephrologist is indicated.[1] Management of MPGN is covered elsewhere.[11]
- If the child with hematuria has sustained trauma or has obstructing stone disease, tumor, or structural abnormalities referral to an urologist is indicated. Such referral can also provide reassurance in cases where no cause of hematuria has been found.
- Cystitis is treated with appropriate antibiotics based on knowledge of the sensitivities of *E. coli* in the individual practice location (there is increasing resistance to amoxicillin).
    - First line choices are trimethoprim-sulfamethoxazole, amoxicillin/clavulanate, or cephalosporins such as cefixime.[7] Symptoms usually improve within 24 to 36 hours.
- Uncomplicated pyelonephritis can be treated with appropriate antibiotics as an outpatient (e.g., amoxicillin/clavulanate, cefixime, ceftibuten) for 10 to 14 days or with short-courses (two to four days) of intravenous therapy followed by oral therapy.[7,23] The urine should always be cultured in pyelonephritis to help guide therapy. Pregnant women or children with complicated pyelonephritis may need hospitalization.
- See Chapter 68, Nephritic Syndromes and Chapter 70, Kidney Stones for management of patients with these conditions.

PREVENTION AND SCREENING

- According to the Institute for Clinical Systems Improvement, urinalysis for screening in children and adolescents is among tests considered of low predictive value and/or uncertain beneficial action for true positives and is not recommended.[24]

- A yearly screening urinalysis is recommended for certain populations such as survivors of childhood cancers exposed to radiation or some chemotherapeutic agents.[25]
- A national urine screening program of school children in Korea (1999–2008) resulted in over 5,000 children being referred to pediatric nephrologists.[26] Renal biopsies were performed on 1,478 children [28.79 % of total subjects; 26.77 % for isolated hematuria (IH), 9.09 % for isolated proteinuria (IP), and 51.19 % for both] with chronic glomerulonephritis identified in 25% (40% with IgA) nephropathy, 24% with mesangial proliferative and 13% with GN with thin basement membrane nephropathy).
- For healthy children following a first UTI, prophylactic antibiotics do not appear to reduce subsequent UTI, even in children with mild to moderate vesicoureteral reflux.[27,28]

65 HYDRONEPHROSIS AND URETEROPELVIC JUNCTION OBSTRUCTION

Debby Chuang, MD
Lynn L. Woo, MD

PATIENT STORY

An otherwise healthy 7-year-old boy presents with a one day history of crampy left-sided abdominal and flank pain associated with nausea and non-bilious vomiting. He is afebrile and denies recent trauma. He is voiding and stooling normally. Exam is unremarkable except for some tenderness to palpation over the left costovertebral angle. Urinalysis is negative for blood or infection. Serum creatinine is within normal limits. Radiographic imaging reveals moderate left-sided hydronephrosis without ureteral dilation and an absence of stones or masses (**Figure 65-1**). The contralateral kidney and bladder are normal. Renal function testing is consistent with obstruction in the left kidney. The boy undergoes surgical repair for ureteropelvic junction obstruction (UPJO). On follow-up, he has resolution of hydronephrosis and his symptoms.

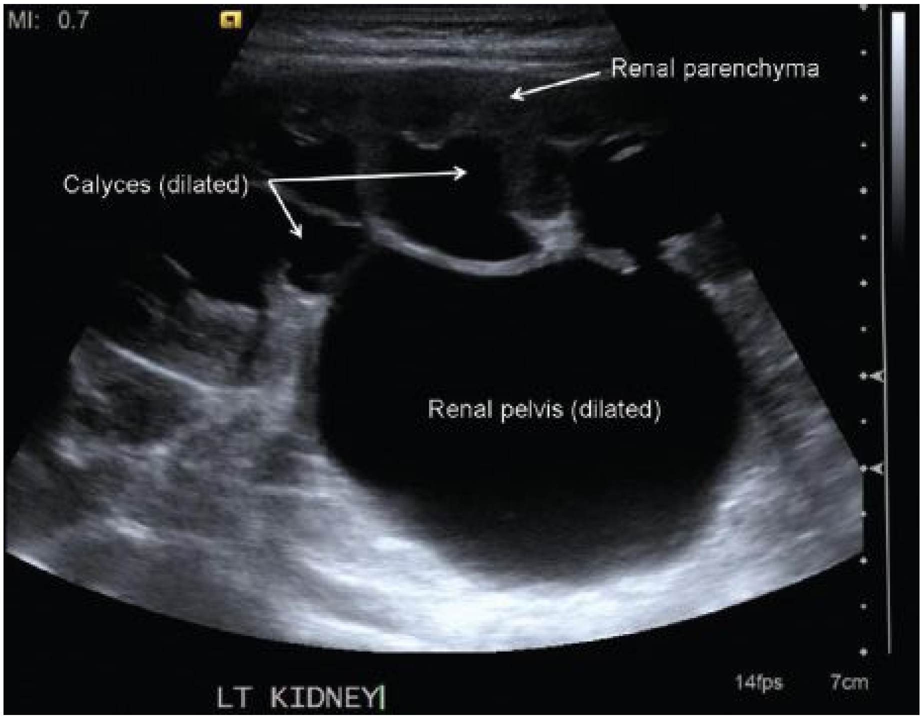

FIGURE 65-1 Ultrasound image of the left kidney. The findings of hydronephrosis with no dilation of the ureter are suggestive of ureteropelvic junction obstruction (UPJO). (*Used with permission from Lynn L. Woo, MD*)

INTRODUCTION

Prenatal detection of congenital abnormalities has significantly increased in the past two decades with advancements in ultrasound technology and improvements in prenatal care. Common genitourinary abnormalities, such as hydronephrosis and UPJO, are not only being identified more frequently in the perinatal period but are also being managed effectively in children at younger ages. Earlier treatment of such conditions is believed to improve the growth and development of the genitourinary system in these children as they mature into adulthood.

SYNONYMS

- Pelviureteric junction obstruction.
- Proximal ureteral narrowing or stricture.
- Renal pelvic dilation.
- Pelviectasis.

EPIDEMIOLOGY

- Of all congenital abnormalities detected during pregnancy, approximately 20 to 30 percent involve the genitourinary system, with the majority being hydronephrosis.[1–4]
    - Hydronephrosis is defined as abnormal dilation of the renal pelvis, with the anteroposterior diameter of the renal pelvis measured to be ≥5 mm in the perinatal period.[5–7]
    - Hydroureteronephrosis is defined as abnormal dilation of the renal pelvis *and* ipsilateral ureter.
- UPJO is the most common cause of perinatal hydronephrosis, accounting for approximately 40 percent of cases.[8]
- Large population studies have demonstrated a predominance of UPJO in males, with the male-to-female ratio being greater than 2:1, as well as a predilection for occurrence on the left side, particularly among neonates.[9–12]
- Bilateral UPJO has been reported to range from 10 to 40 percent cases.[10,11,13]

RISK FACTORS

- While there have been case reports of UPJO occurring in families,[14–16] there is currently no established genetic predisposition for congenital UPJO.

    - However, recent studies have postulated that abnormalities in various factors involved in nephrogenesis, including bone morphogenetic proteins (BMP’s), Wilm’s Tumor (WT1) gene, and human leukocyte antigen (HLA) genes, may contribute to familial cases of UPJO.[15,17–19]
- UPJO may often present in association with other congenital renal and non-renal abnormalities.[20]
    - UPJO is found in ≥15 percent cases of horseshoe kidneys, and is reported to also occur with malrotated kidneys.[12,21–25]
    - More than 1/3 of cases of hydronephrosis in ectopic kidneys, particularly pelvic kidneys, are due to UPJO.[25,26]
    - Approximately 20 percent of children with VATER syndrome have UPJO.[27]

ETIOLOGY AND PATHOPHYSIOLOGY

- UPJO may be primary (congenital) or secondary.
- Primary UPJO (**Figure 65-2**).

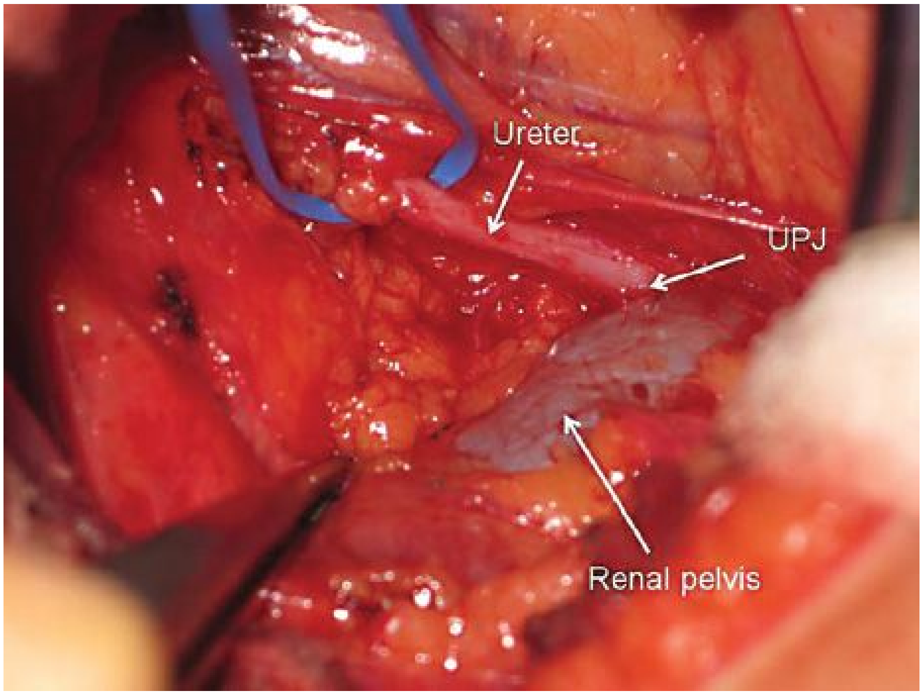

FIGURE 65-2 Intraoperative image of primary congenital UPJO. The ureter is found to be narrowed and kinked at the ureteropelvic junction. The renal pelvis is dilated and filled with urine. (*Used with permission from Lynn L. Woo, MD*)

- Involves a congenital defect in which there is a narrowing of the ureteral lumen at the ureteropelvic junction that is associated with impairment of urinary transport and renal function.
- True underlying etiology is still unknown but is believed to be likely multifactorial.[20,28]
  - Intrinsic factors (**Figure 65-3**).

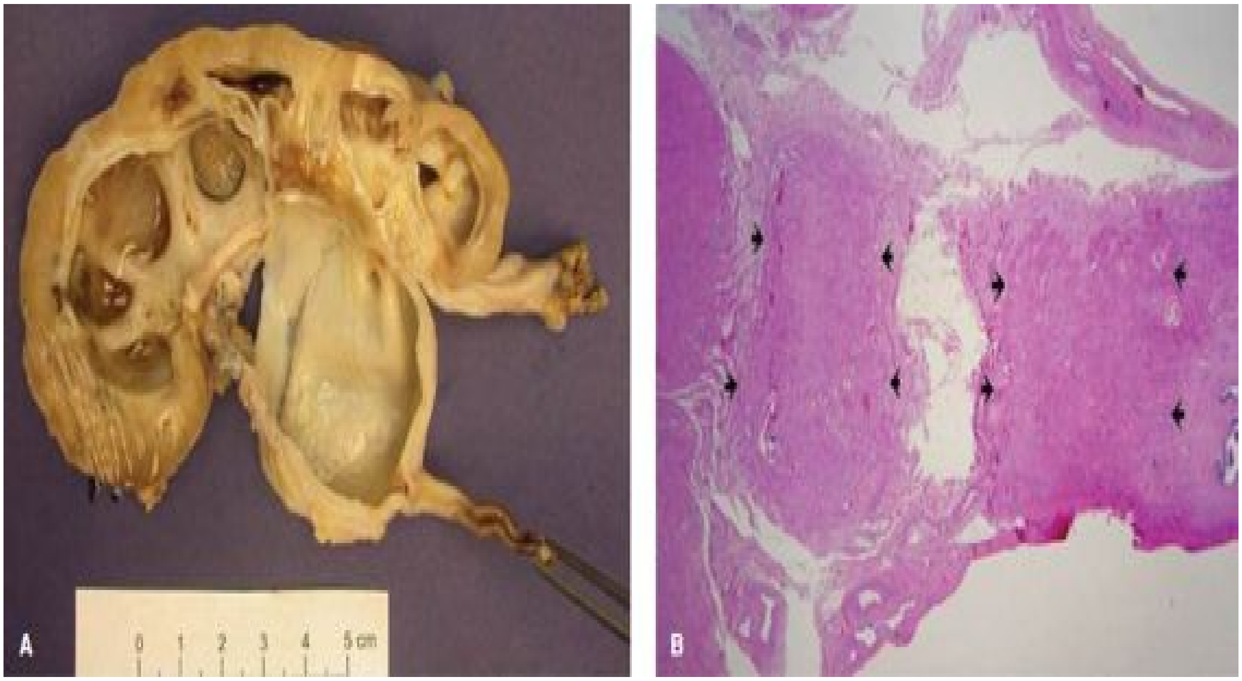

FIGURE 65-3 Pathology of congenital ureteropelvic junction obstruction (UPJO). **A.** Gross specimen of kidney with congenital UPJO. The renal pelvis and all calyces are dilated, and there is marked loss of renal parenchyma. The ureter distal to the UPJ is of normal caliber. **B.** Histologic view of congenital UPJO at lower power. Renal pelvic muscle is at far left. Muscle at the UPJ appears discontinuous, surrounded by two collars of muscle, as indicated by opposing sets of arrows, with disorganized muscle bundle orientation, separated by paucicellular collagenous areas. (*Used with permission from Lynn L. Woo, MD*)

    - Incomplete recanalization of the ureter during embryologic development.[29,30]
    - Abnormal ureteral muscle and fibrous tissue development that affects ureteral peristalsis.[31,32]
  - Extrinsic factors (**Figure 65-4**).

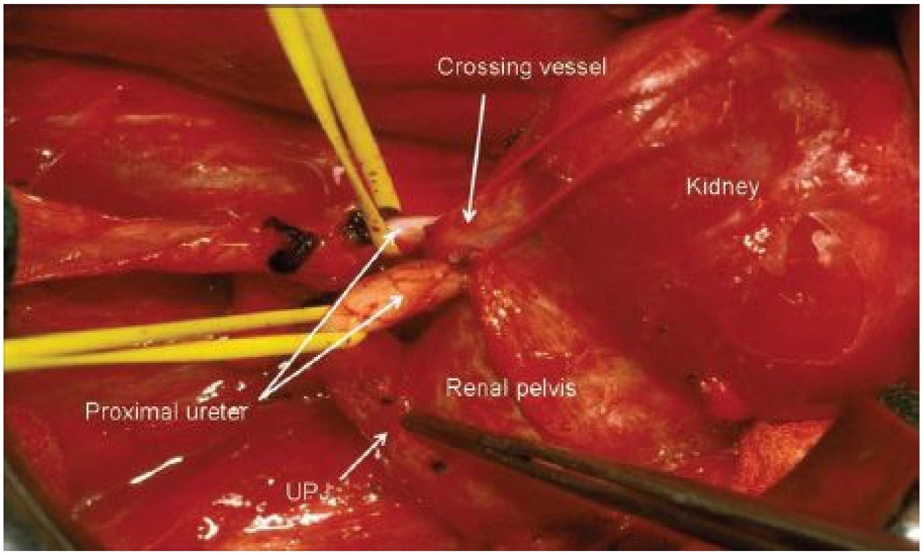

FIGURE 65-4 Intra-operative view of UPJO with crossing vessel. The ureter is identified by the yellow vessel loops, while the crossing vessel is denoted by the red vessel loop. Crossing vessels typically arise from the lower pole of the kidney and cross *anterior* to UPJ or proximal ureter, resulting in "kinking" of the ureter. Whether the aberrant vessel is the primary cause or a co-variable that is associated with intrinsic narrowing is unclear. (*Used with permission from Lynn L. Woo, MD*)

    - Mechanical obstruction from lower-pole crossing vessel, which can be seen in up to 63 percent cases of UPJO.[33,34]

- Secondary UPJO.
  - Obstruction develops as a result of kinking at the UPJ from a severely dilated and tortuous ureter. The ureteral dilation is most often secondary to severe vesicoureteral reflux or congenital megaureter.

DIAGNOSIS

CLINICAL FEATURES

- As many cases of hydronephrosis and UPJO are detected by prenatal ultrasound imaging, or incidentally during imaging for pediatric trauma, many infants and children will be asymptomatic.
  - Hydronephrosis identified in the prenatal period may spontaneously resolve in the immediate postnatal period.[35]
  - Hydronephrosis identified in the perinatal period may remain stable or spontaneously resolve as a child gets older, obviating the need for any intervention, especially in the absence of symptoms.[36,37]
  - Hydronephrosis is not necessarily indicative of obstruction.
- Symptoms/Presentation.
  - Flank/abdominal pain.
  - Nausea/vomiting (non-bilious).
  - Hematuria.
  - Urinary tract infection.
  - Failure to thrive.
- *Dietl's crisis* describes a combination of episodic upper abdominal pain or flank pain with nausea/vomiting, particularly during diuresis, which is associated with UPJO.
- As children with UPJO may present with abdominal pain, nausea, and vomiting, they may often undergo prior evaluation for gastrointestinal or psychological etiologies before the genitourinary etiology is identified and a referral to a pediatric urologist is made.[38,39]
- Untreated UPJO may be associated with increased risk for failure of the affected renal unit, kidney atrophy, pain, recurrent infections, stone development, and/or hypertension in adulthood.

LABORATORY STUDIES

- Urinalysis may demonstrate gross or microscopic hematuria, thought to be due to rupture of mucosal vessels in the dilated renal pelvis.

- Basic metabolic panel may reveal renal insufficiency, although in the setting of a normal contralateral kidney, this would be unlikely.
    - In evaluating newborns, one must bear in mind that postnatal serum creatinine will reflect maternal serum creatinine until at least 48 hours after birth.

DIAGNOSTIC STUDIES

- Retrograde Pyelogram (**Figure 65-5**).

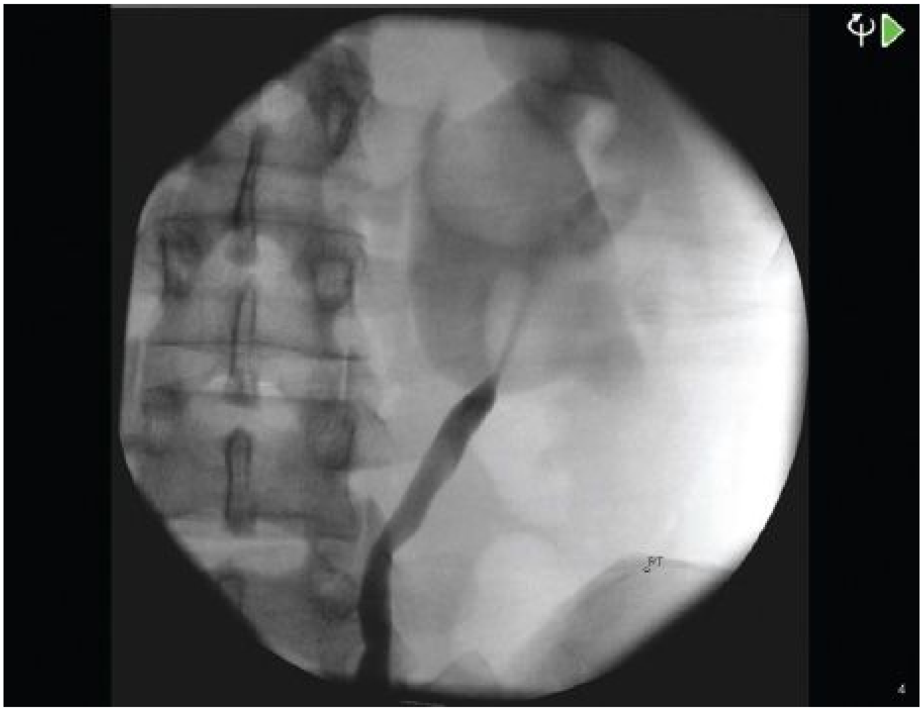

FIGURE 65-5 Retrograde pyelogram of left kidney. The pelvis appears massively dilated with blunted calyces. There is also an area of narrowing at the proximal ureter, consistent with ureteropelvic junction obstruction (UPJO). (*Used with permission from Lynn L. Woo, MD*)

  - Anatomic study, typically performed at time of surgical repair.
  - Allows confirmation of anatomical abnormality and helps exclude the possibility that the hydronephrosis is actually from a more distal obstructive lesion.

- Findings—Dilated renal pelvis with characteristic narrowing or kinking at the UPJ and a distal ureter of normal caliber.

- Ultrasound Imaging (US) (**Figure 65-1**).
  - Anatomic study.
  - Findings suggestive of UPJO:
    - Hydronephrosis or dilated renal pelvis; AP diameter ≥5 mm in children.
    - Non-visualization of the ureter is the rule (as a normal ureter is not dilated, it is usually not visible on US).
    - Thinned parenchyma.
    - Abnormal renal growth.

- Computed Tomography (CT) or Magnetic Resonance Imaging (with or without contrast) (**Figure 65-6**).

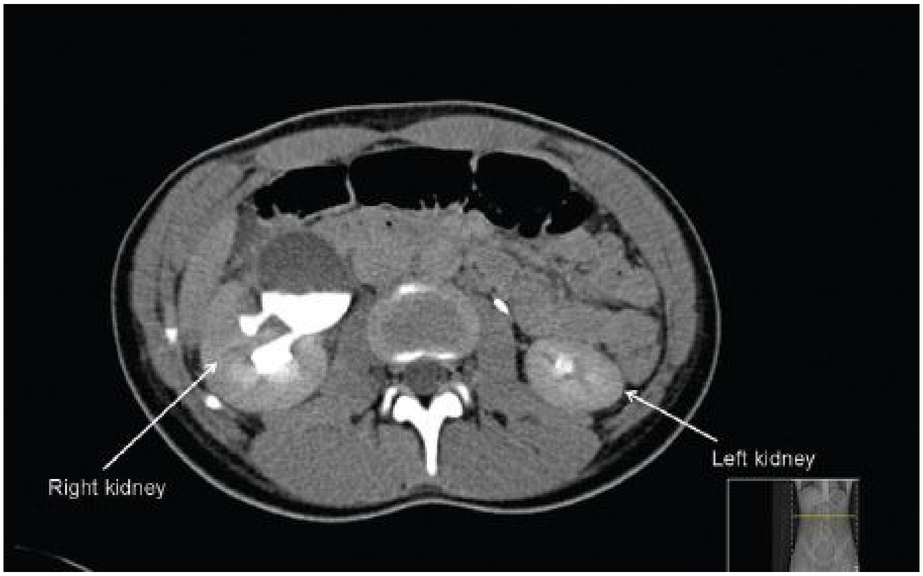

FIGURE 65-6 Computed Tomography of abdomen with intravenous contrast demonstrating right UPJO. The right renal pelvis and calyces are dilated, and contrast can be seen pooling dependently in the collecting system, while the normal left kidney shows normal excretion of contrast into the ureter. (*Used with permission from Lynn L. Woo, MD*)

  - Anatomic and functional studies, more often used in older children.
  - CT involves considerable radiation exposure and should therefore be minimized in children.

    - Findings suggestive of obstruction:
        - Dilated renal pelvis +/− dilated calyces.
        - Narrowing of ureter at UPJ.
        - Crossing vessel.
        - Delayed uptake or excretion of contrast agent from the affected kidney.
- Diuretic Renography/Renal Flow Scan (**Figure 65-7**).

Table of Results (Summary)

Parameters	Left	Right	Total
Split Function (%)	28.0	72.0	
Kidney Counts (cpm)	58037	149203	207240
Time of Max (min)	30.5	3.502	
Time of 1/2 Max (min)		7.980	

FIGURE 65-7 MAG-3 Lasix Renal Scan (interpreted from a posterior view). **A.** Differential renal function. The radiotracer uptake is severely diminished in the left kidney (red outline), with the left kidney contributing only 28 percent to overall renal function, and the right kidney (yellow outline) contributing 72 percent to overall renal function. **B.** Renal uptake and excretion. The graph depicts the tracer uptake and excretion pattern for each kidney. The right kidney (yellow) quickly takes up and excretes the tracer. The time it takes to excrete ½ of the maximum tracer agent that was taken up is 7.98 minutes, which is consistent with normal renal function. The left kidney (red) takes up the agent, but does not excrete the agent in the documented time period (30 minutes), as demonstrated by the plateau, which is consistent with obstruction. **C.** Summary of renal differential function and T1/2. (*Used with permission from Lynn L. Woo, MD*)

  - Functional nuclear medicine study.
  - Measures differential renal function as well as renal excretion and drainage.
    - Most commonly used radiotracer agent is technetium-99m. mercaptoacetyltriglycine (*MAG-3*).
    - Furosemide is administered during the study to promote diuresis of agent.
  - Findings suggestive of obstruction:
    - Differential renal function of <40 percent in affected kidney.
    - Impaired or lack of uptake and/or clearance of radiotracer agent.
- Time to clearance of 50 percent tracer agent ($T_{1/2}$).
  - Normal: <10 minutes.
  - Indeterminate: 10 to 20 minutes.
  - Obstructed: >20 minutes.

DIFFERENTIAL DIAGNOSIS (OF PEDIATRIC HYDRONEPHROSIS) (FIGURE 65-8)

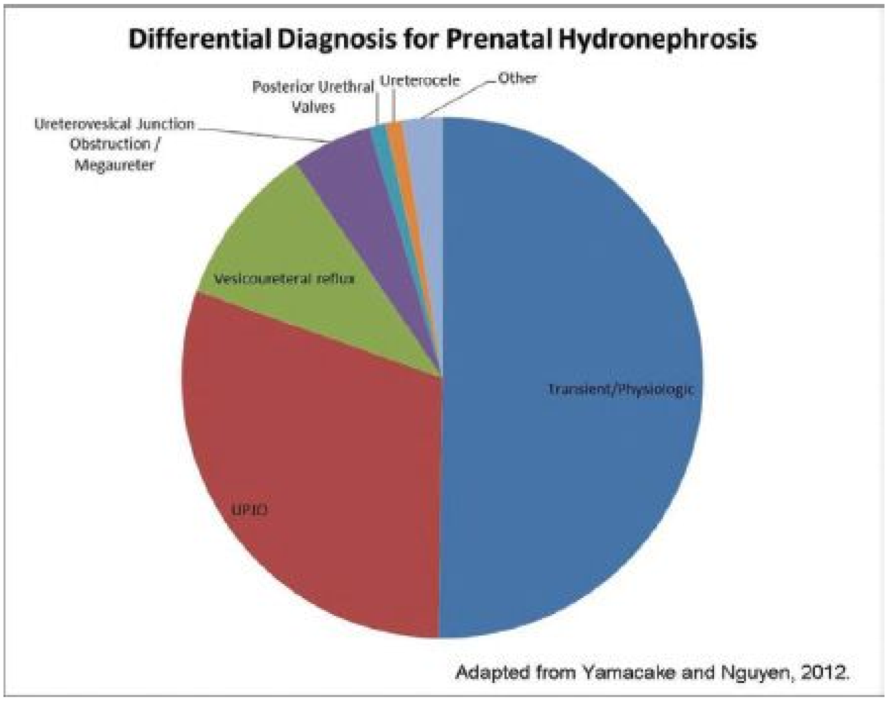

FIGURE 65-8 Differential diagnosis for prenatal hydronephrosis.[65] As most cases of prenatal hydronephrosis will resolve in immediate postnatal period, UPJO is the most common cause of persistent hydronephrosis in the perinatal period. (*Adapted from Yamacake KG, Nguyen HT: Current management of antenatal hydronephrosis. Pediatr Nephrol 2012;28(2):237-243. With kind permission from Springer Science and Business Media*.)

- Transient/physiologic hydronephrosis.
- Vesicoureteral reflux (backflow of urine into upper collecting system).
- Posterior urethral valves (congenital obstruction of urethra or other bladder outlet obstruction).
- Congenital megaureter.
- Ureterovesical junction obstruction.
- Duplicated collecting system.
- Ectopic ureter (abnormal insertion of ureteral orifice).
- Ureterocele (cystic dilation of distal ureter).
- Obstructing urinary calculus, ureteral polyp or neoplasm.
- Multicystic dysplastic kidney.

MANAGEMENT

- As prenatal hydronephrosis may result from different etiologies and may be obstructive or nonobstructive, referral to a pediatric urologist and close follow-up are necessary for optimal management.
- With improvements in pediatric imaging technology, as well as the expansion in the field of pediatric urology, there has been a growing trend towards more conservative management for hydronephrosis and UPJO.[40,41] SOR C
    - More than 40 percent children with UPJO may not require surgical intervention.[42]
    - Current proposed indications for intervention.[43]
        - Persistent symptoms (pain, nausea, failure to thrive).
        - Significant obstruction on diuretic renal scan.
        - Impairment of overall renal function or abnormal renal growth.
        - Hypertension.
        - Worsening ipsilateral renal function.
        - Recurrent urinary tract infections.
        - Development of stone disease.
        - Renal failure.

INTERVENTION

- Since its introduction in 1949, the Anderson-Hynes open dismembered pyeloplasty (**Figure 65-9**) has been considered the gold standard for treatment of pediatric UPJO, with success rates reported to be ≥98 percent.[44,45] SOR A

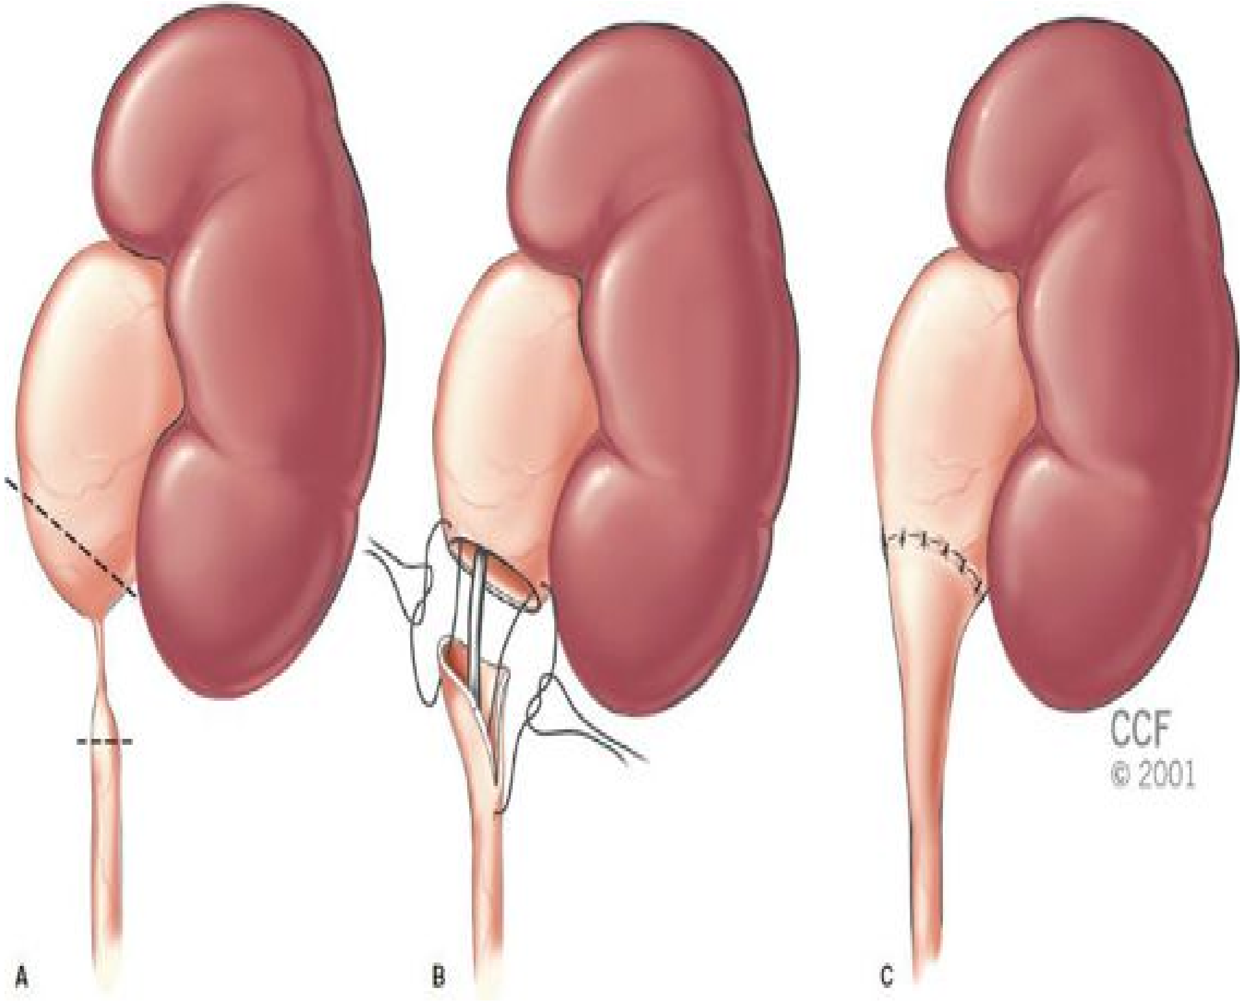

FIGURE 65-9 Illustration of dismembered pyeloplasty. **A.** The area of abnormal ureter is excised. **B.** The ureter is spatulated laterally. **C.** The renal pelvis is then re-anastomosed to the proximal ureter, re-establishing continuity of the UPJ. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2001-2013. All Rights Reserved.)

  - Even about 90 percent of children with UPJO in poorly functioning kidneys (relative renal function <30%) will demonstrate persistent improvement in post-operative renal function more than three years after pyeloplasty.[46]

- The recent decade has seen a surge in advancement of laparoscopic and robotic pyeloplasty techniques, as well as in endoscopic procedures, all of which are becoming more accepted alternatives to the open dismembered pyeloplasty (**Figure 65-10**).

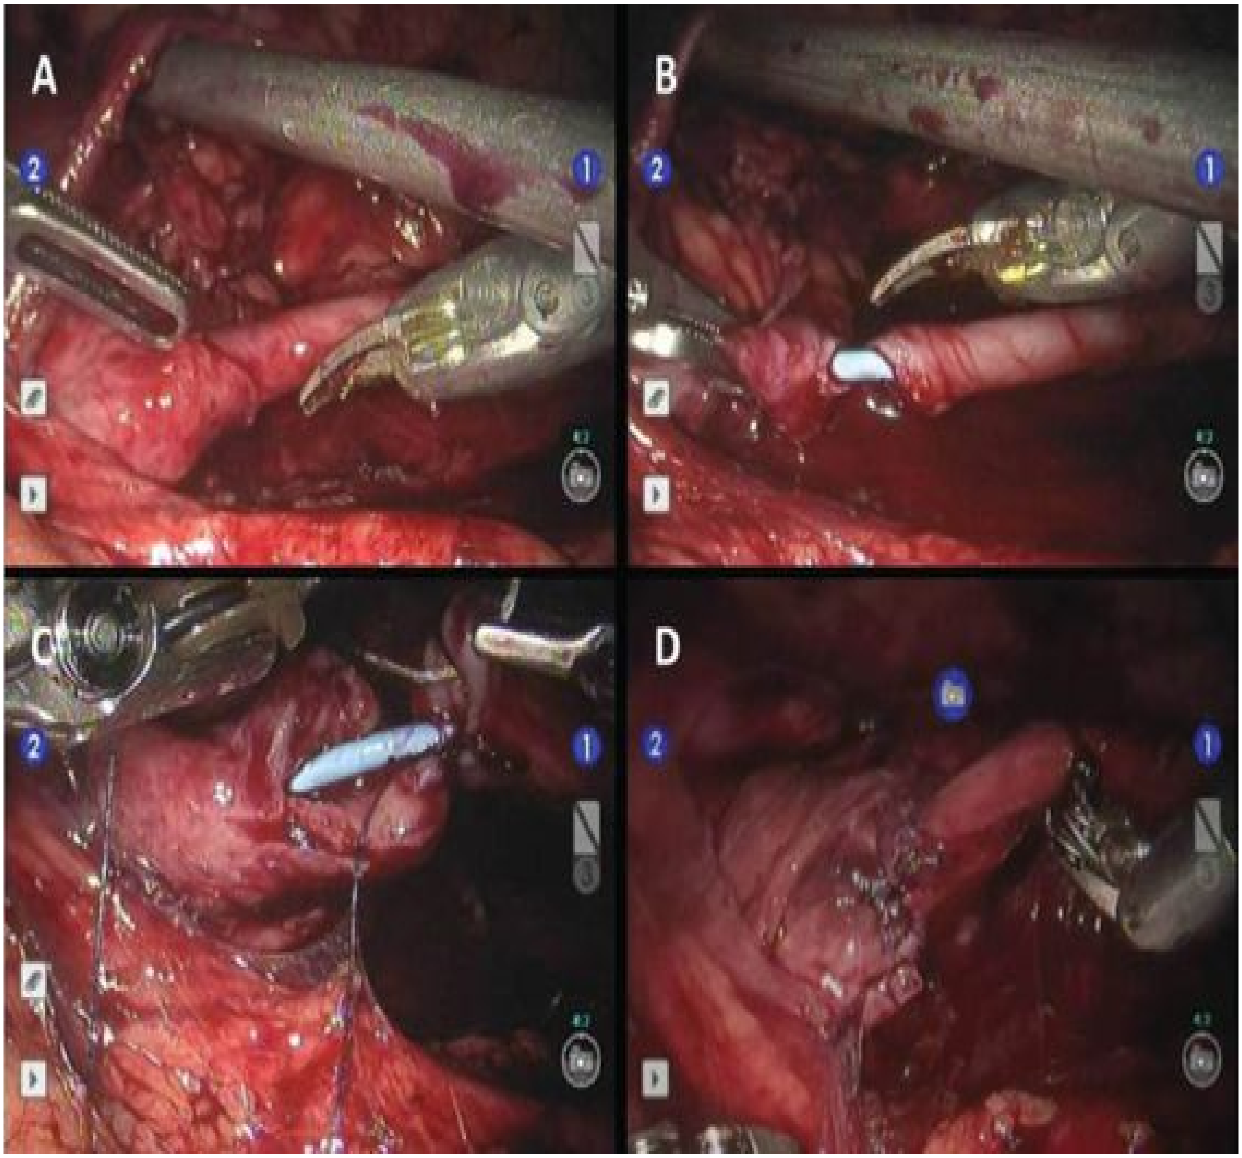

FIGURE 65-10 Robotic-assisted laparoscopic pyeloplasty. The principles of repair are identical to open dismembered pyeloplasty. In this case, a ureteral stent was placed initially. **A.** The UPJ is identified. **B.** The UPJ is transected, revealing narrowing at the renal pelvis. **C.** The pelvis and spatulated ureter are then re-anastomosed over the stent. **D.** The completed repair. (*Used with permission from Lynn L. Woo, MD*)

- Recent studies have demonstrated that robotic and laparoscopic techniques are feasible and safe, and may have success rates of ≥97 percent.[47,48] SOR A
- Endopyelotomy has been reported to have a 65 percent success rate.[49]

- A ureteral stent is often placed during the pyeloplasty to assist with healing of the anastomosis.
    - Children with ureteral stents placed during the pyeloplasty will need to undergo a subsequent outpatient procedure for stent removal approximately 2 to 6 weeks after the pyeloplasty.

PREVENTION AND SCREENING

- As the etiology of UPJO is still unclear and may be multifactorial, there is currently no known prevention for the development of UPJO.
    - In children with severe VUR or megaureter concurrently with secondary UPJO, early surgical repair may help to prevent the development of symptoms and/or further renal deterioration.
- Most cases of hydronephrosis and UPJO are detected by routine prenatal ultrasound imaging, and patients may be referred to a pediatric urologist for prenatal counseling or shortly after birth, as further imaging studies may be required. Cases of bilateral hydronephrosis should be followed closely in the prenatal period for potential oligohydramnios. There are no additional *screening* studies recommended for hydronephrosis or UPJO.
- Children with recurrent urinary tract infections, fevers, and/or flank or lateralizing abdominal pain should undergo evaluation for infection, as well as renal and bladder ultrasound imaging for detection of possible underlying abnormalities.
- Cases of newly diagnosed hydronephrosis from imaging studies should be referred to a pediatric urologist for further work-up and management.

PROGNOSIS

- The overall risk of obstruction recurrence after surgical repair with pyeloplasty is reported to be as low as 1.3 percent after 5 years.[50]

  - Complete resolution of obstruction is typically seen in up to 94 percent children within the first 3 to 6 months after pyeloplasty.[44,46,51]
  - Preservation of renal function has been reported to persist at least 6 to 19 years after surgery, even into adulthood.[52–54]
  - Risk factors for recurrence are cited to be younger age of initial surgery, prolonged urinary leakage, missed anatomical findings, lack of intra-operative retrograde pyelogram, and dorsal lumbotomy approach.[55,56]

FOLLOW-UP

- While the literature suggests that resolution of obstruction and renal function appears to be stabilized in the long term, there is still a lack of consensus on the optimal amount time needed for follow-up time after pyeloplasty.
  - Most pediatric urologists will follow children with serial ultrasound imaging and/or post-repair diuretic renography to ensure resolution of obstruction.[45,57]
  - With improved and stable renal function, children may be referred back to their pediatrician as early as 2 years after UPJO repair.[20]
- With recurrence of obstruction, a percentage of children may be referred back to a pediatric urologist for management.
  - Recurrent UPJO may result from development of scar tissue or stricture, redundant renal pelvis, and/or persistent or missed crossing vessel.
  - Children may be symptomatic or asymptomatic with recurrent obstruction.
    - Symptomatic children may present in a similar manner as their initial presentation for UPJO (pain, nausea/vomiting, renal insufficiency, or worsening hypertension).
  - Imaging may demonstrate hydronephrosis and UPJ narrowing.
  - Diuretic renography may reveal obstruction and/or decreased differential renal function.
  - Indications for intervention are similar to those for initial UPJO repair.
  - Management options.

  - Ureteral stent placement.
    - May provide symptomatic relief from obstruction as well as preserve renal function in the short-term, but not typically considered to be a long-term solution for children.
    - Retrograde pyelogram performed at the time of stent placement may help to delineate the extent of obstruction and length of ureter involved.
- Endopyelotomy.
  - The area of ureteral obstruction can be directly visualized with ureteroscopy and scar or stricture tissue may be excised with cold-knife incision, electrocautery, and/or laser ablation.[58]
  - Success rates have been reported to be as high as 70 percent.[59]
- Endoscopic balloon dilation.
  - Endoscopic dilation of scarred tissue at the ureteropelvic junction.
  - Success rates are variable when compared to endopyelotomy.[58,60]
- Repair of obstruction with re-do pyeloplasty or ureterocalicostomy.
  - Open, laparoscopic, and robotic techniques have been demonstrated to be safe, feasible, and effective, with success rates reported to be >83 percent.[60–63]
- Nephrectomy.
  - Indications for nephrectomy include severe obstruction with significant fibrosis that may prevent surgical repair, poor differential renal function (usually <20%), decreased renal growth/development, recurrent urinary tract infections, and/or persistent and severe symptoms.[64]
  - Considered to be the definitive management for recurrent and persistent UPJO in the setting of poor renal function.

66 POLYCYSTIC KIDNEYS

Mindy A. Smith, MD, MS

PATIENT STORY

A 17-year-old boy is seen in the office with mild abdominal pain and blood in his urine noticed after playing football with his friends. Exam is significant only for left flank tenderness and his vital signs, including blood pressure, are normal. His urine tests positive for blood (3+) and 1+ protein; microscopic urinalysis reveals numerous red blood cells but no white blood cells or casts. On further questioning, his mother reports that the boy's father and paternal aunt have some type of "kidney problem" but she and his father have been divorced for many years and he rarely sees his father. An ultrasound reveals bilateral enlarged kidneys with multiple cysts and a calculus in the left kidney. A CT scan confirms the diagnoses (**Figure 66-1**).

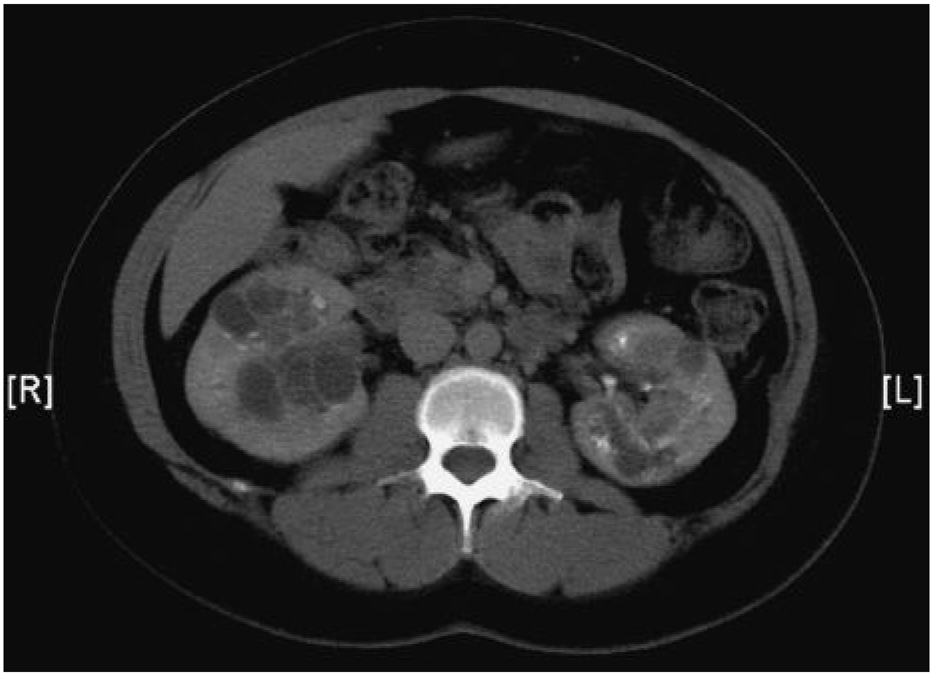

FIGURE 66-1 Polycystic kidneys in a patient with hematuria. (*Used with permission from Michael Freckleton, MD.*)

INTRODUCTION

Polycystic kidney disease (PKD) is a manifestation of a group of inherited disorders resulting in renal cyst development. In the most common form, autosomal-dominant polycystic kidney disease (ADPKD), extensive epithelial-lined cysts develop in the kidney; in some cases, abnormalities also occur in the liver, pancreas, brain, arterial blood vessels, or a combination of these sites. In autosomal recessive polycystic disease (ARPKD), the disease primarily causes enlarged cystic kidneys and hepatic fibrosis and usually presents in infancy. The cysts in ARPKD form only in the collecting tubule and are smaller and typically not visible on gross examination.

EPIDEMIOLOGY

- Most common tubular disorder of the kidney, affecting 1 in 300 individuals.
- Autosomal dominant in 90 percent of cases.[1] The majority of cases of ADPKD are diagnosed in adults but can be diagnosed at any age.[2] In a German population study, the overall prevalence of ADPKD was 32.7/100,000 reaching a maximum of 57.3/100,000 in the 6th decade of life.[3]
- Sporadic mutation in approximately 1:1000 individuals.
- ADPKD accounts for approximately 5 to 10 percent of cases of end-stage renal disease (ESRD) in the US.
- ADPKD is most frequently seen in the third and fourth decades of life, but can be diagnosed at any age.

- ARPKD is estimated to occur in 1:10,000 to 1:40,000 live births, although this may be an underestimate as severely affected neonates do not survive beyond the first few days of life and may not be correctly diagnosed.[2]
- Both diseases are seen in all races and ethnicities and affect males and females equally.

ETIOLOGY AND PATHOPHYSIOLOGY

- ADPKD results from mutations in either of 2 genes that encode plasma membrane–spanning polycystin 1 (PKD1) and polycystin 2 (PKD2).[4] Polycystins regulate tubular and vascular development in the kidneys and other organs (liver, brain, heart, and pancreas). PKD1 and PKD2 are colocalized in primary cilia and appear to mediate Ca^{2+} signaling as a mechanosensor, essential for maintaining the differentiated state of epithelia lining tubules in the kidney and biliary tract.[5]
- In ADPKD, few (1% to 5%) nephrons actually develop cysts. The remaining renal parenchyma shows varying degrees of tubular atrophy, interstitial fibrosis, and nephrosclerosis.
- ADPKD can also be a component of tuberous sclerosis.[2]
- In ADPKD, cysts are also found in other organs such as liver (**Figure 66-2**), spleen, pancreas, and ovaries; liver cysts are found in up to 80 percent of patients with ADPKD.[3] There is also an increased incidence of intracranial aneurysms (5% to 12%).

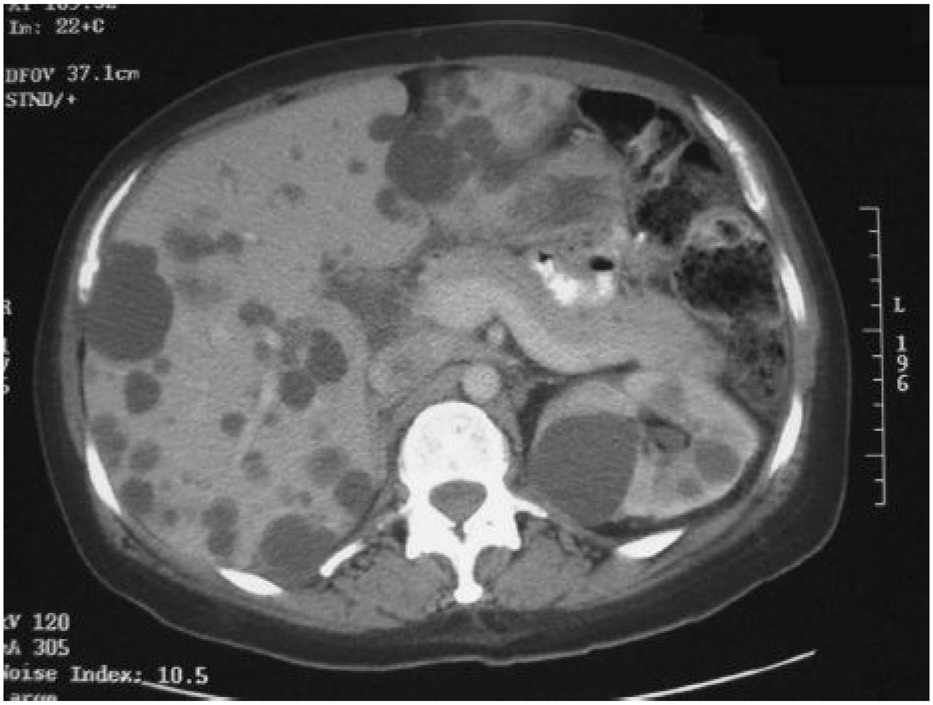

FIGURE 66-2 CT scan showing multiple liver cysts and multiple cysts in both kidneys in a patient with polycystic kidney disease. (*Used with permission from Vesselin Dimov, MD, Cleveland Clinic, ClinicalCases.org*.)

- ARPKD, previously thought to be the neonatal form of PKD, is caused by genetic mutations in PKHD1 (polycystic kidney hepatic disease 1). This gene encodes the protein, fibrocystin/polyductin, that is localized to cilia/basal body and complexes with PKD2. This large, receptor-like protein is thought to be involved in the tubulogenesis and/or maintenance of duct-lumen architecture of epithelium.
- ARPKD can be associated with pulmonary hypoplasia, generally as a result of the oligohydramnios (Potter's) sequence.[2]
- In one study of young patients (mean age 16 years) with ADPKD, serum log(10) vascular endothelial growth factor was negatively correlated with creatinine clearance indicating a possible role for angiogenesis in the early progression of renal disease in these patients.[6]
- Rare syndromic forms of PKD include defects of the eye, central nervous system, digits, and/or neural tube.[5]

- A variant of PKD is glomerulocystic kidney (GCK), which refers to a kidney with greater than 5 percent cystic glomeruli.[7] This condition is usually diagnosed in young patients. Although PKD-associated gene mutations have been excluded in many cases, there is a familial form of GCK presenting with cystic kidneys, hyperuricemia, and isosthenuria (concentration similar to plasma).[7]

DIAGNOSIS

Family history is a useful tool for diagnosing early ADPKD.

CLINICAL FEATURES

- ADPKD is usually asymptomatic in children, diagnosed incidentally on imaging studies done for other reasons.[2]
- Chronic flank pain as a result of the mass effect of enlarged kidneys.
- Acute pain with infection, obstruction, or hemorrhage into a cyst.
- Enlarged liver.
- Hypertension is common in adults (75%) and is present in 10 to 30 percent of children. Left ventricular hypertrophy can be seen in adolescents/young adults even before overt hypertension is present.[2]
- Mitral valve prolapse (MVP) occurs in up to 15 percent of children and adults with ADPKD.[2]
- Gross hematuria or urinary tract infection; the former can effect up to 40 percent of patients.[2] Because renal cysts can be disconnected from the urinary tract, infection can result in abscess; persistent fever and flank pain should raise suspicion even if the urine culture is negative.[2]
- Kidney stones (calcium oxalate and uric acid) develop in 15 to 20 percent of affected individuals because of urinary stasis from distortion of the collecting system, low urine pH, and low urinary citrate. Kidney stones

are uncommon in children, but have been reported in children as young as age 11 years.[8]

- Nocturia can also be present from impaired renal concentrating ability.
- In a Danish study, low birth weight was a risk factor for earlier onset of ESRD in patients with ADPKD as was male gender and increased mean arterial pressure.[9]
- Up to half the cases of ARPKD are diagnosed prenatally, usually with evidence of its sequelae (e.g., oligohydramnios, pulmonary hypoplasia).[2] Neonates and infants can present with palpable flank masses, hepatomegaly, hypertension, or respiratory distress due to pulmonary hypoplasia.[2]
- The diagnosis of children with ARPKD is clinical, based on the presence of enlarged, echogenic kidneys and one or more of the following: absence of renal cysts in both parents; history of a previously affected sibling; parental consanguinity; or clinical, laboratory, or pathologic features of hepatic fibrosis.[2]
- A small subset of patients with ARPKD present as older children or young adults with hepatic (portal hypertension, hepatomegaly) and/or renal disease.[2]
- In a case series of Brazilian patients with ARPKD (N = 25), median age at diagnosis was 61 months, half had arterial hypertension, 40 percent had urinary tract infections, almost 1/3 had portal hypertension, and about 1/4 had chronic kidney disease stage ≥2.[10]

LABORATORY TESTING

- Gross or microscopic hematuria (60% with ADPKD).[4] Obtain a urinalysis to document hematuria and a complete blood count or hemoglobin to identify anemia.
- Genetic testing is available for both disorders but is unnecessary in patients with a family history and typical appearance of bilateral renal cysts. Screening asymptomatic children with a family history of ADPKD is not recommended due to financial and psychosocial concerns and lack

of disease-specific treatment; annual monitoring of blood pressure and urine (hematuria, proteinuria) should be considered, with additional evaluation as needed.[2] In one retrospective study, renal outcomes were similar between children with ADPKD diagnosed by screening or presenting with symptoms.[11]

IMAGING

- Diagnosis is often made with ultrasound. More than 80 percent of patients with ADPKD have cysts present by age 20 years and 100 percent by age 30 years. In one study, the sensitivity of ultrasound in at-risk individuals younger than age 30 years was 70 to 95 percent, depending on the type of PKD present.[12] For younger patients or those with small cysts, CT scan (**Figures 66-1** and **66-2**) or MRI can be helpful. Authors of one case series found MRI satisfactory for following total kidney and cyst volume in children with ADPKD.[13]
- In the neonatal period, ultrasound of patients with ARPKD shows markedly enlarged echogenic kidneys, indicating the presence of numerous microscopic cysts not discernible by ultrasound (**Figure 66-3**).[2] Larger cysts, more typical of ADPKD, are usually absent in neonates.

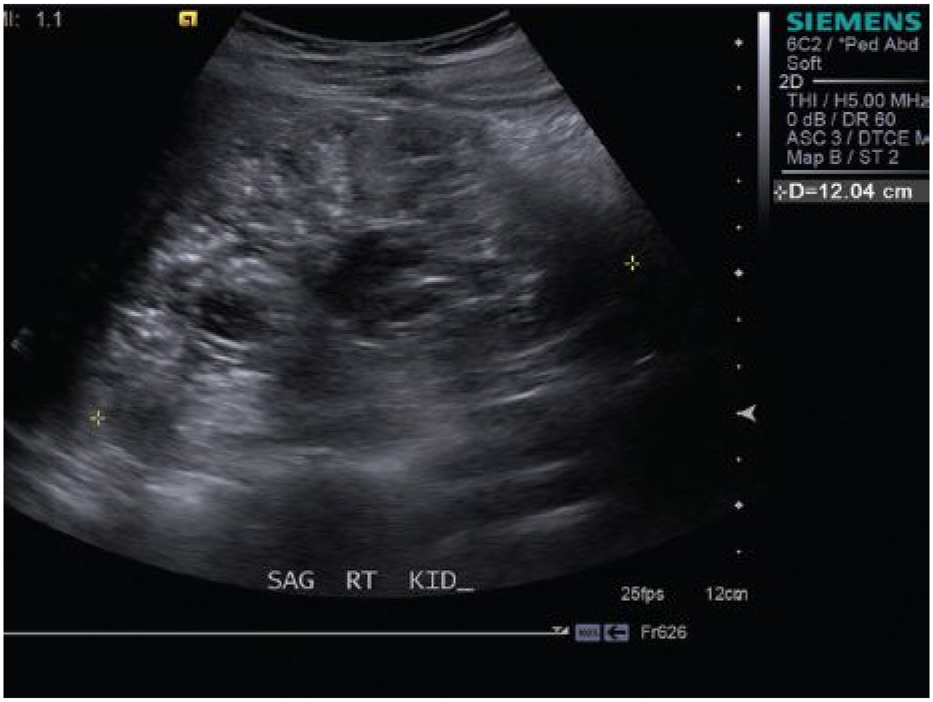

FIGURE 66-3 Autosomal-dominant polycystic kidney disease in an eight-year-old boy. Note the multiple bright echoes through both kidneys due to many interfaces of the numerous small cysts. (*Used with permission from Karl Rew, MD.*)

- Over time, the appearance of the kidneys in patients with ARPKD looks similar to ADPKD.[2]
- Children with ADPKD can have asymmetric involvement or even isolated unilateral cysts.[2] Because simple cysts are rare in children, the finding of a single cyst in a patient at-risk for ADPKD is considered diagnostic by some authors.
- If an infected cyst is suspected, positron emission tomography has been reported to be the optimal test.[14]
- In patients with ADPKD, cysts are commonly found in the liver (50% to 80%) (**Figure 66-2**), spleen, pancreas, and ovaries.
- Age-dependent ultrasound criteria have been established for both diagnosis and disease exclusion in subjects at risk of PKD1 (the more severe disorder),[15] but criteria for at-risk children have not been established.[2]
- Transient elastography can be useful in detecting liver fibrosis in cystic kidney diseases.[16]

DIFFERENTIAL DIAGNOSIS[2]

- Simple cyst—Diagnosed at any age; few cysts seen; benign features.
- Acquired cystic disease—Diagnosed in adulthood; few to many cysts; cyst development preceded by renal failure.
- Tuberous sclerosis—Diagnosed at any age; few to many renal angiomyolipomas; inherited nonmalignant tumors grow in the skin, brain/nervous system, kidneys, and heart.

MANAGEMENT

The current role of therapy in PKD is to slow the rate of progression of renal disease and minimize symptoms. However, specific treatments are on the horizon.

NONPHARMACOLOGIC

- Neither protein restriction nor tight blood pressure control decreased the decline in glomerular filtration rate (GFR) in clinical trials.[17,18] However, in a UK population study, increasing coverage (from 7% to 46% of the population prescribed an antihypertensive agent) showed a trend towards decreasing mortality, and increased intensity of antihypertensive therapy was associated with decreasing mortality in people with ADPKD.[19]
- Nutritional interventions in animal PKD studies shown to be beneficial are avoidance of caffeine, consumption of soy-based protein or flaxseed, and increased water consumption; none have been tested in human studies.[2]
- For episodes of gross hematuria, one author recommends bed rest, analgesics, and hydration sufficient to increase the urinary flow rate to 2 to 3 L/day; hematuria generally declines to microscopic levels in a few days.[4] SOR Ⓒ

MEDICATIONS

- Control blood pressure to reduce the risk of associated cardiovascular disease. SOR Ⓐ
- In one randomized controlled trial (RCT) (N = 46 patients with ADPKD and hypertension), no differences in renal function, urinary albumin excretion, or left ventricular mass index were detected between those treated with ramipril versus metoprolol, during 3 years of follow-up.[20] Renal function declined significantly in both groups. Angiotensin-

converting enzyme (ACE) inhibitors and angiotensin receptor blockers are the traditionally used agents for children with chronic kidney disease, including ADPKD and ARPKD, and hypertension but have not been tested in this population. SOR C Patients with ARPKD can require several medications to control hypertension.[2]

- There is an ongoing RCT of children and young adults with ADPKD already on an ACE inhibitor to assess the effect of pravastatin treatment on renal and cardiovascular disease progression.[21]
- Treat infection as early as possible. If pyocyst is suspected, agents that penetrate cysts such as trimethoprim-sulfamethoxazole and ciprofloxacin are used. SOR C
- Future therapies focus on exploiting signaling mechanisms underlying disease pathogenesis. Experimental and observational studies suggest that the mammalian target of rapamycin (mTOR) pathway plays a critical role in cyst growth.
- A 2-year RCT of the mTOR inhibitor everolimus for patients with ADPKD (N = 46) demonstrated a slowing of the increase in total kidney volume over placebo but not the progression of renal impairment.[22] An open-label trial (N = 100 patients with ADPKD and early chronic kidney disease) of the mTOR inhibitor sirolimus did not show slowing of kidney growth or improved function over standard care.[23]
- In a RCT of octreotide (a long-acting somatostatin analog) versus placebo for patients with polycystic liver disease (some of whom had ADPKD), patients with ADPKD randomized to octreotide had a stabilization of kidney volume (versus an increase in the control group) and all patients randomized to treatment showed a reduced liver volume; there was no difference between groups in GFR.[24]

SURGERY AND OTHER PROCEDURES

- Cyst puncture and a sclerosing agent (i.e., ethanol) can be used for painful cysts. SOR C Alternatives include decortication (unroofing of the cyst) or denervation.[2]

- For painful liver enlargement, partial hepatectomy can be performed, with good outcomes reported at experienced centers;[25] this is rarely a problem in children. SOR Ⓒ
- For patients with ESRD as a result of PKD, transplantation and dialysis are options.
- In a nationwide study of 15-year outcomes following renal transplantation (N = 534 patients with ADPKD and 4779 patients without ADPKD), patients with ADPKD had better graft survival and no difference in infections, but more thromboembolic complications, more metabolic complications, and increased incidence of hypertension.[26]
- Combined liver-kidney transplantation are also considered for patients with PKD and significant liver involvement.[2]

REFERRAL

- Patients with PKD with progressive renal failure and/or ESRD should be managed by a team of providers as they often require dialysis or kidney transplantation and can develop multiple complications; other considerations include anemia management, aneurysm screening pre-transplantation, and nephrectomy of the native ADPKD kidneys.[27] SOR Ⓒ
- Consider hospitalization for patients with PKD who develop acute pyelonephritis and symptomatic cyst infection.[4]

PROGNOSIS

- Approximately 50 percent of patients with ADPKD progress slowly to ESRD; kidney failure requiring renal-replacement therapy typically develops in the fourth to sixth decade of life.[26] Patients with ADPKD and ESRD seem to have more favorable outcomes compared to those with other causes of kidney failure.[28]

- The following are the characteristics that predict a faster rate of decline in GFR in persons with ADPKD:[29]
    - Greater serum creatinine (independent of GFR).
    - Greater urinary protein excretion.
    - Higher mean arterial pressure (MAP).
    - Young age.
    - Increased kidney volume (>1500 mL).[2]
    - Disease caused by PKD1 mutation.[2,30]
    - The presence of tubulointerstitial fibrosis.[31]
    - Urinary stones.[32]
- The vast majority of pediatric patients with ADPKD, however, have normal renal function throughout childhood.[2]
- ARPKD phenotype is highly variable ranging from causing neonatal death to causing minimal kidney disease presenting later in life.[5] Estimated mortality in the neonatal period is 30 percent; 10-year survival of children who survive the neonatal period is about 80 percent.[33] About one third progress to ESRD in the first decade of life and an additional 20 to 30 percent will progress during adolescence.[2] The renal survival rate is only 42 percent by adulthood.[2]
- In a small retrospective study of 14 patients aged 3 to 24 years with ARPKD who underwent renal transplantation with or without liver transplantation, first renal graft survival was 92 percent at 1 year but only 14 percent by 10 years post-transplantation. Mortality rate was 21 percent (3/14) and was directly related to infectious complications (recurrent angiocholitis) or severe dilatation of hepatic bile ducts.[34] Outcomes were better in another study of 15 combined liver kidney transplants performed in 14 pediatric patients (median age 8 years, of whom 7 had ARPKD).[35] Six patients had postoperative bleeding complications and three required operative revision for intra-abdominal bleeding. Half needed dialysis but 1- and 5-year patient survival was 100 percent and 1- and 5-year graft survival was 80 percent for the liver and 93 percent for the kidney allograft.

- Patients with ADPKD are more prone to kidney stones (Chapter 68, Kidney Stones)[36] and cerebral aneurysms (present in 10% to 12% of adults).[2]
- Neonates can develop respiratory distress, oliguria, fluid and electrolyte abnormalities and hypertension.[2] In the case series noted above of 25 children with ARPKD, after an average follow-up time of 152 months, arterial hypertension was detected in 76 percent of the cases (up from half), portal hypertension in 68 percent (up from 32%), CKD ≥2 in 44 percent (up from 24%), and UTI in 52 percent.[10]

FOLLOW-UP

- Monitor patient’s renal function and watch for hypertension and posttransplantation diabetes mellitus; imaging to assess the rate of increased kidney and total cyst volume can be useful in prognosis.[37]
- For all patients with PKD with renal dysfunction, review medications to adjust for level of kidney function and avoid nephrotoxic drugs if possible. SOR Ⓒ
- Management of metabolic derangements (e.g., hyperkalemia, metabolic acidosis, anemia, metabolic bone disease) is also needed, particularly in children with ARPKD.[2]
- Attention to feeding is important, particularly for neonates with ARPKD where feeding can be hampered by massively enlarged kidneys impinging on the stomach and creating early satiety and gastroesophageal reflux. Enteral feedings are often needed to ensure adequate calories and nephrectomy is sometimes considered.[2]
- UTIs are common in patients with ADPKD (30% to 50%) and ARPKD, although cyst infection and abscess is uncommon in those with ARPKD (for whom standard antimicrobials are usually adequate).[2] In one retrospective study of 256 patients with ADPKD, the annual incidence of asymptomatic pyuria was 0.492 episodes/patient/year and those with persistent asymptomatic pyuria experienced an upper UTI more

frequently (hazard ratio = 4.612; 95% confidence interval, 1.735 to 12.258 adjusted for gender and hypertension).[38]

- Children with ARPKD who survive the neonatal period but have congenital hepatic fibrosis (also called Caroli’s disease) should be monitored yearly by a hepatologist for complications associated with portal hypertension, including periodic endoscopy for esophageal varices and monitoring for cholangitis.[2] These children are also prone to splenomegaly causing anemia, thrombocytopenia, and leukopenia and are at increased risk of cholangiocarcinoma.[2]
- Posttransplantation, patients with ADPKD may be more prone to the development of diabetes mellitus (odds ratio 2.3; 95% confidence interval, 1.008 to 5.14).[28]
- In the absence of a family history of aneurysm, screening is not routinely recommended for asymptomatic patients; diagnostic testing should be considered in patients with ADPKD and new-onset or severe headache or other central nervous system symptoms or signs.[2]

PATIENT EDUCATION

- Explain the genetics (among patients with ADPKD disease will develop in half of their offspring) and prognosis to patients. Referral to a genetic counselor may be useful for patients considering childbearing. Preimplantation genetic screening for ARPKD is possible.[39]
- Hypertension is common and should be treated.
- Kidney dysfunction is also common and should be monitored.
- Avoid high-impact sports in which abdominal trauma may occur (e.g., boxing).[2]
- In otherwise healthy women with ADPKD, pregnancy is usually uncomplicated but the risks of severe hypertension and preeclampsia are higher than those in the general population when elevated blood pressure or renal insufficiency is present before conception.[40]

67 NEPHROTIC SYNDROME

Charles Y. Kwon, MD
Raed Bou Matar, MD
Halima S. Janjua, MD

PATIENT STORY

A 3-year-old boy has had intermittent facial swelling for the past 3 weeks. Symptoms were self-limited and attributed to seasonal allergies. He awoke with significant periorbital and facial edema (**Figure 67-1**), and pitting edema to his mid-tibia bilaterally. He denies any abdominal pain, headache, rash, or gross hematuria. His evaluation reveals a normal blood pressure, normal renal function, and 4+ protein on a urine dipstick. He was presumptively diagnosed with minimal change disease and started on a course of prednisone. His edema gradually subsided (**Figure 67-2**) and his proteinuria resolved within the first two weeks of therapy.

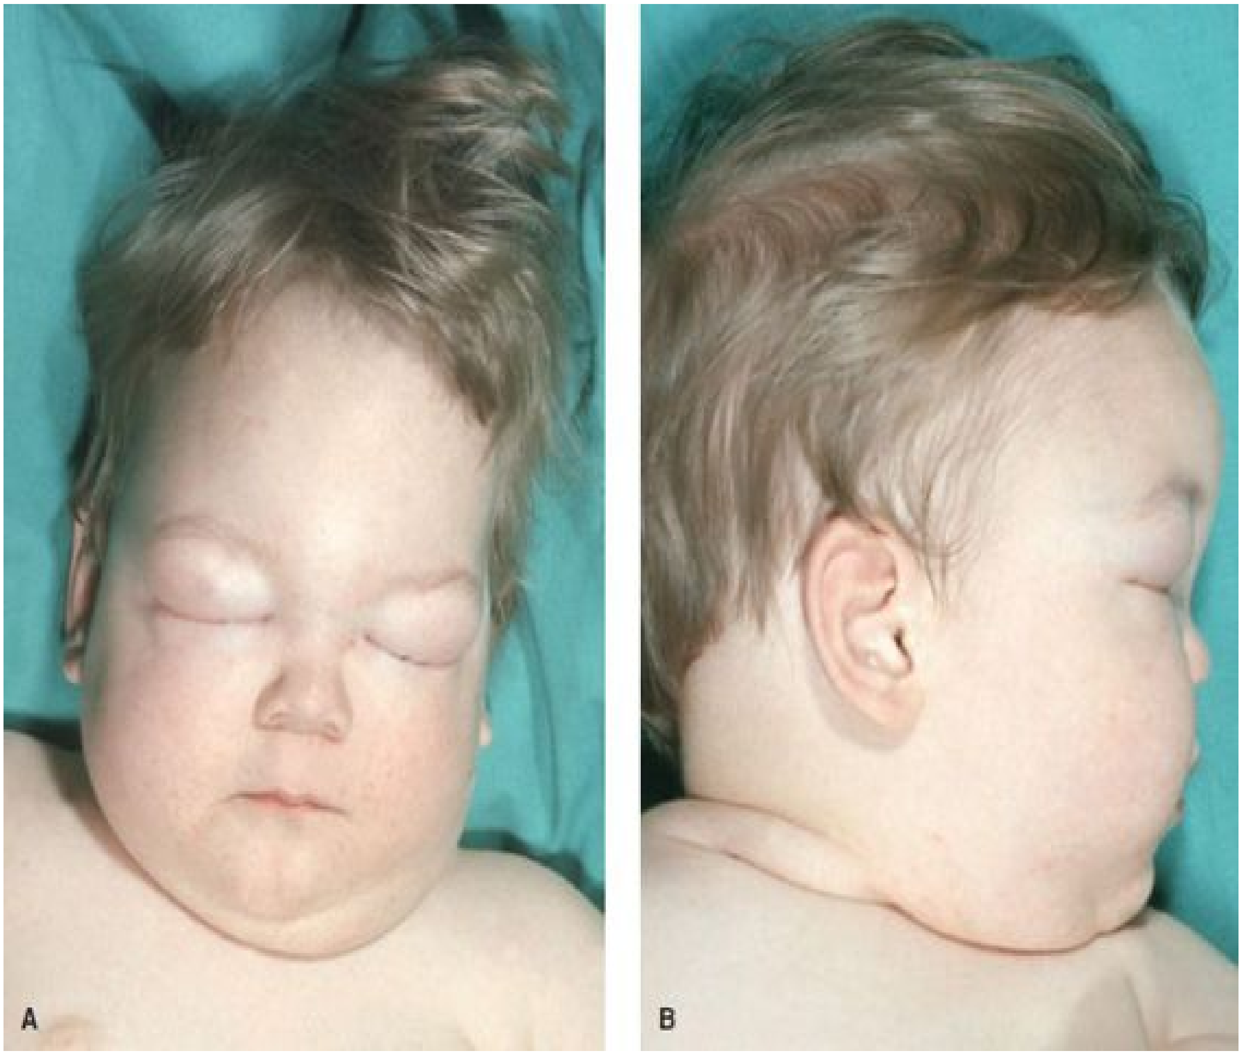

FIGURE 67-1 Significant facial edema on frontal (**A**) and lateral (**B**) views in a 3-year-old boy secondary to minimal change disease. (*Used with permission from Cleveland Clinic Children’s Hospital Photo Files*.)

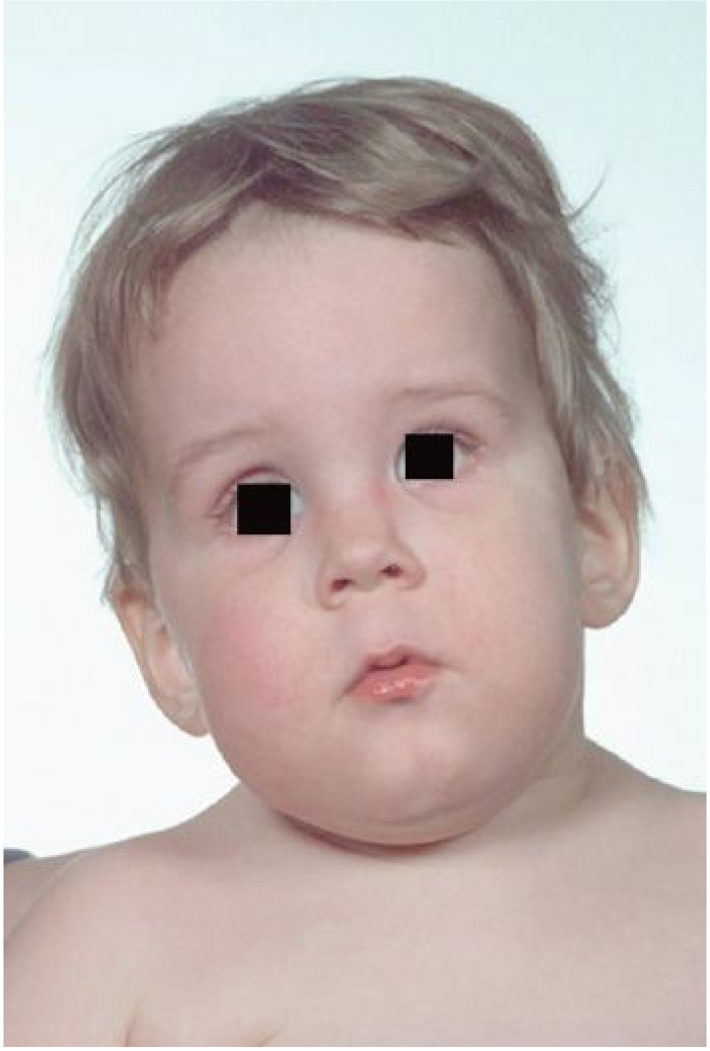

FIGURE 67-2 Resolution of facial edema in the same child from figure 67-1 following a course of prednisone. (*Used with permission from* Cleveland Clinic Children’s Hospital Photo Files)

INTRODUCTION

Nephrotic syndrome is a tetrad of signs and symptoms: proteinuria (>50 mg/kg/day), hypoalbuminemia (serum albumin <3 gm/dL), edema, and hyperlipidemia. Prognosis is largely dependent on the glomerular etiology of the proteinuria. Minimal change disease is by far the most common etiology of nephrotic syndrome in childhood and carries an excellent long-term renal prognosis.

SYNONYM

- Nephrosis.

EPIDEMIOLOGY

- Estimated incidence of minimal change disease is 5 per 100,000 children under the age of 16 with a median age of 2.5 years.
- Boys are more commonly affected.[1]
- Rare familial cases have been reported.

ETIOLOGY AND PATHOPHYSIOLOGY

- Nephrotic syndrome begins with a glomerular lesion, causing significant proteinuria. Protein losses result in hypoalbuminemia. This produces edema, typically facial, lower extremity, and genital. The etiology of the associated hyperlipidemia is not fully elucidated.
- Although minimal change disease is the most common cause of nephrotic syndrome, little is known about the disease etiology. The most common hypothesis involves an unidentified circulating factor.[2]

RISK FACTORS

- Most cases of minimal change disease are preceded by an acute illness, often an upper respiratory infection.

DIAGNOSIS

CLINICAL FEATURES

- Children typically present initially with edema (**Figures 67-1** and **67-3**).

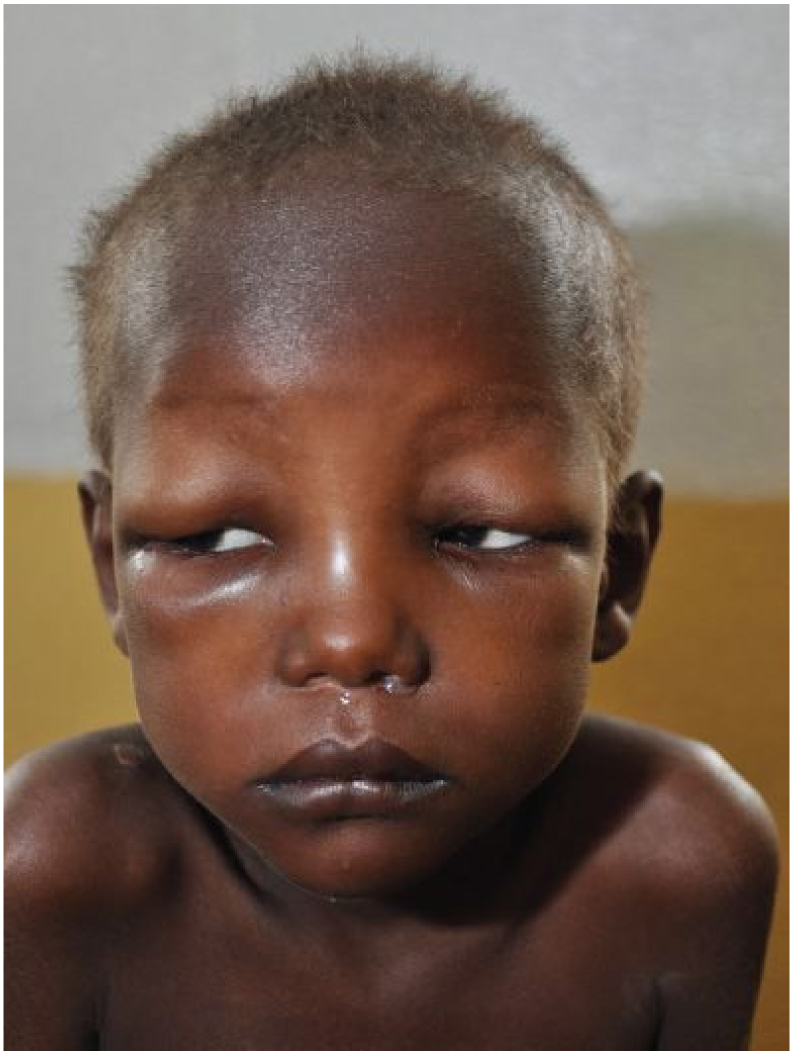

FIGURE 67-3 Young boy with nephrotic syndrome and malnutrition in Africa. Note the prominent periorbital edema from the low albumin due to

the combination of renal protein loss and malnutrition. The red hair is a sign of kwashiorkor. (*Used with permission from Richard P. Usatine, MD.*)

- Urinary symptoms are rare. Microscopic hematuria can be seen in up to 10 percent of children with nephrotic syndrome. Gross hematuria has also been rarely described with minimal change disease and is more indicative of glomerulonephritis.[5]

LABORATORY TESTING

- A urine dipstick will show significant proteinuria.
- Urine microscopy is often unremarkable. Occasionally, it will show fatty casts (acellular casts containing fat droplets).
- Serum tests show low serum albumin.
- Renal function (BUN/creatinine) is typically normal in minimal change disease.
- Abnormal kidney function can be attributed to pre-renal injury secondary to significant third-spacing and decreased intravascular volume. It may also indicate a different etiology, such as focal segmental glomerulosclerosis (FSGS) or glomerulonephritis.[2,3]
- Lipid studies are abnormal. LDL, total cholesterol, and triglycerides are elevated. HDL can be normal or low.[3]

IMAGING

- Renal ultrasonography is most often normal and not pursued in nephrotic syndrome unless a biopsy is planned.
- Chest x-ray may show pulmonary edema (**Figure 67-4**).

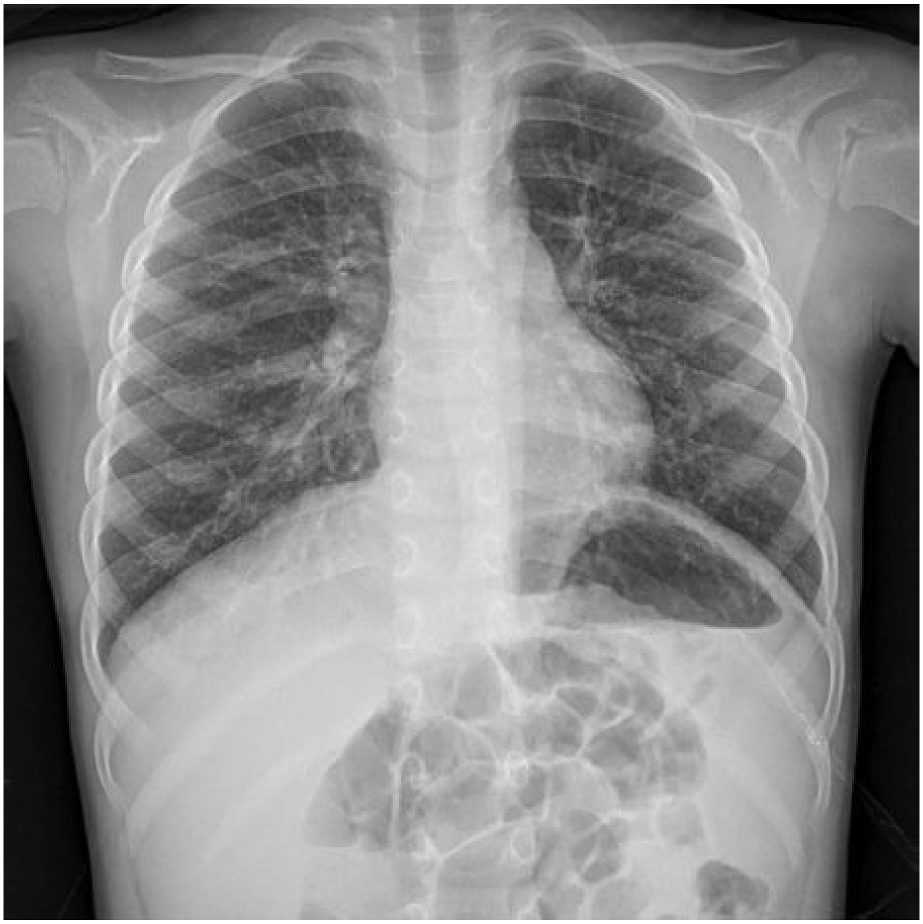

FIGURE 67-4 Mild pulmonary edema on chest x-ray of a 5-year-old girl with nephrotic syndrome. (*Used with permission from Camille Sabella, MD*.)

DIFFERENTIAL DIAGNOSIS

- Primary/Idiopathic.
  - Minimal change disease.[1]
    - Up to 90 percent of nephrotic patients between 1 to 10 years.
    - Can be seen in all ages but likelihood decreases with age.
  - Focal segmental glomerulosclerosis—To be considered when renal function is not normal. Steroid resistant. Diagnosis made histologically (**Figure 67-5**).

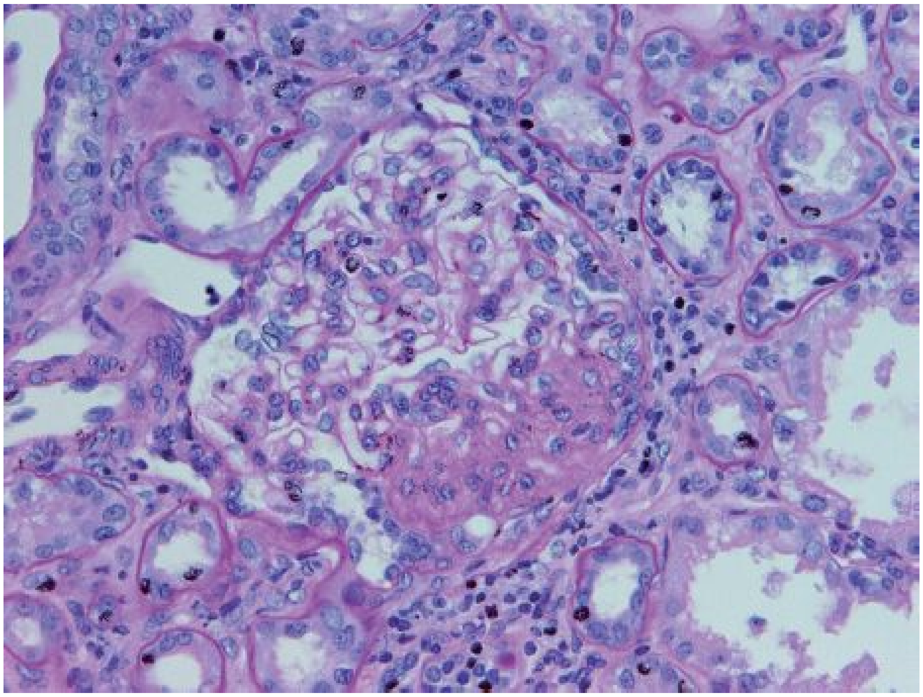

FIGURE 67-5 Focal segmental glomerulosclerosis seen on light microscopy. Note the collapsed and sclerotic tuft seen in the visualized glomerulus. (*Used with permission from Kemp, Burns, Brown, Pathology: The Big Picture. Figure 16-2. www.accessmedicine.com.McGraw-Hill*).

- Secondary.
  - Most glomerulonephritic disorders can have associated nephrotic syndrome.
    - IgA nephropathy.
    - Post-streptococcal glomerulonephritis.
    - Systemic lupus erythematosus.
  - Infection can have associated nephrosis.
    - Hepatitis B and C.
    - HIV.
    - Syphilis.
  - Malignancy—Very rare cause of nephrotic syndrome.
- Congenital nephrotic syndrome.[6]
  - Should be considered in all patients under 1 year of age.
  - Etiology most often is a genetic defect leading to absence of a structural protein important in podocyte function.

MANAGEMENT

SUPPORTIVE

- Sodium restriction is critical to limit edema. Fluid restriction plays a comparatively minor role and is typically not aggressively pursued except in patients who are hyponatremic.
- Diuretics should be used with caution in children due to a high risk of intravascular volume depletion.
- Diuretics with albumin can effectively remove fluid but the effect is transient.[4]
- Close monitoring for complications, such as spontaneous peritonitis and thrombotic disease, is important.

MEDICATIONS

- Prednisone is the first line therapy for children with presumed minimal change disease.
- Response to prednisone closely correlates with long-term outcome.[3,7] SOR A
    - Steroid-responsive—Patients who respond and are successfully weaned off steroids. High likelihood of long-term remission.
    - Steroid-dependent—Patients who respond but cannot be fully weaned off steroids. Typically require alternative immunosuppression to maintain long-term remission.
    - Steroid-resistant—No response to steroids. Remission is difficult to achieve and risk of eventual chronic kidney disease is high.
- Patients with congenital nephrotic syndrome do not respond to immunosuppression.

SURGERY

- Renal biopsy (most often percutaneous) is considered in patients who are steroid-resistant or who present with evidence of glomerular injury (abnormal kidney function, hypertension, or cellular casts). SOR Ⓒ

REFERRAL

- Patients with nephrotic syndrome should be referred to a specialist with expertise in management of pediatric renal disorders.

SCREENING

- There is no indication for routine urinalysis screening in children. Diagnosis of nephrotic syndrome before the onset of edema does not alter patient outcomes.

FOLLOW-UP

- Patients who are steroid-responsive have >50 percent risk of relapse during their first year post-diagnosis. Relapses are typically triggered by acute illnesses. While these relapses typically do require additional steroids, the occurrence of a relapse does not alter the patients’ favorable long-term prognosis.[7]
- Follow-up for potential complications of nephrotic syndrome, such as primary peritonitis and thrombotic disease, is important.

68 NEPHRITIC SYNDROMES

Raed Bou Matar, MD
Charles Y. Kwon, MD
Halima S. Janjua, MD

PATIENT STORY

An 8-year-old girl presents to the emergency room with severe headache and tea-colored urine of 2 days duration (**Figure 68-1**). She has just completed a 10-day course of amoxicillin for streptococcal pharyngitis. Her blood pressure upon arrival is 132/88. She is diagnosed with probable post-streptococcal glomerulonephritis and treated with salt restriction and a diuretic, and recovers.

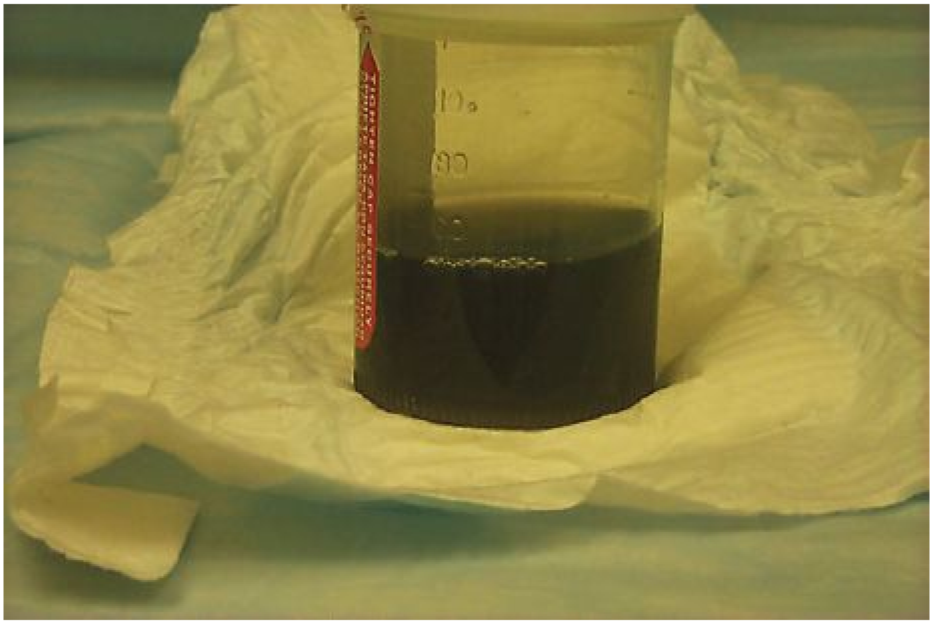

FIGURE 68-1 Tea-colored urine suggestive of glomerular gross hematuria. (*Used with permission from Rudolph's Pediatrics, 22nd edition, eFigure 467.1, McGraw-Hill.*)

INTRODUCTION

Nephritic syndrome is characterized by gross hematuria, acute kidney injury and retention of salt and water (manifested as hypertension with/without edema).

SYNONYMS

Acute glomerulonephritis, acute nephritis.

EPIDEMIOLOGY

- Peak incidence is between the age of 5 and 12 years.
- Post-streptococcal glomerulonephritis is uncommon in children less than 3 years of age.
- Incidence ranges from 9.5 to 28.5 per 100,000.[1]
- Post-streptococcal glomerulonephritis is far more common in the developing countries.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Post-streptococcal glomerulonephritis is the most common cause of nephritic syndrome in children. It follows a pharyngeal or skin infection involving a nephritogenic strain of group A beta-hemolytic streptococci.
- Streptococcal antigens form immune complexes that activate a complement mediated cascade of inflammatory glomerular injury.[2]

- Less common etiologies for nephritic syndrome include: membranoproliferative glomerulonephritis, lupus nephritis, IgA nephropathy, Henoch-Schonlein purpura, infectious glomerulonephritis (commonly associated with endocarditis), and post-infectious glomerulonephritis due to other bacterial, viral, or parasitic etiologies.
- Rapidly progressive glomerulonephritis is a syndrome characterized by rapid loss of renal function (over a period of days to weeks) and the presence of glomerular crescents on renal biopsy (**Figure 68-2**). It represents the most severe presentation of any form of acute nephritis.[3]

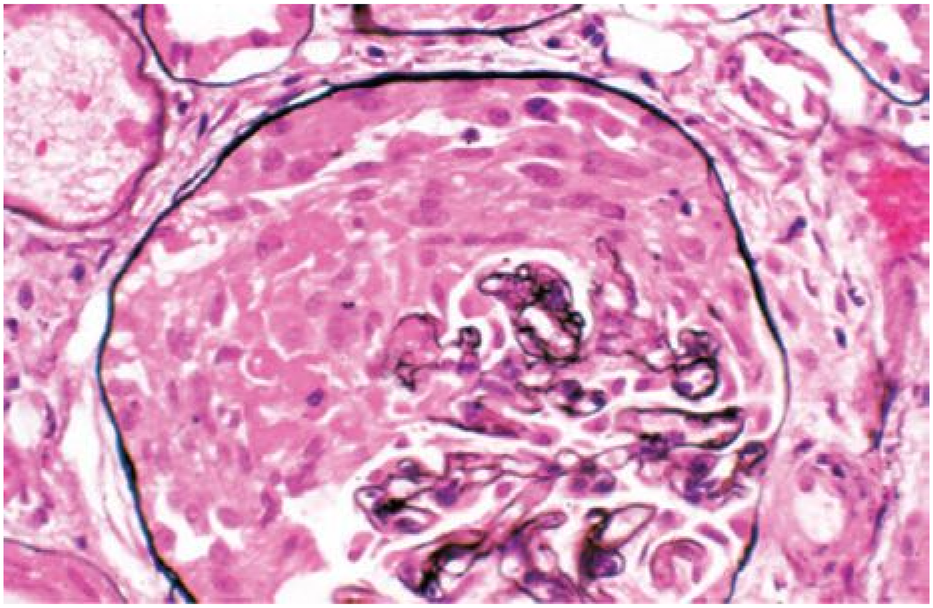

FIGURE 68-2 Cellular crescents. (*Used with permission from Harrison's Principles of Internal Medicine, 18th edition, Fig e14-14A, McGraw-Hill*).

DIAGNOSIS

CLINICAL FEATURES

- Nephritic syndrome classically presents with an abrupt onset of gross hematuria (tea-colored urine; **Figure 68-1**), oliguria, elevated blood pressure, and/or generalized edema.

- Onset of gross hematuria is 1 to 2 weeks following streptococcal pharyngitis and 3 to 6 weeks following streptococcal skin infection. In contrast, gross hematuria associated with IgA nephropathy commonly occurs concurrently with an upper respiratory infection.
- Mild (subclinical) cases of nephritis may be reflected by microscopic hematuria detected on urinalysis.[4]

LABORATORY TESTING

- Acute kidney injury is often present, manifested by variable elevation in serum creatinine.
- Urinalysis shows microscopic hematuria. Red blood cell casts confirm the glomerular origin of hematuria (**Figure 68-3**).

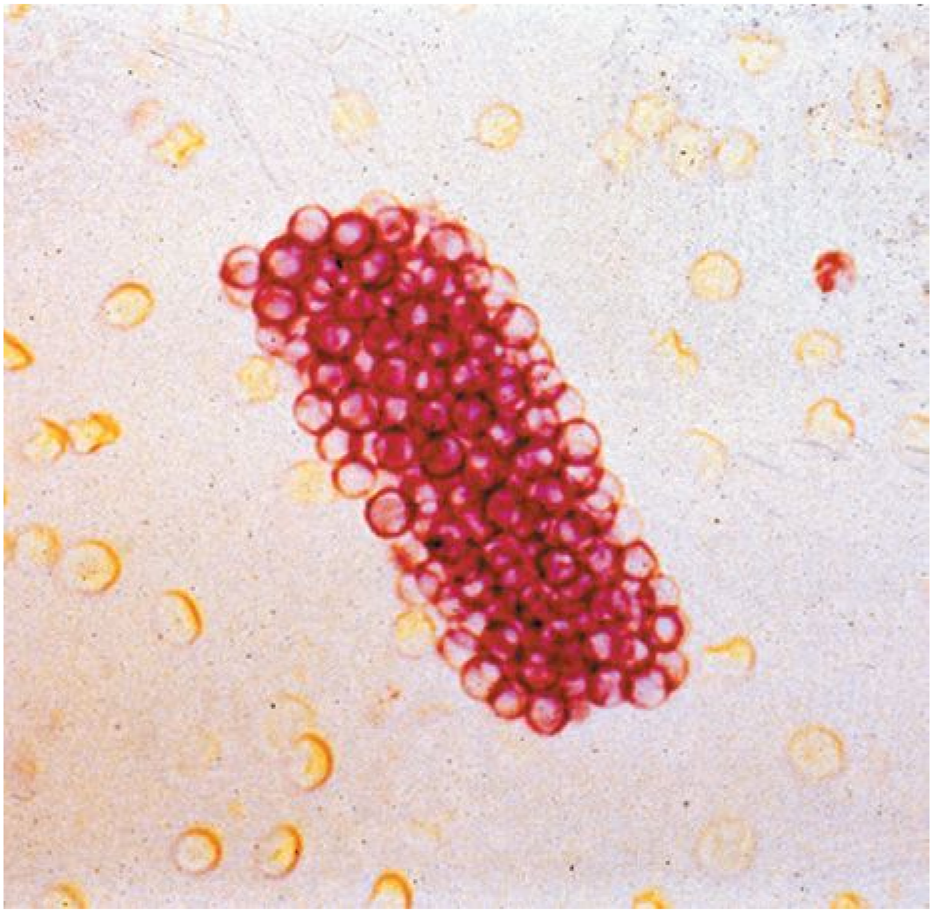

FIGURE 68-3 Red blood cell cast. (*Used with permission from Agnes B. Fogo, MD.*)

- Proteinuria may be present, but is usually low grade.
- Complement levels vary by etiology:
  - Transiently low C3 (for up to 8 weeks) with normal C4: post-streptococcal glomerulonephritis.
  - Chronically low C3—Membranoproliferative glomerulonephritis.
  - Low C3 and C4—Lupus nephritis.
  - Normal C3 and C4—IgA nephropathy or Henoch Schonlein purpura.
- Serology.
  - Streptozyme test measures five different streptococcal antibodies. It is highly sensitive for detecting evidence for a recent group A streptococcal infection.[5]
  - Positive ANA, anti-double stranded DNA, and/or anti-Smith antibodies suggest lupus nephritis.

RENAL BIOPSY

The diagnosis of post-streptococcal glomerulonephritis is typically based on clinical and laboratory findings. A renal biopsy is only indicated in atypical presentations or when an alternative etiology is suspected.

Characteristic histologic findings in post-streptococcal glomerulonephritis include diffuse (involving all glomeruli) cellular proliferation on light microscopy (**Figure 68-4**), coarse granular pattern of IgG & C3 deposits on immunofluorescence (**Figure 68-5**), and sub-epithelial hump-like immune deposits on electron microscopy (**Figure 68-6**). Presence of glomerular crescents (**Figure 68-2**) indicates rapidly progressive glomerulonephritis.

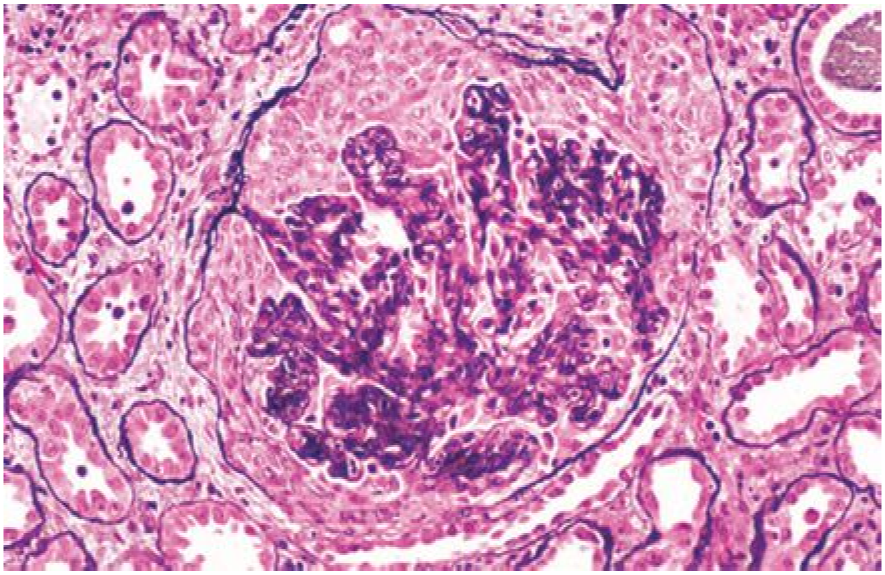

FIGURE 68-4 Post-streptococcal glomerulonephritis. Glomeruli show proliferative changes with an inflammatory infiltrate on light microscopy. (*Used with permission from Harrison's Principles of Internal Medicine, 18th edition, Fig e14-6A, McGraw-Hill*.)

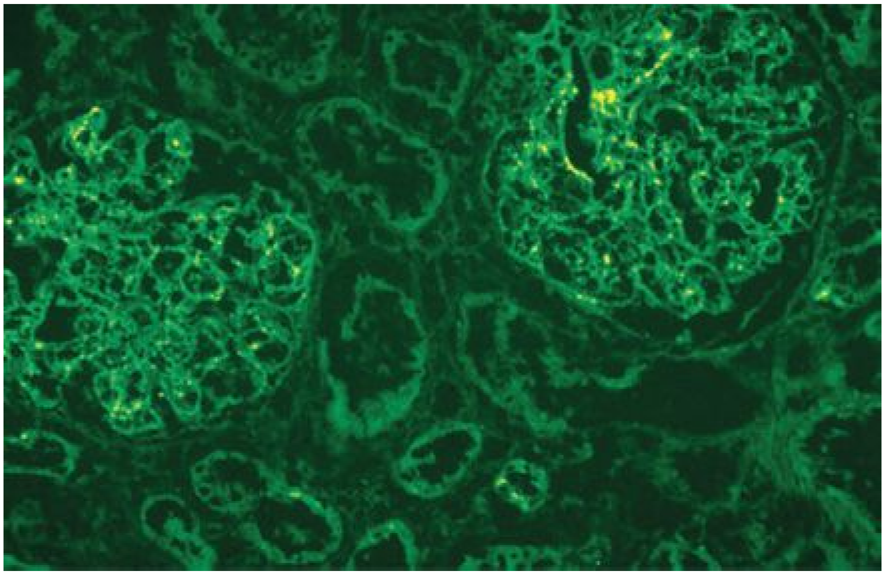

FIGURE 68-5 Post-streptococcal glomerulonephritis. Immunofluorescence shows C3 and IgG deposits localized to the mesangium and along the capillary walls. (*Used with permission from Harrison's Principles of Internal Medicine, 18th edition, Fig e14-6B, McGraw-Hill*.)

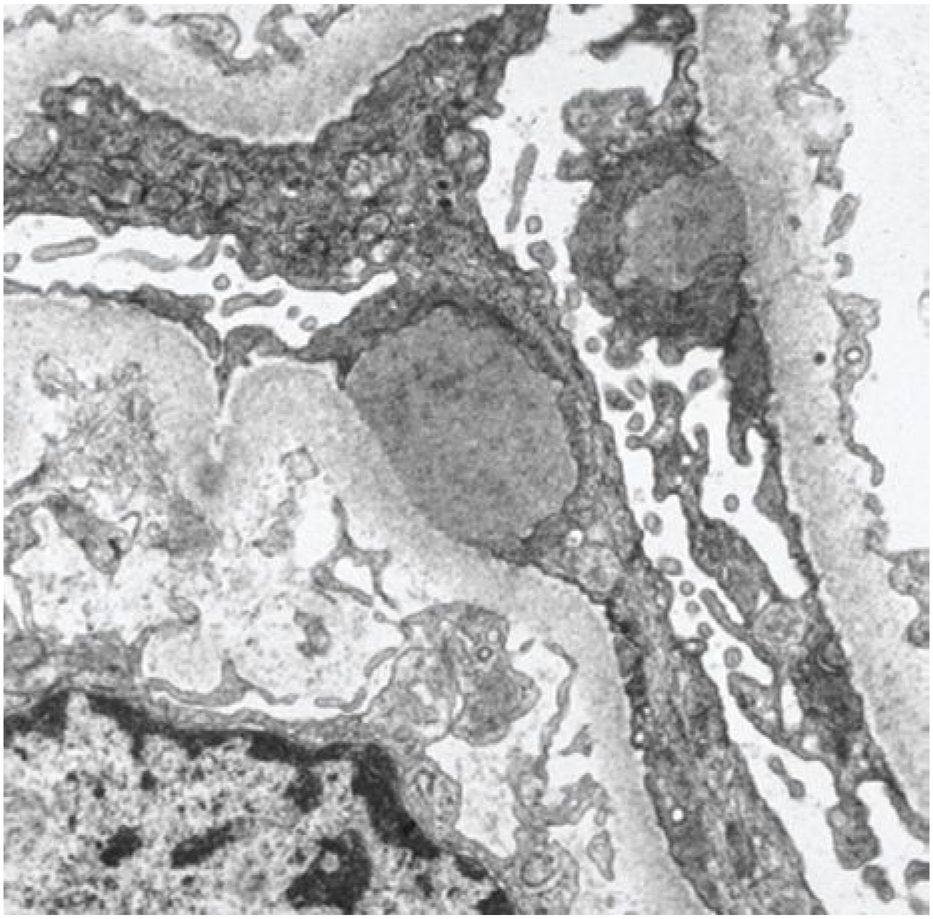

FIGURE 68-6 Post-streptococcal glomerulonephritis. Electron microscopy reveals the typical sub-epithelial hump-like immune deposits. (*Used with permission from Harrison's Principles of Internal Medicine, 18th edition, Fig e14-6C, McGraw-Hill.*)

DIFFERENTIAL DIAGNOSIS

- Membranoproliferative glomerulonephritis (**Figure 68-7**): may be undistinguishable from post-streptococcal glomerulonephritis at disease onset. However, complement C3 levels remain persistently low beyond 8 weeks following the disease onset, indicating chronic immune complex deposition.

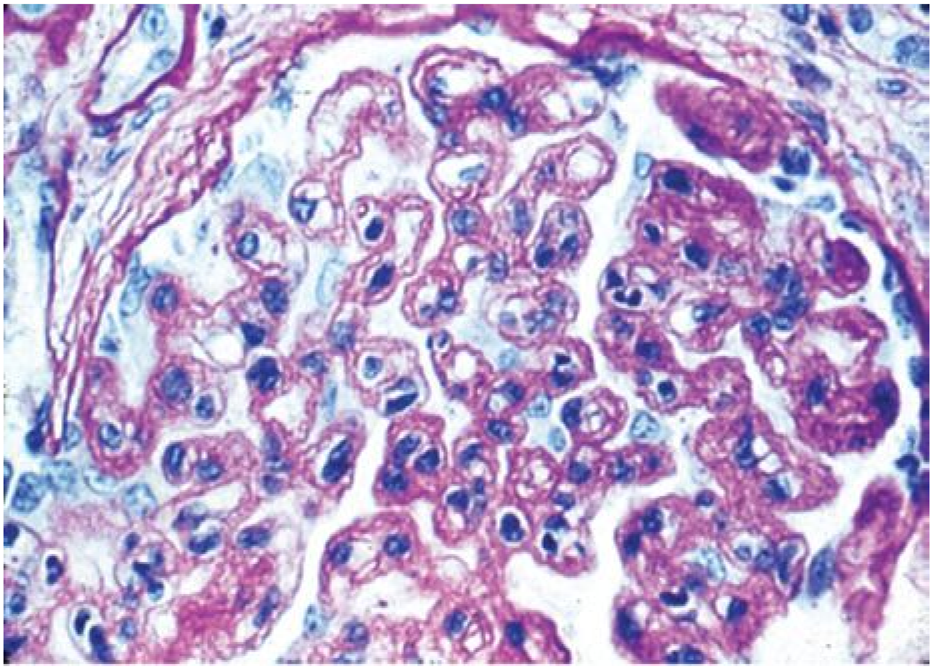

FIGURE 68-7 Membranoproliferative glomerulonephritis. Light microscopy shows mesangial expansion and endocapillary proliferation resulting in the typical “tram-track” duplication of glomerular basement membrane. (*Used with permission from Harrison’s Principles of Internal Medicine, 18th edition, Fig e14-9, McGraw-Hill*.)

- Lupus nephritis—Distinguished by the systemic manifestations and the persistently low complement C3 and C4. Positive anti double stranded DNA antibodies and/or anti Smith antibodies confirms the diagnosis. Renal biopsy reveals glomerular deposition of immunoglobulins, C3 and C1q (Full house immunofluorescence).
- IgA nephropathy—Gross hematuria tends to occur concurrently with upper respiratory infections (In contrast, post-streptococcal glomerulonephritis presents following a 1- to 2-week latency period.) Complement levels are normal. Renal biopsy shows prominent mesangial deposition of IgA on immunofluorescence.
- Henoch-Schönlein purpura: characterized by a palpable purpuric rash commonly involving the lower extremities and buttocks. Complement levels are normal.

MANAGEMENT

Post-streptococcal glomerulonephritis is generally self-limited. There is no known specific treatment and the management is generally supportive.

NONPHARMACOLOGIC

- Dietary salt restriction may attenuate hypertension and generalized swelling. SOR Ⓒ

MEDICATIONS

- Diuretics effectively offset hypertension and salt retention during the acute illness. SOR Ⓒ
- Calcium channel blockers or vasodilators may be used for severe hypertension. SOR Ⓒ
- Dialysis may be needed for electrolyte disturbances (like hyperkalemia), volume overload, or uremia. SOR Ⓒ
- High dose steroids may improve outcome in rapidly progressive glomerulonephritis.[6] SOR Ⓒ

REFERRAL

Patients with acute nephritis and significant hypertension or renal dysfunction should be referred to a specialist with expertise in management of renal disorders.

PREVENTION AND SCREENING

Antibiotic therapy has not been shown to decrease the risk of post-streptococcal glomerulonephritis, but may prevent the spread of nephritogenic group A streptococcal strains to other individuals.

PROGNOSIS

- Most children with post-streptococcal glomerulonephritis have an excellent prognosis with complete or near complete recovery from their disease.
- Children with rapidly progressive glomerulonephritis frequently progress to end-stage renal disease.[3]
- The prognosis of other forms of nephritis varies according to the nature and severity of the underlying etiology.

69 HEMOLYTIC UREMIC SYNDROME

Kshama Daphtary, MBBS, MD, FAAP

PATIENT STORY

A 4-year-old boy presents to his pediatrician because of swelling over the face, malaise, fatigue, and decreased appetite. On further questioning, his parents state that he appears pale and has reduced urine output. He recently finished a course of antibiotics for bloody diarrhea. On exam, he is found to be hypertensive and pale and has anasarca. Initial laboratory studies show a hemoglobin of 7 g/dL, platelet count of 44,000/mm^3, blood urea nitrogen of 39 mg/dL and creatinine of 2.9 mg/dL. Peripheral smear shows the presence of schistocytes and a paucity of platelets (**Figures 69-1** and **69-2**). He is admitted to the pediatric intensive care unit for hemolytic uremic syndrome. He is treated conservatively with close attention to fluid intake and output, restriction of sodium and fluid intake, and antihypertensive medications as needed. A stool culture obtained at the onset of his bloody diarrhea grows Escherichia coli and is identified as serotype O157:H7. Hemoglobin declines to 5.2 g/dL for which he is transfused packed red blood cells. Platelet count decreases over the next few days and then improves. He has no evidence of bleeding. Azotemia and oliguria improve over a week, appetite improves and anasarca resolves. He is discharged home with an excellent prognosis for full recovery.

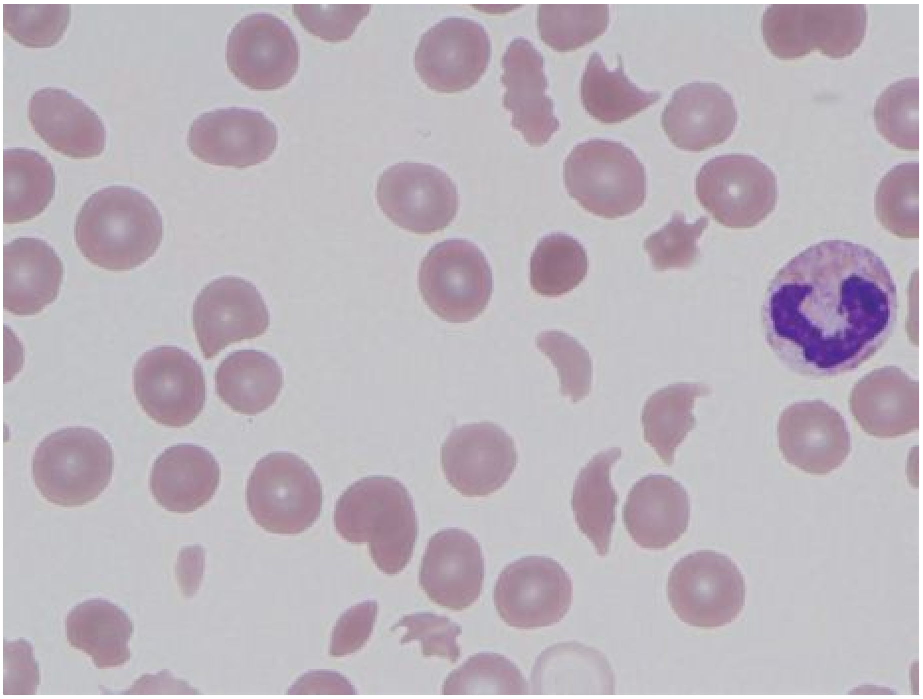

FIGURE 69-1 Schistocytes (fragmented "helmet" cells) and paucity of platelets, characteristic features of hemolytic uremic syndrome on blood peripheral smear, high magnification. (*Used with permission from Megan Nakashima, MD.*)

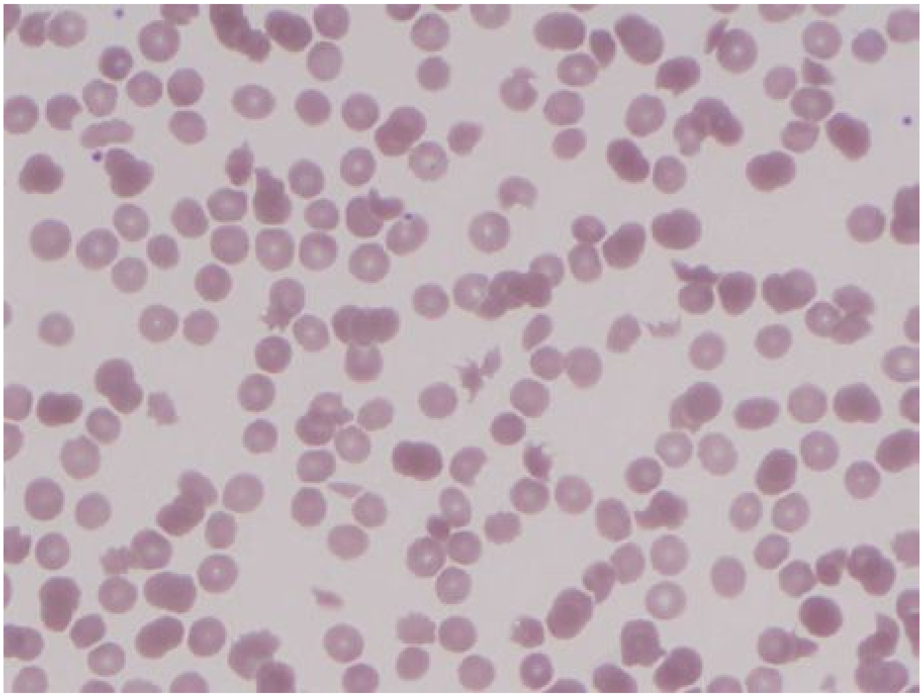

FIGURE 69-2 Schistocytes (fragmented “helmet” cells) and paucity of platelets, characteristic features of hemolytic uremic syndrome on blood peripheral smear, low magnification. (*Used with permission from Megan Nakashima, MD.*)

INTRODUCTION

The hemolytic uremic syndrome (HUS) was first described in 1955 by Gasser et al.[1] HUS is a thrombotic microangiopathy characterized by a triad of hemolytic anemia, thrombocytopenia and acute kidney injury.

SYNONYMS

- Typical HUS is also known as D(+) HUS, Shiga toxin-producing *Escherichia* coli (STEC) HUS, verocytotoxin producing *Escherichia* coli (VTEC) HUS, or Shiga-like toxin associated (Stx) HUS.
- Atypical HUS is also referred to as D(−) HUS and non-Shiga-like toxin associated (non-Stx) HUS.

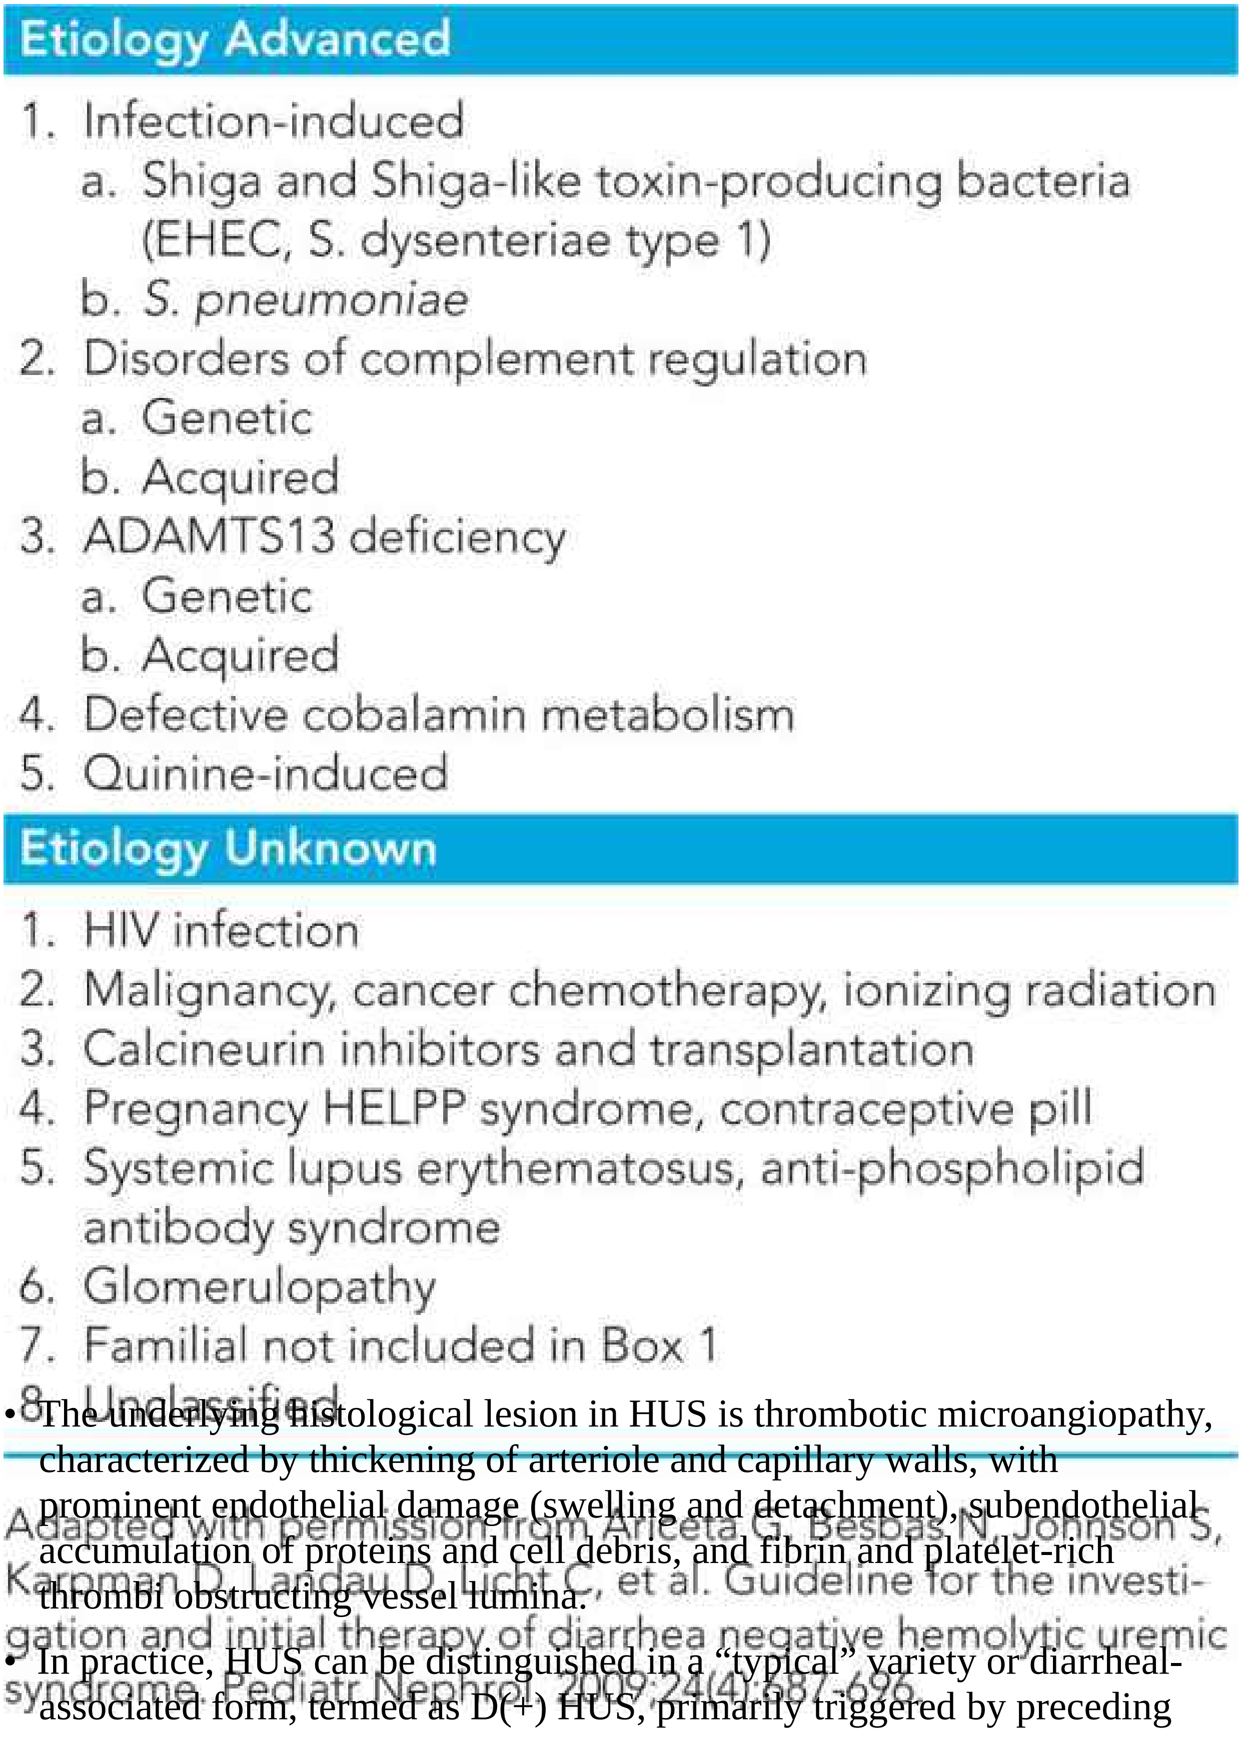
EPIDEMIOLOGY

- It is the most common cause of renal failure in childhood.[2]
- Worldwide, the incidence is 0.2 to 4 cases per 100,000 per year.[3]
- It is more common in children under 5 years with an incidence of approximately 6 cases per 100,000 per year.[4]
- There is also a geographical variation, with the highest incidence reported in Argentina.[5]

ETIOLOGY AND PATHOPHYSIOLOGY

- In 2006, the European Study Group for HUS proposed a classification for HUS, thrombotic thrombocytopenic purpura (TTP) and related disorders, which is summarized in **Table 69-1**.[6]

TABLE 69-1 Classification of HUS, TTP and Related Disorders



Etiology Advanced

1. Infection-induced
   - a. Shiga and Shiga-like toxin-producing bacteria (EHEC, S. dysenteriae type 1)
   - b. *S. pneumoniae*
2. Disorders of complement regulation
   - a. Genetic
   - b. Acquired
3. ADAMTS13 deficiency
   - a. Genetic
   - b. Acquired
4. Defective cobalamin metabolism
5. Quinine-induced

Etiology Unknown

1. HIV infection
2. Malignancy, cancer chemotherapy, ionizing radiation
3. Calcineurin inhibitors and transplantation
4. Pregnancy HELPP syndrome, contraceptive pill
5. Systemic lupus erythematosus, anti-phospholipid antibody syndrome
6. Glomerulopathy
7. Familial not included in Box 1
8. Unclassified

Adapted with permission from Ariceta G, Besbas N, Johnson S, Karpman D, Landau D, Licht C, et al. Guideline for the investigation and initial therapy of diarrhea negative hemolytic uremic syndrome. Pediatr Nephrol. 2009;24(4):687-696.

- The underlying histological lesion in HUS is thrombotic microangiopathy, characterized by thickening of arteriole and capillary walls, with prominent endothelial damage (swelling and detachment), subendothelial accumulation of proteins and cell debris, and fibrin and platelet-rich thrombi obstructing vessel lumina.
- In practice, HUS can be distinguished in a “typical” variety or diarrheal-associated form, termed as D(+) HUS, primarily triggered by preceding

diarrheal illness with Shiga toxin-producing *Ecoli*, mostly serotype O157:H7. This form accounts for 90 percent of all cases of HUS.[7]

- Ten percent of cases of HUS fall into the "atypical" category known as atypical HUS or D(−) HUS. It occurs in a familial as well as in a sporadic form.
- Atypical HUS (aHUS) is a heterogeneous group of disorders caused by defective complement regulation in the majority of cases.[7,8] Mutations have been identified in genes encoding the regulatory proteins of the complement alternative pathway, complement factor H (CFH), membrane cofactor protein (MCP or CD46), complement factor I (CFI) and complement factor H-related proteins (CFHR) as well as complement activators, complement factor B (CFB) and C3 as well as thrombomodulin (THBD). Inhibitory autoantibodies to CFH account for an additional 5 to 10 percent of cases and can occur in isolation or in association with these mutations.[7]
- Atypical HUS has an equal incidence in boys and girls.[9] Seventy percent of children have the first episode before the age of 2 years and approximately 25 percent before the age of 6 months.[9]
- In contrast, less than 5 percent of D(+) HUS occurs in children below the age of 6 months.[9]

RISK FACTORS

- Only 10 to 15 percent of children who are infected with *E coli* O157:H7 develop HUS.[10,11]
- Higher initial leukocyte counts, vomiting, and use of antibiotics are associated with subsequent development of HUS.[11]
- About 80 percent of cases of aHUS are also triggered by infections, either upper respiratory tract infections or gastroenteritis.[9] Other triggers reported are varicella, H1N1 influenza and, interestingly, Shigatoxin associated diarrheal illness.[9]

DIAGNOSIS

CLINICAL FEATURES

- Patients with D(+) HUS develop diarrhea about 2 to 5 days after contracting a Shiga toxin-producing bacterial infection.[4] The diarrhea is often profuse and bloody. Depending on the virulence of the strain, 10 to 15 percent (25% in the German outbreak of 2011 with *E coli* O104:H4) of cases present with features of HUS 3 to 8 days later.[12]
- Onset is generally sudden and symptoms consist of pallor (**Figure 69-3**), poor feeding, vomiting, fatigue, drowsiness, and sometimes generalized edema. Often, there is oliguria or anuria, hypertension, and signs of fluid overload and anemia.

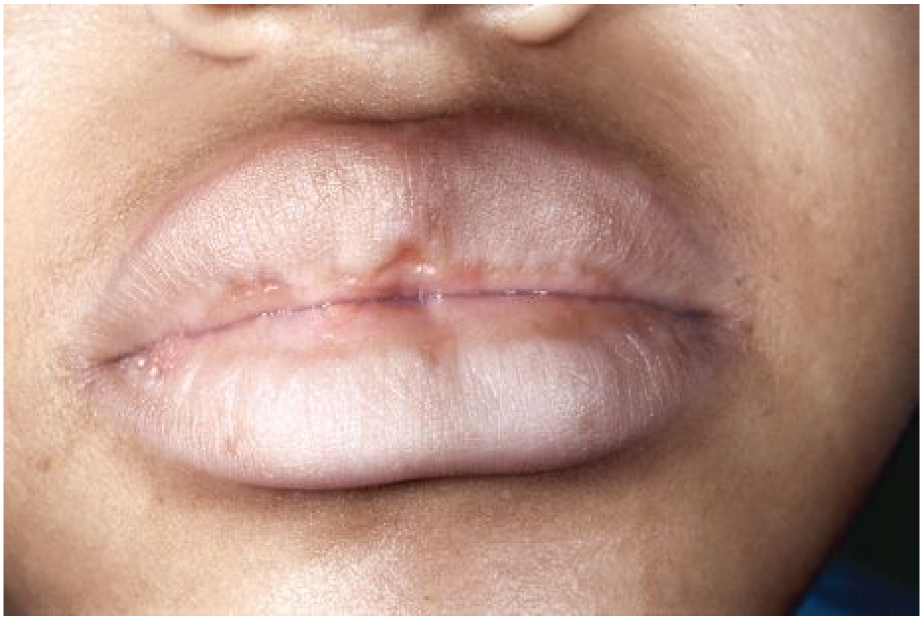


FIGURE 69-3 Lip pallor evident in this adolescent with hemolytic uremic syndrome and a hemoglobin of 5 g/dL. (*Used with permission from Binita R. Shah, MD, www.accessemergencymedicine.com*.)

- Three to forty-one percent of cases of aHUS develop signs of central nervous system involvement including irritability, altered level of consciousness, and seizures, which usually develop after the onset of HUS.[12]

- Atypical HUS is usually recognized after the diagnosis of HUS is made. Atypical HUS should be considered if the presentation is before 6 months of age, onset is insidious, and there is a history of previous episode of HUS, previous unexplained anemia, asynchronous family history of HUS or HUS following transplantation of any organ.[8]

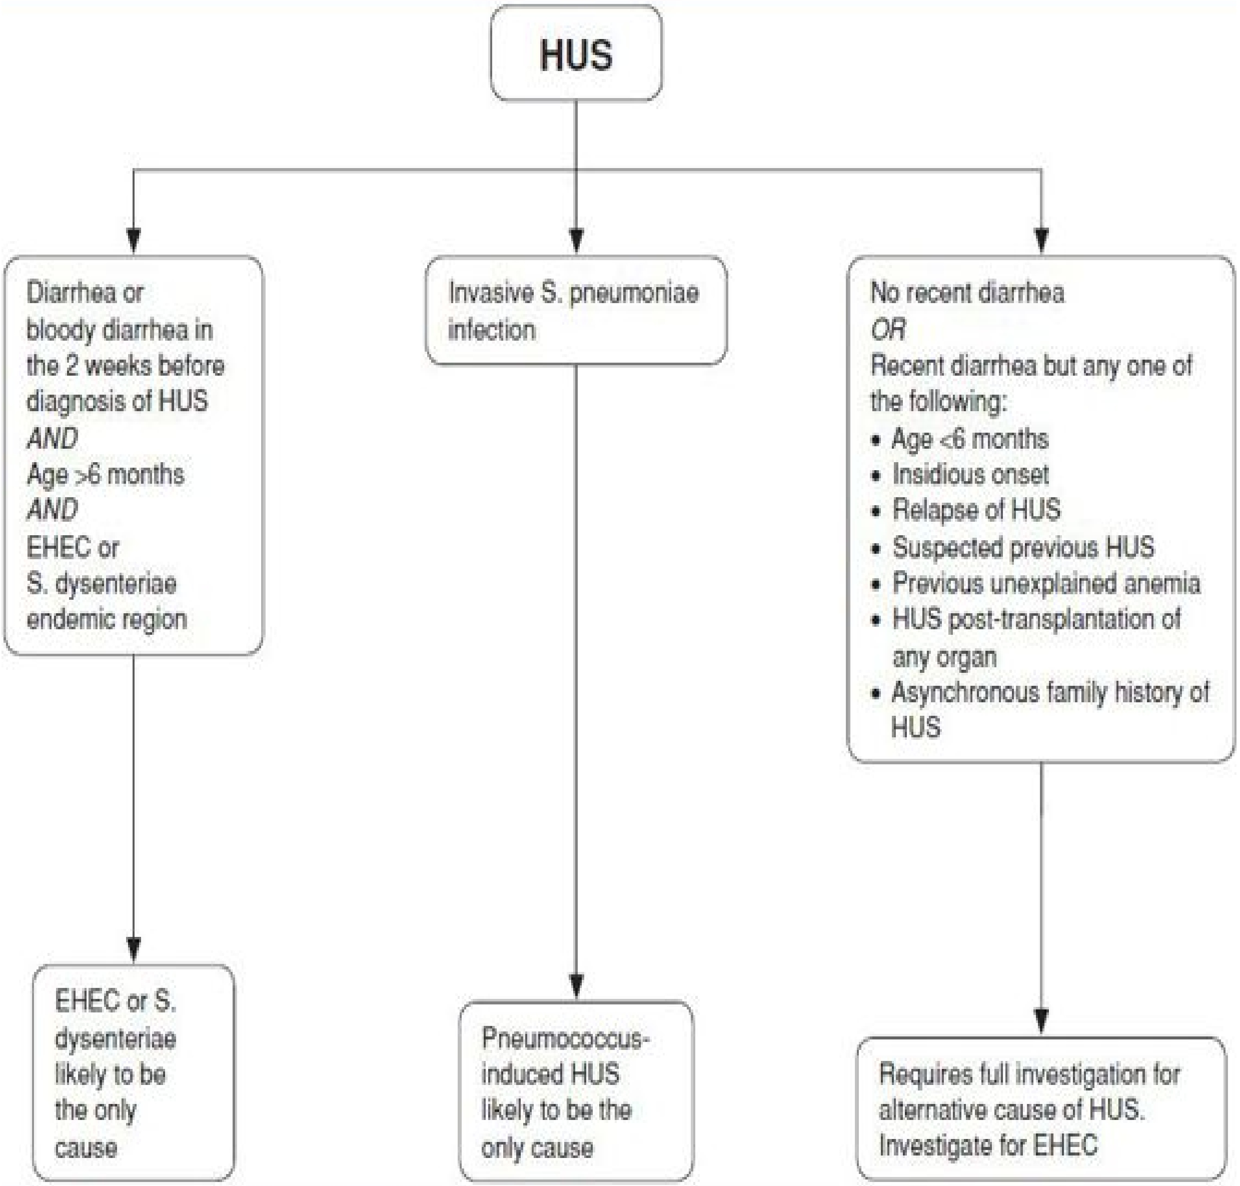
LABORATORY TESTING

HUS is defined by the simultaneous appearance of:

- Hemolytic anemia (hemoglobin <10 g/dL). The presence of fragmented erythrocytes (schistocytes) (see **Figures 69-1** and **69-2**), undetectable haptoglobin levels and elevated lactate dehydrogenase (LDH) confirm the presence of intravascular hemolysis.
- Thrombocytopenia (platelets <150,000/mm^3).
- Renal impairment (serum creatinine > upper limit of normal for age).
- Hyperkalemia, metabolic acidosis and hyponatremia may also be seen.
- In children, a renal biopsy is not needed for the diagnosis.

Table 69-2 shows the investigative work up recommended for patients with HUS and is also a flowchart that aids in the recognition of aHUS.[8]

TABLE 69-2 Work Up for HUS and Recognition of Atypical HUS



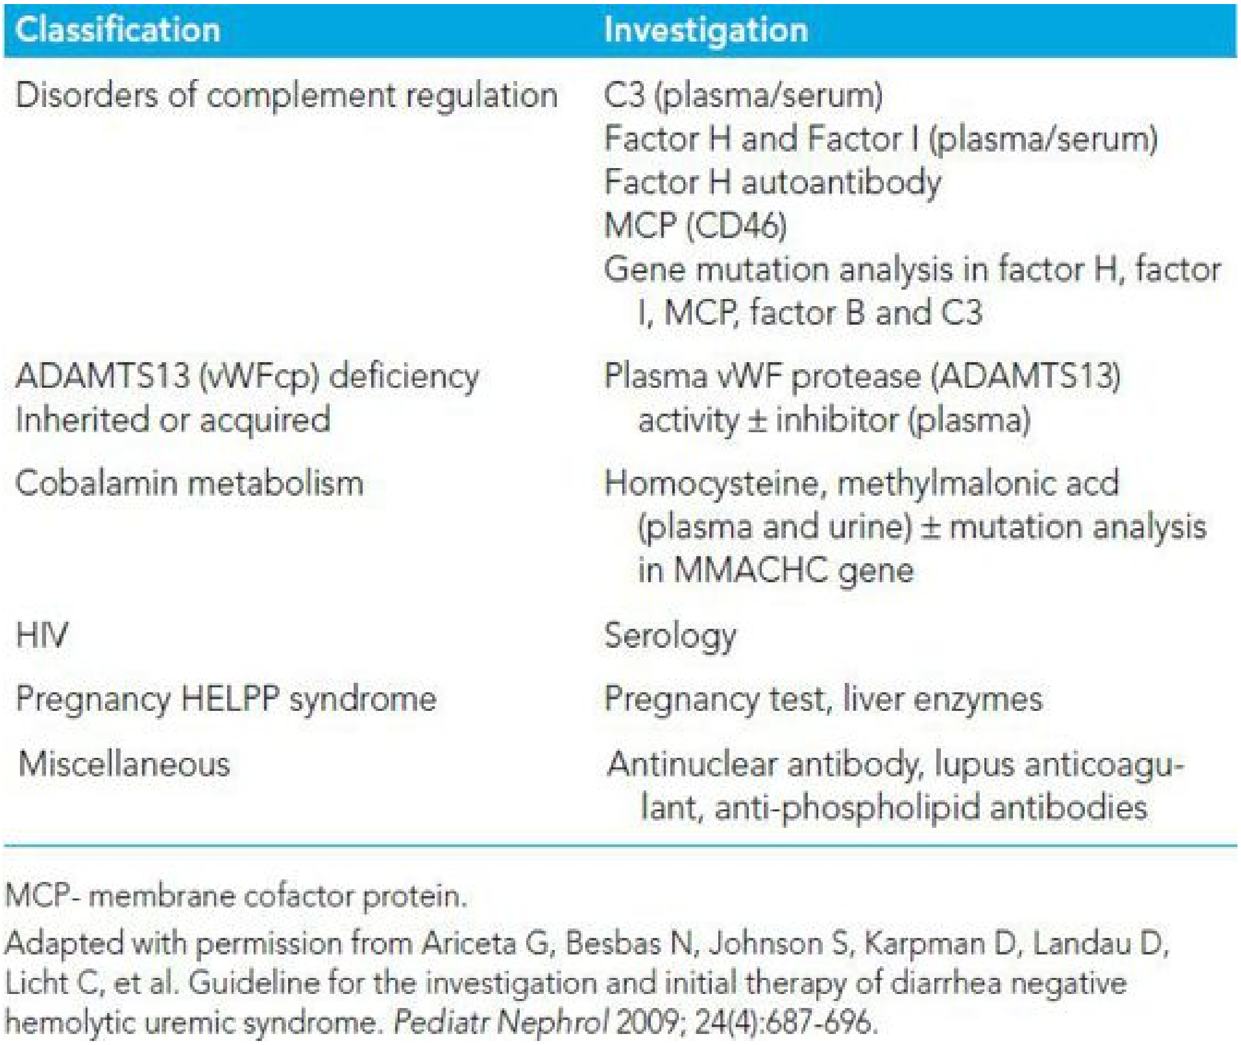
HUS
Diarrhea or bloody diarrhea in the 2 weeks before diagnosis of HUS
AND
Age >6 months
AND
EHEC or S. dysenteriae endemic region
Invasive S. pneumoniae infection
No recent diarrhea
OR
Recent diarrhea but any one of the following:
• Age <6 months
• Insidious onset
• Relapse of HUS
• Suspected previous HUS
• Previous unexplained anemia
• HUS post-transplantation of any organ
• Asynchronous family history of HUS
EHEC or S. dysenteriae likely to be the only cause
Pneumococcus-induced HUS likely to be the only cause
Requires full investigation for alternative cause of HUS. Investigate for EHEC

EHEC- enterohemorrhagic Escherichia coli.

Adapted with persmission from Ariceta G, Besbas N, Johnson S, Karpman D, Landau D, Licht C, et al. Guideline for the investigation and initial therapy of diarrhea negative hemolytic uremic syndrome. *Pediatr Nephrol*. 2009; 24(4):687-696.

- Children older than 6 months who have a history of diarrhea or bloody diarrhea should be investigated for enterohemorrhagic *E coli* (EHEC) or *Shigella dysenteriae*. Even if there is no recent diarrheal illness or if there is recent diarrhea and the presence of atypical features, investigate for EHEC infection as unusual presentations have been known to occur. These patients also require a full investigation for alternative causes of HUS (see **Table 69-3**).[8]

TABLE 69-3 Investigations for Patients with Suspected Atypical HUS



Classification	Investigation
Disorders of complement regulation	C3 (plasma/serum) Factor H and Factor I (plasma/serum) Factor H autoantibody MCP (CD46) Gene mutation analysis in factor H, factor I, MCP, factor B and C3
ADAMTS13 (vWFcp) deficiency Inherited or acquired	Plasma vWF protease (ADAMTS13) activity ± inhibitor (plasma)
Cobalamin metabolism	Homocysteine, methylmalonic acd (plasma and urine) ± mutation analysis in MMACHC gene
HIV	Serology
Pregnancy HELPP syndrome	Pregnancy test, liver enzymes
Miscellaneous	Antinuclear antibody, lupus anticoagulant, anti-phospholipid antibodies

MCP- membrane cofactor protein.

Adapted with permission from Ariceta G, Besbas N, Johnson S, Karpman D, Landau D, Licht C, et al. Guideline for the investigation and initial therapy of diarrhea negative hemolytic uremic syndrome. *Pediatr Nephrol* 2009; 24(4):687-696.

- In infants (<6 months) presenting with HUS, CFH, CFI and C3 should be screened first, regardless of whether C3 plasma concentration is decreased or not. If onset is after infancy and C3 level is normal, MCP mutation should be investigated. Anti-CFH antibodies-HUS is common after the age of approximately 7 years and in pre-adolescents and adolescents. Patients in these age groups should be screened for anti-CFH antibodies especially if C3 concentration is decreased. At any age, if no mutation is found in CFH, CFI, MCP and C3, screening for CFB and THBD mutation should be undertaken.
- ADAMTS13 activity determination is required in all patients with aHUS as manifestations of aHUS and TTP may overlap. Blood must be collected

before transfusion of fresh frozen plasma (FFP) or plasma exchange (PE). ADAMTS13 activity below 10 percent of normal is suggestive of TTP.

- Screening for defects of cobalamine metabolism (homocystinuria with methylmalonic aciduria) is mandatory.
- Patients with HELPP syndrome, post-partum HUS, and post-transplant HUS require an investigation of the complement system.

DIFFERENTIAL DIAGNOSIS

- TTP may have similar symptoms. Traditionally, TTP and HUS were distinguished clinically, considering TTP to have predominant neurological involvement and HUS to primarily have renal dysfunction. Both share a common pathology of thrombotic microangiopathy and symptoms can overlap with neurological manifestations seen in HUS and renal problems seen in TTP. Therefore, TTP and HUS are often considered together.[6,13]

MANAGEMENT

NONPHARMACOLOGIC

- Most patients can be managed with close attention to fluid and electrolyte balance, management of hypertension, and nutritional support.
- Patient with more severe renal impairment and anuria are likely to require renal replacement therapy with either peritoneal dialysis or hemodialysis.
- Red blood cell transfusions may be given for anemia.
- Platelet transfusions should be limited to cases of severe thrombocytopenia or to cases of hemorrhage or in anticipation of an invasive procedure.

- Recently, the European Working Group on HUS published consensus guidelines with the aim of establishing a standardized approach to the initial management of aHUS.[8] SOR Ⓒ Due to a lack of randomized controlled trials, these guidelines are based on combined personal experiences and published case reports.
    - Plasma exchange (PE) should be initiated within 24 hours of the initial presentation along with supportive treatment. Initially, 1.5 times (60 to 75 ml/kg) the expected plasma volume should be exchanged (replaced with FFP). Daily PE is recommended for the initial 5 days followed by five sessions a week for the next 2 weeks and then three sessions a week for the subsequent 2 weeks.
    - Blood counts, electrolytes, and serum creatinine should be monitored daily to determine the impact on degree of hemolysis and renal dysfunction.
    - In patients with low initial C3 levels, daily C3 levels should be measured.
    - PE can be discontinued if an alternative diagnosis is made that is not expected to respond to PE (such as cobalamin-C disorder), congenital ADAMTS13 deficiency, complications arise, or if remission is achieved.
    - Remission is achieved if platelet count is sustained above 150 × 109/l for 2 weeks and there is no evidence of hemolysis. A relapse is said to occur if there is recurrence of thrombocytopenia and hemolysis after 2 weeks of recovery. Reinstitution of PE is recommended if it had been successful initially.
    - If PE cannot be performed and the patient is not volume-overloaded or hypertensive and in cardiac failure, 10 to 20 mL/kg of body weight of FFP should be transfused (to replace a deficient factor).

MEDICATIONS

- Eculizumab, a humanized monoclonal antibody against C5, has recently been shown to be an effective treatment in aHUS.[7] There have been reported benefits of eculizumab in individual cases of aHUS and its efficacy has recently being evaluated in controlled clinical trials.[14] The

Food and Drug Administration has approved the use of eculizumab in the treatment of pediatric and adult patients with aHUS.[15] SOR Ⓐ

- The initial success of eculizumab and the practical difficulties involved in PE demonstrate the potential for eculizumab to be used early in children in the near future. It is administered as an intravenous infusion. The most frequently reported adverse effects are hypertension, upper respiratory infection, diarrhea, headache, anemia, vomiting, urinary tract infection, and leukopenia.
- Although it has been used in patients with severe Shiga toxin-associated HUS, the safety and efficacy of eculizumab have not been established for, and it is not recommended for use in D(+) HUS.[15]
- Treatment with eculizumab has been associated with meningococcal infections.[15] Providers are required by the FDA to enroll in a registration program, certify that they will counsel and provide educational materials to patients about the risks of eculizumab, and agree to promptly report cases of meningococcal infection.[15] Patients should be immunized with a polyvalent meningococcal vaccine.
- Patients treated with eculizumab may be an increased risk of serious infections due to *S. pneumoniae* and *H. influenza* type b, and if not immunized, patients should receive vaccinations for the prevention of these infections. Patients may require antibiotic prophylaxis as well.

SURGERY

- Patients with HUS who reach end stage renal failure (ESRF) may be candidates for renal transplantation. There is a 30 to 100 percent risk of recurrence of aHUS after renal transplantation.[7]

REFERRAL

- Pediatric Nephrology for management and follow up.
- Pediatric Surgery for vascular access for hemodialysis or PE, or for placement of a catheter for peritoneal dialysis.

PREVENTION AND SCREENING

- There are no specific measures to prevent HUS. However, it is advisable to take precautions against EHEC and other foodborne illnesses by washing hands, utensils and food surfaces often, keeping raw food separate from read-to-eat food, thoroughly cooking meat, washing fruits and vegetables, avoiding unpasteurized milk, juice and cider, and avoiding swimming in water potentially contaminated with feces.

PROGNOSIS

- Typical HUS carries a mortality rate of up to 5 percent.[6,12] Patients with a milder course gradually improve with resolution of renal impairment over a few weeks. Approximately 25 percent have residual defects which range from persistent proteinuria and hypertension to end-stage renal disease.[12] Oligoanuria persisting for longer than 4 weeks increases the risk of a poorer prognosis.[16]
- Atypical HUS has a poorer prognosis than D(+) HUS with a 25 percent mortality rate.[7] It is characterized by frequent relapses and progression to end-stage renal failure in approximately 50 percent of cases.[16,17] Disease recurrence following isolated renal transplantation is high and has been reported to occur in up to 30 to 100 percent of aHUS patients depending on the underlying complement defect.[7]

70 PEDIATRIC KIDNEY STONES

Karl T. Rew, MD

PATIENT STORY

A 13-year-old girl presents with pain in the right flank and mid-abdomen. Several family members have had kidney stones. Her urinalysis shows blood but no signs of infection. A pregnancy test is negative. Abdominal x-ray reveals bilateral stones (**Figure 70-1**). A CT shows a right ureteral stone and a non-obstructing stone in the left kidney (**Figures 70-2** and **70-3**). She successfully passes and catches the symptomatic stone. Stone analysis shows calcium oxalate. A metabolic workup shows idiopathic hypercalciuria as the cause of her stones.

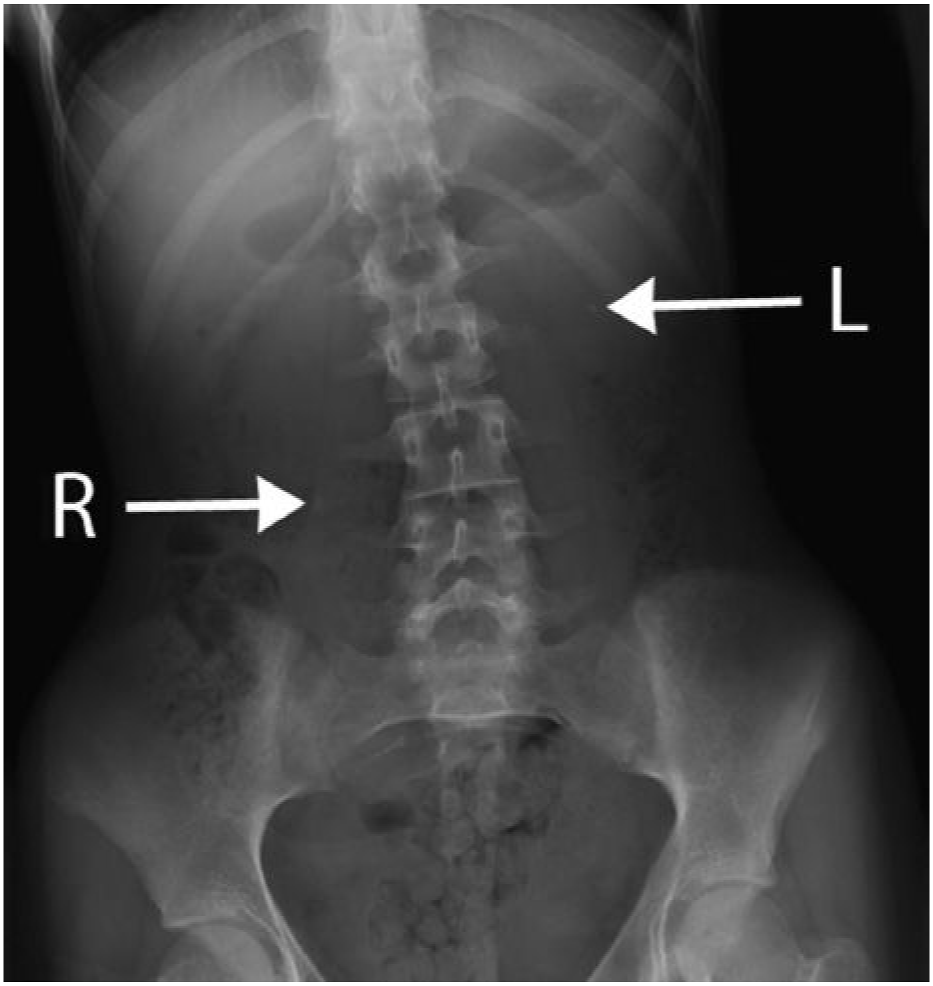

FIGURE 70-1 Plain abdominal x-ray showing with two subtle stones (arrows), one in the right ureter and one in the left kidney of a 13-year-old girl. (*Used with permission from Julian Wan, MD.*)

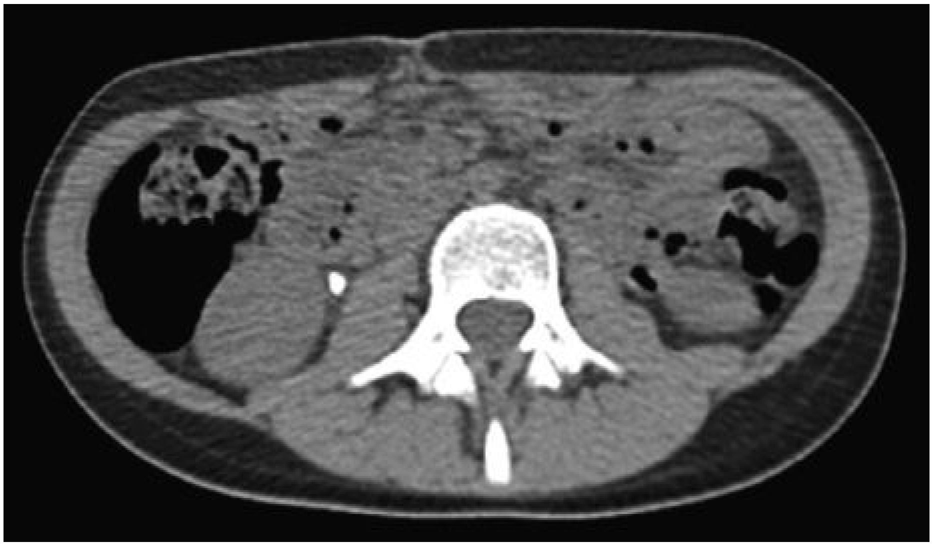

FIGURE 70-2 CT of the abdomen and pelvis of the same girl in **Figure 70-1**, showing a right ureteral stone. (*Used with permission from Julian Wan, MD.*)

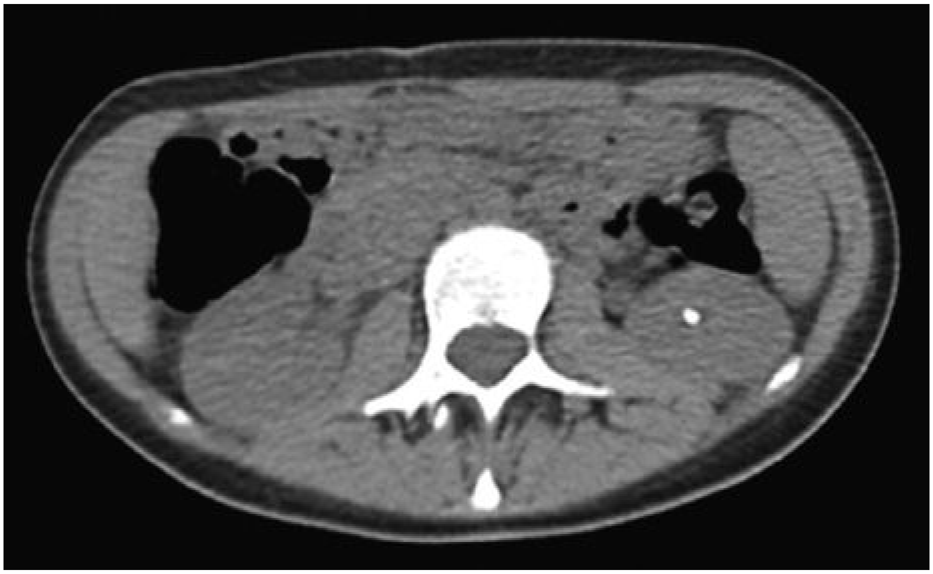

FIGURE 70-3 CT of the abdomen and pelvis of the same girl in **Figure 70-1**, showing a left kidney stone. (*Used with permission from Julian Wan, MD.*)

INTRODUCTION

A kidney stone is a solid mass that forms when minerals crystallize and collect in the urinary tract. Kidney stones can cause pain and hematuria, and may lead to complications such as urinary tract obstruction and infection.

SYNONYMS

Kidney stone, nephrolithiasis, renal calculus, renal stone, urinary tract stone, ureterolithiasis, urolithiasis.

EPIDEMIOLOGY

- The prevalence of kidney stones among children and adults in the US is increasing.[1] Part of this increase may be due to improvements in imaging techniques.[2,3] Although pediatric data are incomplete, children appear to be about 1/10 as likely to develop stones as adults.
- Kidney stones affect children of all ages but are most prevalent among adolescents, who are also more likely than younger children to present with symptomatic ureteral stones.[3,4]
- Boys and girls overall have similar rates of stone formation, although prevalence varies by age, type of stone, and geographic region.[5,6]
- African-American children have a lower rate of kidney stones than white children.[4,7]
- Genetic, metabolic, and anatomic disorders are the main causes of stones in children. Children are at higher risk of recurrent stones and subsequent renal dysfunction than adults for whom environmental and dietary causes are more common.[4] Obesity and weight gain increase the risk of stone formation in adults;[8] the effects of pediatric obesity are being studied.
- Calcium oxalate and calcium phosphate stones are the most common in children, occurring in about 90 percent of cases. Struvite (magnesium

ammonium phosphate) stones occur in about 5 percent of cases and are becoming less common. About 2 percent of pediatric stones are cystine stones. Uric acid stones are less common in children than adults, occurring in less than 1 percent of cases. Medication stones and other types of stones are rare.[6]

ETIOLOGY AND PATHOPHYSIOLOGY

- Kidney stones form when there is supersaturation of otherwise soluble materials, usually from increased excretion of these compounds or from dehydration. Idiopathic hypercalciuria is the most common abnormality found in adolescents. Low urinary citrate can increase the risk of calcium stone formation because citrate in the urine binds calcium and impedes stone formation in several other ways. Urine pH can affect stone formation: calcium phosphate and cystine stones form in more alkaline urine (pH >7), while uric acid stones form in acidic urine (pH <5.5).
- Struvite stones are caused by infection with urea-splitting bacteria, mainly *Proteus*.
- Cystine stones occur in patients with an inherited defect of dibasic amino acid transport. These stones can be pure cystine or cystine mixed with calcium oxalate.
- Uric acid stones form in patients with hyperuricemia from gout, myeloproliferative disorders, chemotherapy, or Lesch-Nyhan syndrome. Acidic urine due to a ketogenic diet or chronic diarrhea can increase the risk of uric acid stones.
- Struvite, cystine, and uric acid stones can grow large, filling the renal pelvis and extending into the calyces to form staghorn calculi (**Figure 70-4**).

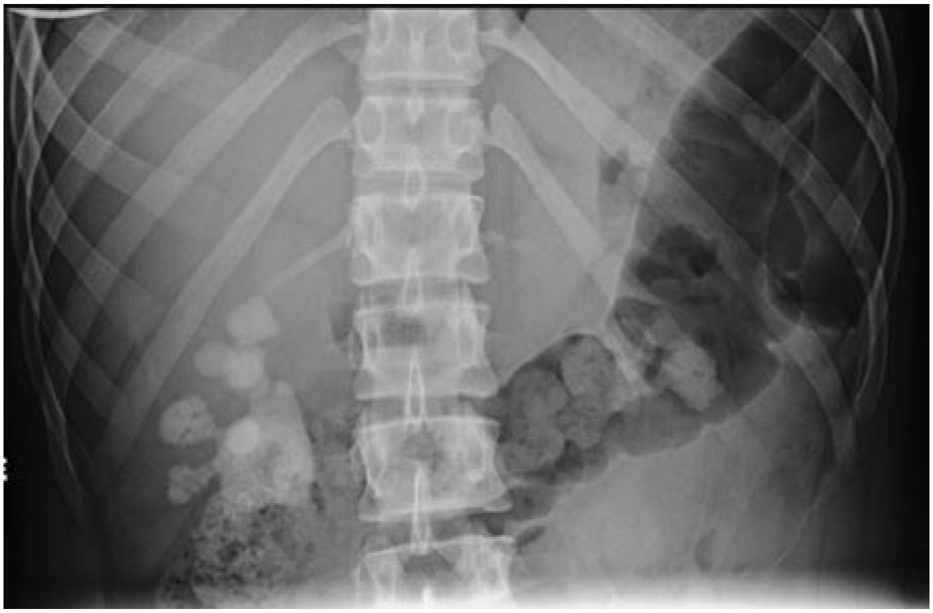

FIGURE 70-4 Plain abdominal x-ray of a 15-year-old girl with cystinuria and a large staghorn calculus in the right kidney. (*Used with permission from Julian Wan, MD.*)

RISK FACTORS

- Many kidney stones occur in patients with no known risk factors. However, a 24-hour urine collection often shows a low urine volume from inadequate fluid intake.
- The risk of forming calcium stones has been shown in adults to be increased by obesity,[8] diabetes mellitus, metabolic syndrome, and by diets high in animal protein, salt, and oxalate-containing foods; these factors are being studied in children.
- Contrary to popular belief, calcium in the diet does not lead to calcium stones; in fact, dietary calcium can help prevent calcium oxalate stones by trapping oxalate in the GI tract.
- Patients with neurogenic bladder, anatomic anomalies causing poor urinary drainage, or long-term catheters are at risk for *Proteus* urinary tract infections and struvite stones.

- Cystine stones are found in families with an autosomal recessive defect in a protein that transports dibasic amino acids in the kidneys, increasing the concentration of insoluble cystine in the urine. All homozygotes and some heterozygotes are at risk for cystinuria and stones.
- Uric acid stones are most likely in patients who have hyperuricemia along with acidic urine from chronic diarrhea, diabetes mellitus, or a ketogenic diet.

DIAGNOSIS

CLINICAL FEATURES

- Stones in the kidneys can be asymptomatic. Such stones, found incidentally on imaging done for other reasons, sometimes remain in the kidneys for years without causing symptoms.
- Stone passage into the ureter usually causes pain and hematuria. The pain of renal colic in adolescents typically begins suddenly in the ipsilateral flank or abdomen and progresses in waves, gradually increasing in intensity over the next 20 to 60 minutes. As the stone moves downward, pain may be felt in the ipsilateral groin, testis, or vulva. Diagnosing urinary tract stones is often more difficult in younger children who may present with hematuria, nonspecific abdominal pain, or urinary tract infection.
- Obstructing stones cause hydronephrosis, often with an associated constant dull flank pain. Stones in the bladder can cause frequency, urgency, dysuria, or recurrent urinary tract infections.

LABORATORY

- Urinalysis usually reveals microscopic hematuria and limited pyuria. Gross hematuria is less common. Cystine crystals are pathognomonic for cystinuria.

- Urine culture should be done to assess for infection.
- Because treatment and prevention depend on stone type, stone capture and analysis is recommended. SOR Ⓒ Stones can be collected with a strainer in older children, and by examining diapers in younger children.
- Metabolic work-up is recommended for all children with a urinary tract stone.[9] This includes testing of urine (ideally with a 24-hour collection) for pH, volume, calcium, oxalate, and citrate, with simultaneous serum tests for calcium, uric acid, electrolytes, and creatinine. When a 24-hour urine cannot be collected, a random urine should be tested. In patients with elevated serum calcium, parathyroid hormone (PTH) should be measured.

IMAGING

- Plain abdominal x-ray will demonstrate most calcium, struvite, and cystine stones. It is recommended for patients with a prior radiopaque stone (**Figures 70-1** and **70-4**).
- Ultrasound can be used to monitor uric acid stones (typically radiolucent), to assess hydronephrosis, or to limit exposure to x-rays (**Figure 70-5**). Ultrasound also may provide clues to diagnoses outside the urinary system.

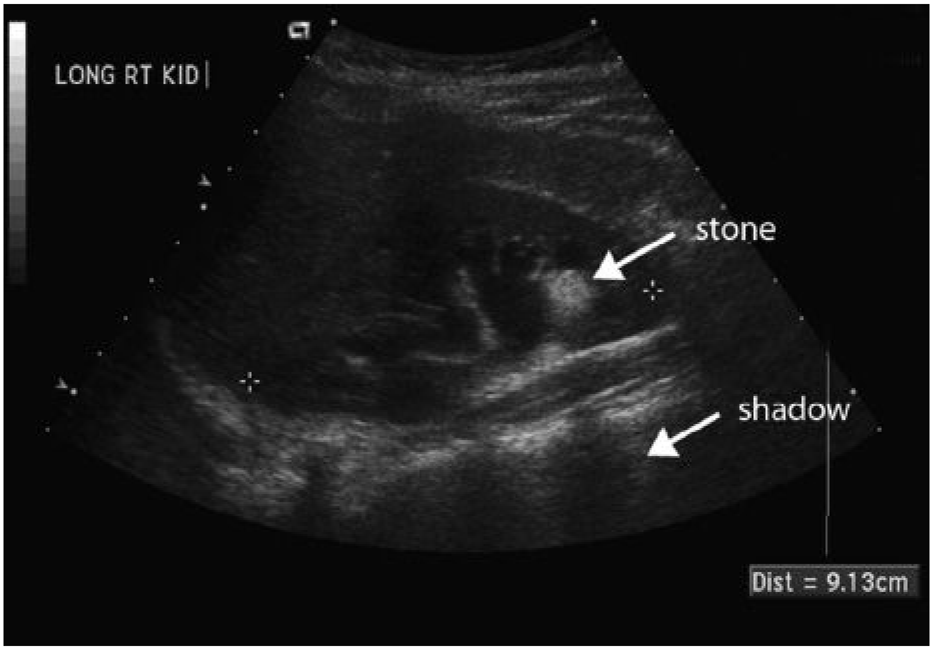

FIGURE 70-5 Ultrasound of right sided kidney stone (arrow) in an 8-year-old girl. Note the shadowing that occurs below the stone. (*Used with permission from Julian Wan, MD.*)

- Noncontrast helical CT (**Figures 70-2** and **70-3**) is the preferred imaging approach for adults with stones and has largely replaced intravenous urography. However, in children, an adequate assessment can often be made using plain x-ray and ultrasound, reducing their radiation exposure. CT is effective for diagnosing stones in children and it may provide clues to diagnoses outside the urinary system, but the radiation exposure is 2 to 10 times that of a single plain abdominal x-ray.[10]

DIFFERENTIAL DIAGNOSIS

Other causes of flank and lower pelvic/groin pain:

- Gynecologic conditions in girls (e.g., ovarian torsion, cyst, or ectopic pregnancy) can often be distinguished on ultrasound. Pelvic inflammatory disease can also present with pain and is diagnosed based on clinical examination and culture.

- In boys, orchitis, epididymitis, or testicular torsion can cause pain that can be confused with kidney stones. Testicular tumors rarely cause pain. Physical examination can help differentiate these conditions.
- Urologic disorders that can cause pain include ureteropelvic junction obstruction, renal subcapsular hematoma, and renal cysts (see Chapter 65, Hydronephrosis and UPJ Obstruction and Chapter 66, Polycystic Kidneys). Imaging assists in differentiating these from kidney stones.

Abdominal pain from renal stones may be similar to pain caused by other diagnoses:

- Colitis or appendicitis—Systemic symptoms may include fever, diarrhea, rectal bleeding, tenesmus (i.e., urgency with a feeling of incomplete evacuation), passage of mucus, and cramping abdominal pain (see Chapter 59, Inflammatory Bowel Disease). GI symptoms with kidney stones are usually limited to nausea and vomiting from stimulation of the celiac plexus.
- Peptic ulcer disease is characterized by epigastric pain along with dyspeptic symptoms (see Chapter 55, Peptic Ulcer Disease). Upper endoscopy is the preferred procedure for diagnosing ulcers. Stool antigen test can confirm *Helicobacter pylori* infection.
- Urinary tract infection (UTI) can mimic stones within the bladder. Helpful indictors of UTI are a urine dipstick positive for nitrates (positive likelihood ratio [LR+] 26.5) and urinary sediment showing 10 or more bacteria/high-power field (LR+ 85).

Hematuria can be seen in patients with:

- Infection including UTI, sexually transmitted infection or schistosomiasis.
- Renal disease such as glomerulonephritis, immunoglobulin [Ig] A nephropathy, lupus nephritis or hemolytic uremic syndrome (see Chapters 67, Nephrotic Syndrome; Chapter 68, Nephritic Syndromes; and Chapter 69, Hemolytic Uremic Syndrome).
- Trauma.

MANAGEMENT

NONPHARMACOLOGIC

- Adequate fluid intake is essential—2 to 3 L of water per day for most adolescent and adult patients.[11] SOR Ⓑ
- Small stones are likely to pass spontaneously. About 3/4 of distal ureteral stones and about half of proximal ureteral stones will pass spontaneously.

MEDICATIONS

- Medical expulsive therapy, with α-adrenergic blockers (such as tamsulosin) or calcium-channel blockers, increases the chance of stone passage in adults and has been used successfully in children, although it is not currently FDA approved.[12] SOR Ⓑ
- Effective pain control should be provided using NSAIDs and narcotics if needed. NSAIDs may need to be avoided if planning lithotripsy because of increased risk of perinephric bleeding.

COMPLEMENTARY AND ALTERNATIVE THERAPY

- For prevention of struvite stones, urine can be acidified with cranberry juice.[11] Drinking lemon juice daily can raise citrate levels in urine and help prevent calcium stones. Other supplements have been suggested as potentially protective against renal stones, but study results are conflicting.

PROCEDURES

- Stones that do not pass spontaneously or with medical expulsive therapy can be treated with extracorporeal shockwave lithotripsy or removed via ureteroscopy. Endoscopic retrograde lithotripsy and laser procedures have been increasingly successful, even in smaller children. Large stones may require percutaneous nephrolithotomy or open surgery.

REFERRAL

- Urgent urologic consultation is recommended for patients with stones and urosepsis, anuria, or renal failure. Urologic consultation is recommended for patients with refractory pain and nausea, extremes of age, major comorbidities, and stones >5 mm. SOR C
- Nephrologic consultation is helpful to guide treatment for patients with acute kidney injury or chronic kidney disease.
- Both parents and patients can benefit from consultation with a dietician to help them adhere to a stone-prevention diet while maintaining adequate nutrition.
- Genetic consultation is recommended for those with cystinuria or other inherited risk factors.

PREVENTION

- High fluid intake and low sodium intake will help prevent most types of stones.
- Low-calcium diets should not be used in patients with calcium stones. A low-calcium diet can increase stone formation and decrease bone mineral density.
- Foods high in oxalate should be avoided by those who form calcium oxalate stones; food sources include rhubarb, spinach, Swiss chard, beets, apricots, figs, kiwi, many soy products, chocolate, and many nuts and seeds.

- Cystine stone formers should avoid methionine, found in higher-protein foods such as fish, meat, eggs, dairy products, and soybeans.
- Uric acid stones are prevented with a low-purine diet. High-purine foods to avoid include fish, shellfish, meats (especially game meats and organ meats), and protein supplements such as brewer's yeast. Daily allopurinol can help prevent uric acid stones.

Additional treatments may be warranted based on the type of stone:

- Patients with recurrent calcium-containing stones caused by idiopathic hypercalciuria can be treated with a thiazide diuretic, which may reduce recurrence by 50 percent over 3 years. Hypokalemia should be avoided because low potassium can reduce urinary citrate and increase stone formation.
- Idiopathic stone disease can be treated with fluids and potassium citrate. Potassium citrate is not FDA approved for use in children but European studies suggest an initial pediatric dose of 1 mEq/kg/d divided into 2 to 3 daily doses.[13]
- For cystine stones, increasing fluid intake, alkalinizing the urine to a pH ≥7.5, and a low-sodium diet are recommended. D-Penicillamine binds with cystine, helping to dissolve and prevent cystine stones, but it is not always well tolerated.

PROGNOSIS

- Half of patients with a first calcium-containing stone have a recurrence within 10 years. Twenty-five percent of struvite stones recur if there was incomplete removal of the stone. Cystine stones recur one or more times per year in most patients.
- Long-term complications can include hypertension and chronic kidney disease. The proportion of nephrolithiasis-related end-stage renal disease (ESRD) in patients of all ages is small (3.2%).

FOLLOW-UP

- A follow-up consultation to discuss kidney stone prevention is important for all patients with an initial stone. Patients started on medical therapy should be reevaluated with a 24-hour urine in 3 months. Those with a history of recurrent stones should be seen at least annually.

PATIENT EDUCATION

Increasing water intake to keep urine specific gravity around 1.005 (or about 2 to 3 L/day in adolescents) is recommended for most patients. In adults this has been shown to reduce stone recurrences by half. Dietary information is available (see the following section, “Patient Resources”).

71 RENOVASCULAR HYPERTENSION

Halima S. Janjua, MD
Raed Bou Matar, MD
Charles Y. Kwon, MD

PATIENT STORY

A 14-year-old girl presents to your office for a routine physical examination. She has history of chronic headaches and complains about abdominal pain after eating. Her vital signs reveal a blood pressure of 163/100 mm Hg. Repeat manual blood pressure is 152/98 mm Hg. You obtain laboratory studies, which reveal a normal serum creatinine, mild hypokalemia, and elevated plasma renin activity and aldosterone level. Her renal ultrasound with Doppler is suspicious for right renal artery stenosis. You start hypertension management with a calcium-channel blocker and refer her to a pediatric nephrologist, who obtains a computed tomography angiography (**Figure 71-1**) that reveals severe narrowing of right renal artery. Her blood pressure remains sub-optimally controlled with calcium-channel blockers. An angiotensin II receptor blocker is added to her hypertension management.

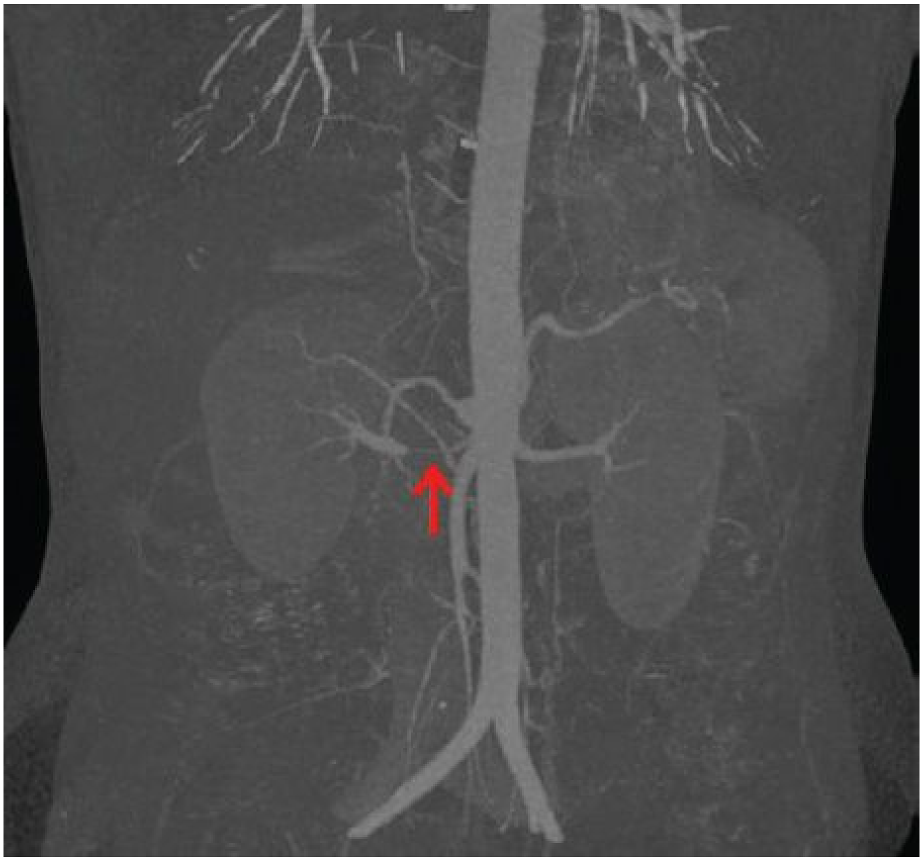

FIGURE 71-1 Stenosis of the right renal artery (arrow) on computed tomography angiography. (*Used with permission from Halima Janjua, MD.*)

INTRODUCTION

Renovascular hypertension is hypertension that results from lesions that impair blood flow to one or both kidneys. It is an important cause of reversible hypertension in children.

SYNONYMS

Renal artery stenosis; renovascular disease.

EPIDEMIOLOGY

- Renovascular hypertension accounts for about 5 to 10 percent of hypertension in children.[1,2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Renovascular hypertension is caused by the interplay of renin-mediated mechanisms, sodium-related volume expansion, and increased sympathetic nervous system activity.
- Specific causes of renovascular hypertension include:
  - Fibromuscular dysplasia.
  - Vasculitis (e.g., Takayasu's disease, Polyarteritis nodosa, or Kawasaki disease).
  - Syndromes (e.g., Neurofibromatosis type 1, Tuberous sclerosis, Williams syndrome, or Marfan syndrome).
  - Umbilical artery catheterization.
  - Mid-aortic syndrome.
  - Renal artery hypoplasia.
  - Extrinsic compression (e.g., Neuroblastoma, Wilms tumor).

DIAGNOSIS

CLINICAL FEATURES

- The clinical presentation of renovascular hypertension can be very variable.

- Children can be asymptomatic and incidentally found to have severe hypertension or they can present with symptoms secondary to end-organ damage from severe hypertension.
- An abdominal or flank bruit, signaling turbulent blood flow, may be heard on physical exam.

LABORATORY TESTING

- Increased plasma renin activity (PRA)—PRA may be elevated in children with renovascular hypertension.
- Hyperaldosteronism—Aldosterone may be elevated due to activation of rennin-angiotensin-aldosterone system.
- Hypokalemia—May be seen due to effect of aldosterone.
- Metabolic alkalosis—May be seen due to effect of aldosterone.

IMAGING

- Doppler Ultrasonography—Renal arteries and its branches can be viewed by color and pulsed-wave Doppler. Ultrasonography allows for measurement of peak systolic velocities in the intrarenal branches, although this study may not be sensitive enough to detect distal sites of stenosis.[3]
- Computed Tomography Angiography (CTA)—It provides three-dimensional images. It has better spatial resolution compared to magnetic resonance angiography (MRA). This study can be conducted quickly and without general anesthesia though there is exposure to ionizing radiation (**Figures 71-1** and **71-2**).[4]

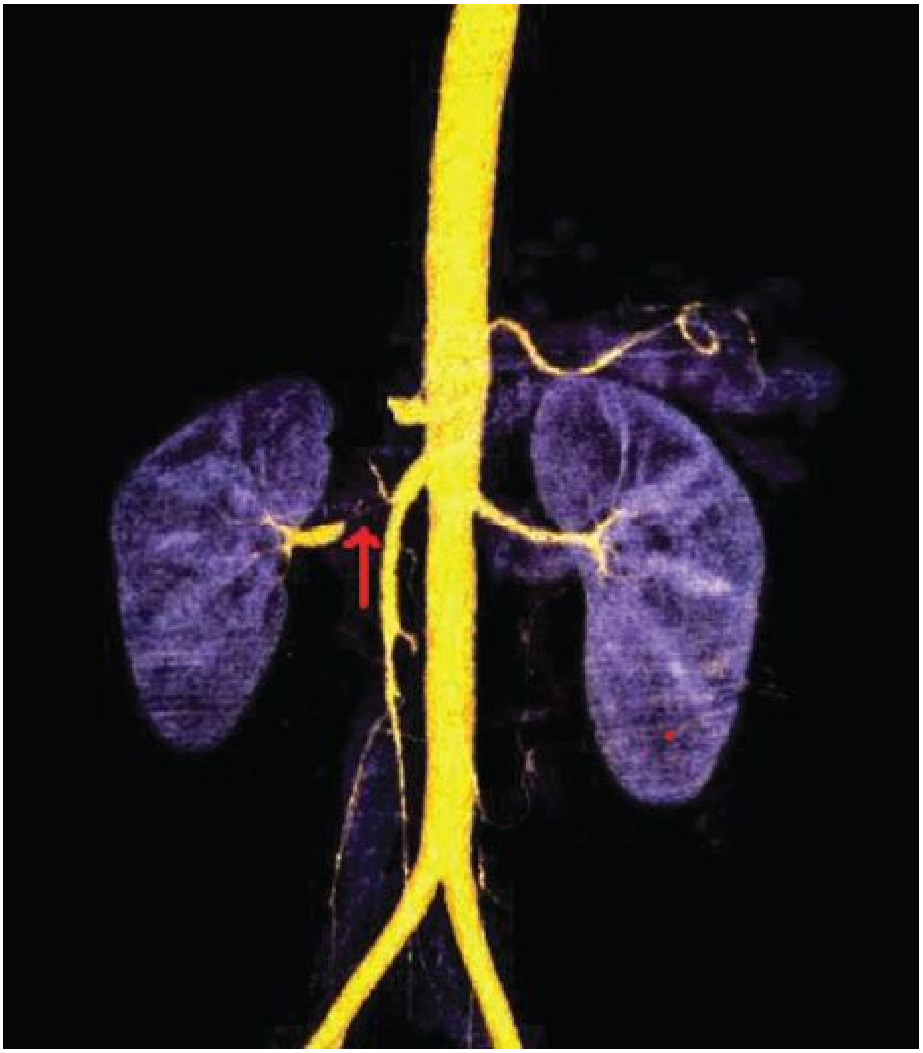

FIGURE 71-2 Right renal artery stenosis (arrow) on color-enhanced computed tomography angiography in the same patient as in **Figure 71-1**. (*Used with permission from Halima Janjua, MD.*)

- Magnetic Resonance Angiography (MRA)—There is no exposure to ionizing radiation though gadolinium-based contrast is used that can lead to nephrogenic systemic fibrosis in children with glomerular filtration rates (GFR) of less than 30 mL/min/1.73 m^2. MRA also requires sedation or general anesthesia (**Figure 71-3**).

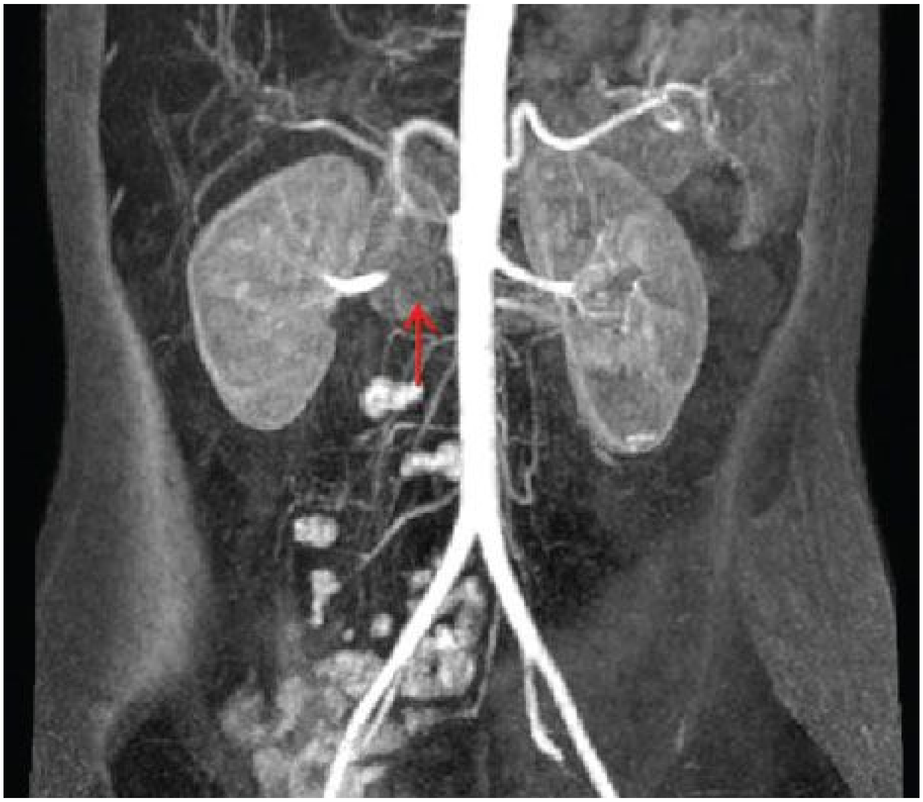

FIGURE 71-3 Magnetic Resonance Angiography of the patient in Figure 71-1 showing diffuse, long (2.4 cm) unilateral narrowing of the proximal/mid segments of the right renal artery (arrow) and mild-moderate narrowing of superior mesenteric artery above it. (*Used with permission from Halima Janjua, MD.*)

- Digital Subtraction Angiography (DSA)—It is considered the "gold standard" for diagnosing renovascular abnormalities. DSA can provide excellent images of the branches of renal arteries as well as show the "string of beads" sign of fibromuscular dysplasia. Presence of unilateral stenosis can be confirmed by sampling blood for renin from both renal veins. Another advantage of DSA is the endovascular treatment that can be performed by the interventional radiologist at the time of DSA. DSA requires higher radiation dose than CTA, general anesthesia, and a pediatric vascular surgical backup.

DIFFERENTIAL DIAGNOSIS

Other than renovascular hypertension, differential diagnosis for children with severe hypertension includes:

- Renal scarring—Usually a history of chronic urinary tract infections is apparent.
- Chronic glomerulonephritis—History of prior renal disease and signs of nephritis usually apparent (see Chapter 68, Nephritic Syndromes).
- Polycystic kidney diseases—Usually detected on imaging studies (see Chapter 66, Polycystic Kidneys).
- Hemolytic uremic syndrome—Suspected on basis on renal dysfunction, hemolytic anemia and thrombocytopenia (see Chapter 69, Hemolytic Uremic Syndrome).
- Chronic renal failure—Signs and symptoms will be apparent.
- Tumors—Detected on imaging studies.
- Vasculitis—Usually accompanied by other systemic manifestations.
- Coarctation of aorta—Apparent on a careful physical examination of all peripheral pulses.
- Pheochromocytoma—Manifests with severe hypertension, tachycardia, and systemic symptoms.
- Neuroblastoma—May be the presenting feature. Usually seen on imaging studies.
- Iatrogenic—Uncommon in infants and children.

MANAGEMENT

Children with renovascular hypertension usually have chronic high blood pressure, which must be lowered gradually.

MEDICATIONS

- Angiotensin-converting enzyme inhibitors (ACEi) and angiotensin II receptor blockers (ARBs) should be used with caution since they can reduce an already diminished glomerular filtration pressure. The resulting drop in glomerular filtration pressure may cause severe acute kidney injury in some patients with bilateral severe stenosis, high-grade stenosis in one kidney or advanced chronic kidney disease.[6] SOR C
- Calcium-channel blockers and beta-blockers are relatively safe initial antihypertensive options. However, it not unusual for these children to require multiple antihypertensive medications to control their blood pressure leading to cautious use of ACEi or ARBs. SOR C

ENDOVASCULAR INTERVENTIONS

- Revascularization and restoration of renal blood flow is required in patients who either cannot tolerate antihypertensive medications or have refractory hypertension.
- Revascularization can be achieved via percutaneous angioplasty, segmental transarterial ethanol ablation, or surgery. In general, the choice of treatment depends on the age and size of the child, technical feasibility, extent of the disease process, and underlying cause.
- Percutaneous angioplasty, with or without stenting, is the most commonly used first line intervention. It has shown clinically significant improvement in about 50 percent of the cases and is associated with a high rate of restenosis (**Figures 71-4** and **Figure 71-5**). SOR C

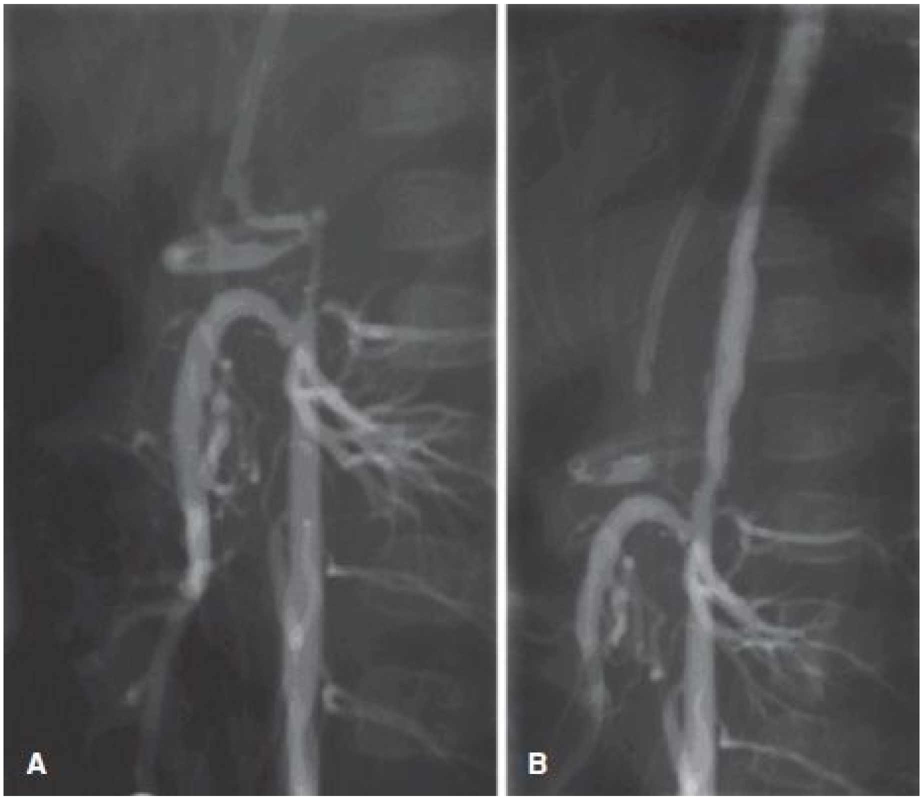

FIGURE 71-4 Severe midaortic syndrome. Note the narrowing of the abdominal aorta before angioplasty (**A**) that improved after angioplasty (**B**). (*Used with permission from Springer Science+Business Media, with kind permission: Clinical Hypertension and Vascular Diseases: Pediatric Hypertension, edited by: J. T. Flynn et al. DOI 10.1007/978-1-60327-824-9_20. Springer Science+Business Media, LLC 2011. Chapter 20. Fig. 2.*)

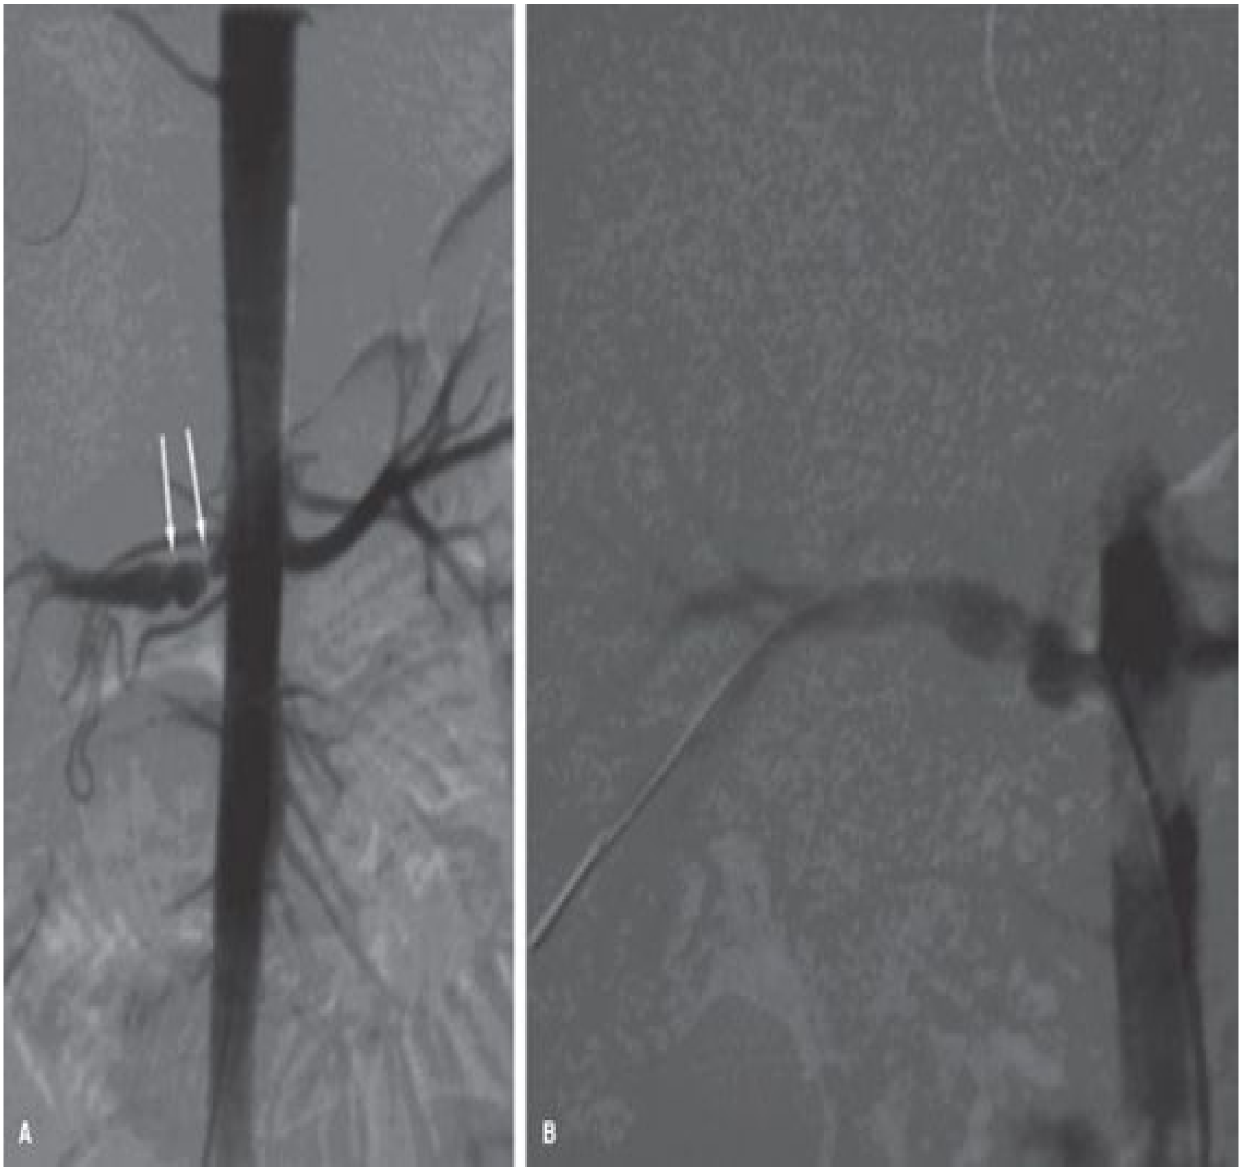

FIGURE 71-5 (**A**) Typical beaded appearance of a renal artery with severe stenosis. The arrows point to areas of stenosis between the beads. (**B**) After treatment with angioplasty. (*Used with permission from Springer Science+Business Media, Clinical Hypertension and Vascular Diseases: Pediatric Hypertension, edited by J. T. Flynn et al. DOI 10.1007/978-1-60327-824-9_20. Springer Science+Business Media, LLC 2011.* Chapter 20*. Fig. 3.*)

- In cases of segmental branch stenosis, for which angioplasty is difficult to perform, segmental ethanol ablation may be a reasonable alternative.[9,10] SOR C

SURGERY

- Partial or complete unilateral nephrectomy or revascularization surgery with autologous or synthetic grafts is reserved for complicated cases or those with failed angioplasty or ethanol ablation. These surgical procedures have shown to be of clinical benefit in about 97 percent of the cases.[11] SOR Ⓒ

REFERRAL

- Renovascular hypertension is best managed by a multidisciplinary team approach that may include pediatric nephrologist, interventional radiologist, and vascular surgeon.

SCREENING

- Blood pressure screening should begin at age 3 years and continue with each health care visit, as recommended by American Academy of Pediatrics.[12]
- Children with severe or stage 2 hypertension defined as blood pressure >5 mmHg above the 99th percentile should be evaluated for secondary causes of hypertension.

PROGNOSIS

- Long-term outcome of renovascular hypertension is not clear.

FOLLOW-UP

- Periodic blood pressure measurements are recommended in patients with history of renovascular hypertension due to a significant risk of restenosis or formation of new vascular lesions.

72 NEONATAL CONJUNCTIVITIS

Dawood Yusef, MD
Camille Sabella, MD

PATIENT STORY

A 6-day-old girl is admitted to the hospital because of profuse yellowish drainage from both eyes. The infant was born at home after a 36-week gestation age to an 18-year-old mother. Maternal screens were not obtained during pregnancy due to poor prenatal care. On exam, the infant had profuse purulent drainage from both eyes with significant eyelid edema (**Figure 72-1**). Gram stain of the purulent drainage revealed gram-negative diplococci, consistent with *Neisseria gonorrhoeae* infection (**Figure 72-2**). Blood and cerebrospinal fluid cultures were negative. The infant was treated with one dose of intravenous ceftriaxone and frequent eye irrigations and recovered completely.

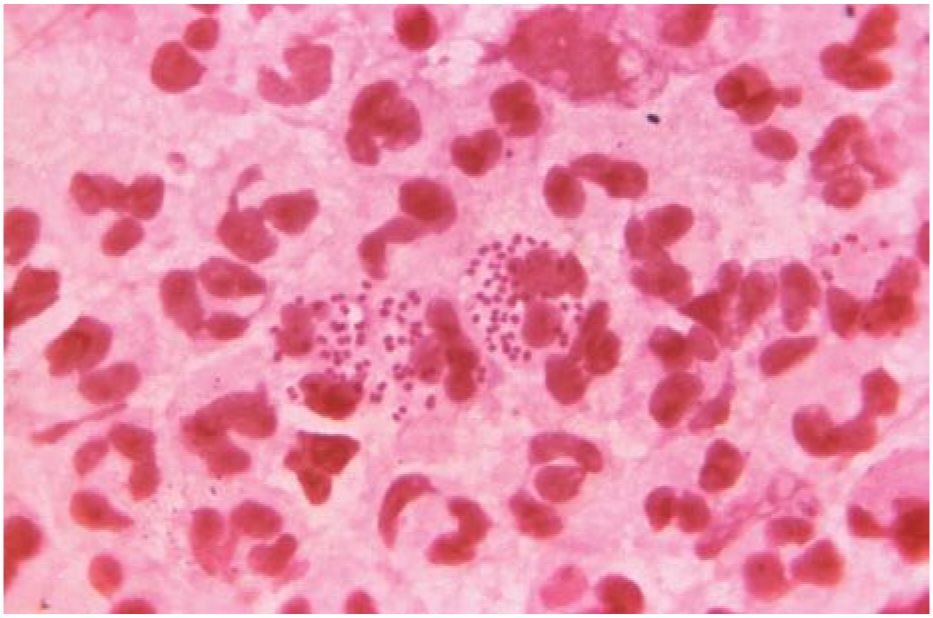

FIGURE 72-2 A Gram stain showing intracellular gram-negative diplococci of *Neisseria gonorrhoea*. (*Used with permissions from CDC/Bill Schwartz.*)

INTRODUCTION

- Neonatal conjunctivitis (Ophthalmia neonatorum) occurs in the first month of life, and may be infectious or noninfectious (chemical) in origin. Knowledge of the differential diagnosis is essential in early diagnosis and management.

SYNONYMS

Ophthalmia neonatorum, inclusion (chlamydial) conjunctivitis.

EPIDEMIOLOGY

- Most infectious causes are acquired by the neonate during vaginal delivery.
- The risk of a newborn acquiring *Chlamydia trachomatis* from the infected mother is estimated to be 50 percent; up to half of these may develop conjunctivitis.[1]
- The incidence of gonococcal conjunctivitis has decreased dramatically since the introduction of newborn antimicrobial ocular prophylaxis.[2]
- Skin, eye, and mouth disease represents up to 45 percent of cases of neonatal herpes simplex infection,[3] which may present as neonatal conjunctivitis.

ETIOLOGY AND PATHOPHYSIOLOGY

- The most common cause of neonatal conjunctivitis is *Chlamydia trachomatis;* Other causative agents include *N gonorrhoeae* and Herpes simplex virus (HSV).[4]
- The role of bacterial agents other than *C trachomatis, N gonorrhoeae*, and HSV in the etiology of neonatal conjunctivitis is controversial; organisms such as *Staphylococcus aureus*, Group B Streptococci, and *Haemophilus influenzae*, which are occasionally isolated from newborns with conjunctivitis have been isolated from the conjunctivae of asymptomatic newborns.[1]
- Although rare, nosocomial neonatal conjunctivitis due to *Pseudomonas aeruginosa* can occur, and is related to prolonged stay in the neonatal intensive care unit.[5]
- Chemical conjunctivitis is a noninfectious cause of neonatal conjunctivitis, which most commonly occurs secondary to silver nitrate infant prophylaxis.

RISK FACTORS

- Maternal infection with *C trachomatis, N gonorrhoeae* or HSV, especially during vaginal delivery, is the most important risk factor.[4]

DIAGNOSIS

CLINICAL FEATURES

- Signs and symptoms vary from mild erythema and watery eye discharge to severe eyelid swelling and purulent eye drainage, sometimes with chemosis (conjunctival edema) and formation of pseudomembranes (**Figures 72-1** to **72-4**).[4,6,7]

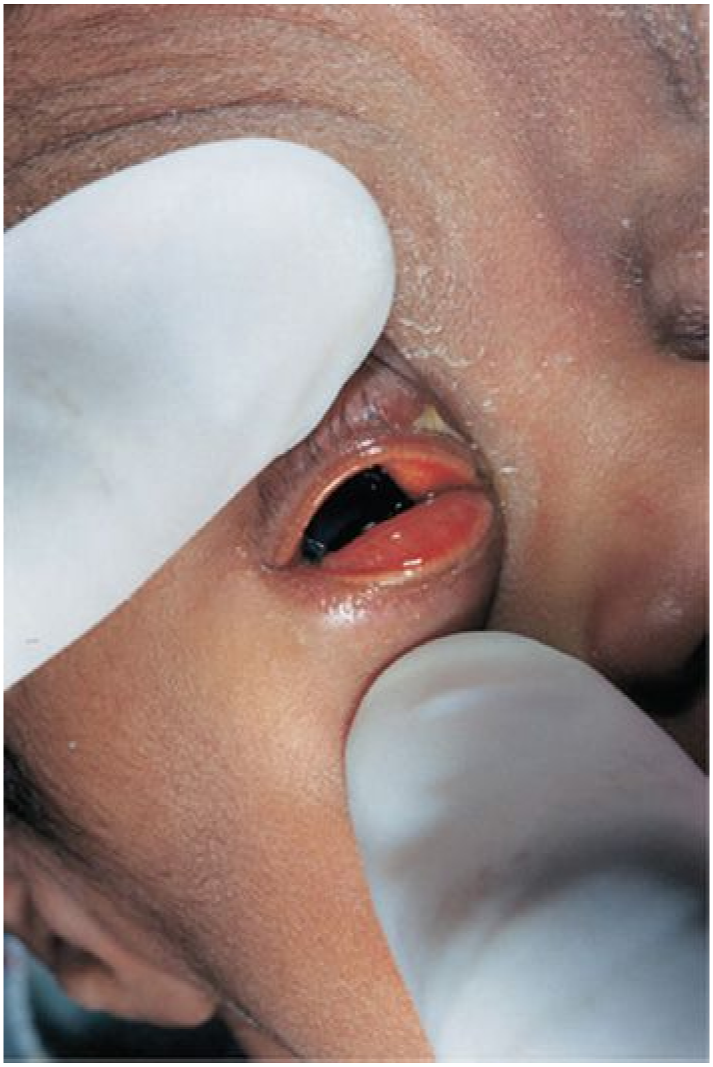

FIGURE 72-3 Chlamydia conjunctivitis in a neonate. (*Used with permission from Shah SS: Pediatric Practice: Infectious Diseases,* *www.accesspediatrics.com*, *and Shah BR, Lucchesi M. Atlas of Pediatric Emergency Medicine, McGraw-Hill*.)

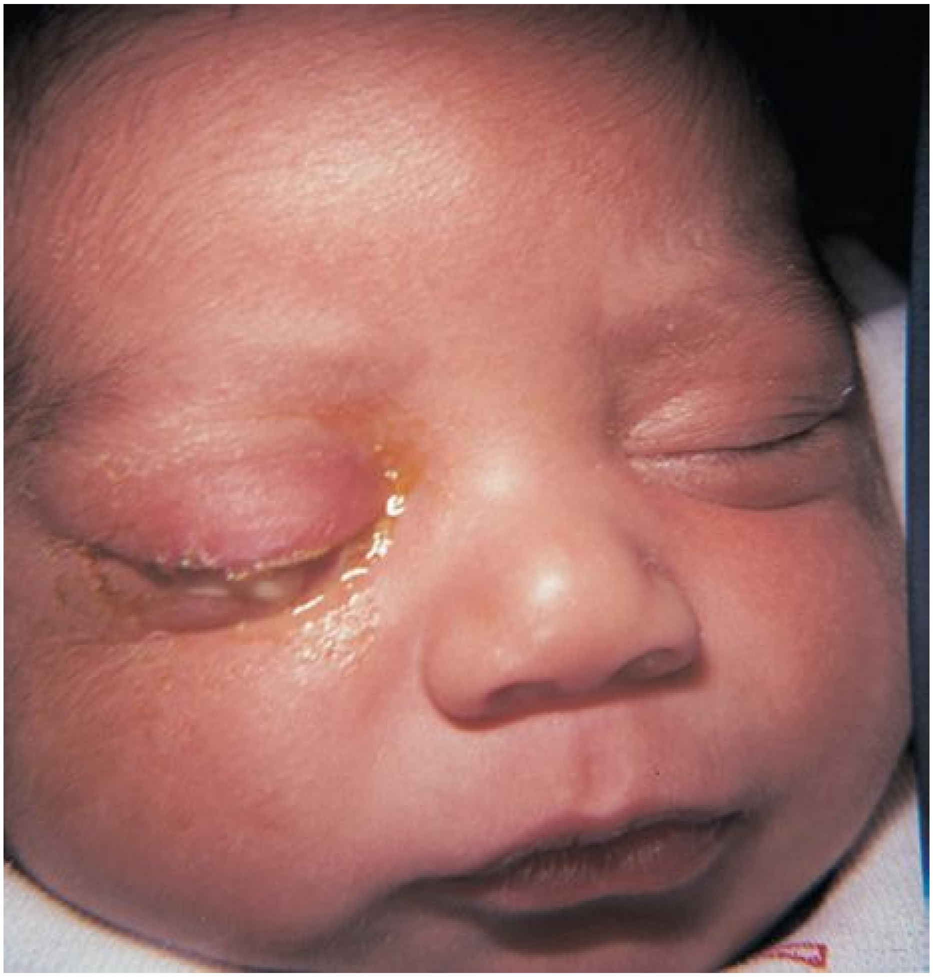

FIGURE 72-4 Neonate with gonococcal conjunctivitis. Note the purulent drainage and eyelid edema. (*Used with permission from Shah SS: Pediatric Practice: Infectious Diseases, www.accesspediatrics.com, and Shah BR, Lucchesi A. Atlas of Pediatric Emergency Medicine, McGraw-Hill*.)

- Systemic signs or symptoms may indicate disseminated gonococcal infection, disseminated HSV infection, or sepsis.[3,6]
- *N gonorrhoeae* causes very severe infection and may lead to ulceration and scarring of the eye if untreated.
- Gonococcal conjunctivitis presents early in life (2 to 7 days of life), while conjunctivitis secondary to *C trachomatis* and other pathogens usually presents in the second week of life.[7]
- Chemical conjunctivitis usually occurs in the first 24 hours of life, and has been associated with eye prophylaxis with silver nitrate, which is no

longer available for use in the US.[7]

- Neonatal HSV conjunctivitis may be the presenting feature of neonatal HSV infection involving the skin, eyes, and mucous membranes.[3]

DISTRIBUTION

- The conjunctivitis is usually bilateral, but can be unilateral.[4,6]
- Concurrent involvement of the skin and mucus membranes is common with HSV infection.

LABORATORY TESTING

- Gram stain of eye discharge that reveals intracellular gram-negative diplococci is highly suggestive of gonococcal conjunctivitis (**Figure 72-2**); culture of the organism confirms the diagnosis.
- Antigen detection tests for *C trachomatis*, such as Direct Fluorescent Antibody (DFA) and Enzyme Immunoassay have high specificity and sensitivity. These tests are approved by the US Food and Drug Administration (FDA) for the diagnosis of Chlamydial conjunctivitis.[9]
- Nucleic Acid Amplification Tests (NAAT) have not been approved by FDA for diagnosis of Chlamydial or gonococcal neonatal conjunctivitis.[7]
- Blood and cerebrospinal fluid cultures should be obtained when gonococcal infection is suspected or confirmed, to rule out disseminated disease.[4,7]
- Specimens from the conjunctivae and skin/mucus membranes lesions should be sent for HSV viral culture when HSV infection is suspected in a newborn. A DFA, which can provide a rapid diagnosis, can also be performed from suspicious lesions. DFA is highly specific but less sensitive than viral culture for detecting HSV.[3]

DIFFERENTIAL DIAGNOSIS

- Chemical conjunctivitis—Usually occurs in the first 24 hours of life, has a less severe course, and often resolves within 48 hours without specific treatment; a history of use of ocular silver nitrate prophylaxis is usually elicited.[7]
- Nasolacrimal duct obstruction—See Chapter 14, Nasolacrimal Duct Obstruction.
- Foreign body—Rarely can cause conjunctival erythema and drainage. History and unilateral presentation helpful in distinguishing from other causes.

MANAGEMENT

NONPHARMACOLOGICAL

- Frequent eye irrigation to prevent damage and scarring to the eye is essential in the management of gonococcal conjunctivitis.[4,6,7] SOR Ⓐ
- Chemical conjunctivitis is managed expectantly, and usually resolves spontaneously within 24 to 48 hours.

MEDICATIONS

- Oral erythromycin for 14 days is recommended by the American Academy of Pediatrics (AAP) for the treatment of *Chlamydial* conjunctivitis.[7] SOR Ⓐ
- Although an association between the use of erythromycin in neonates and infantile hypertrophic pyloric stenosis (IHPS) has been described,[10] there is a lack of adequate data with the use of other antimicrobial agents; thus, erythromycin continues to be the treatment of choice.

- Intravenous ceftriaxone is the treatment of choice for gonococcal conjunctivitis, given in a single dose for isolated ophthalmia neonatorum and for 7 to 14 days for disseminated gonococcal infection.[4,7] SOR A
- The treatment of conjunctivitis caused by other pathogens depends on the likelihood of true infection and the pathogen involved.
- Neonatal HSV infection confined to the eyes, skin, and mucus membranes should be treated with intravenous acyclovir for a minimum of 14 days. A longer duration is required for disseminated or central nervous system involvement.[3,7] SOR A

REFERRAL

- Ophthalmologists should be involved in the management of infants who have ophthalmia neonatorum.

PREVENTION AND SCREENING

- Maternal screening and treatment of maternal chlamydial and gonococcal infections during pregnancy decrease the rate of transmission to the newborn, and therefore, decrease the risk of neonatal conjunctivitis caused by these two pathogens.[8]
- Ocular prophylaxis for the neonate soon after birth is effective in preventing gonococcal conjunctivitis, but not chlamydial conjunctivitis. Topical agents used for this purpose include 0.5 percent erythromycin ointment, 1 percent tetracycline ointment, and 1 percent silver nitrate solution; however, only topical erythromycin ointment is currently available in the US.[2,8]
- Asymptomatic neonates born to mothers with untreated gonococcal infection should receive one dose of intravenous or intramuscular ceftriaxone or cefotaxime.[7,8] SOR A

- Antibiotics are not indicated for newborns born to women with untreated *C trachomatis* because of unknown efficacy of such therapy and the risk of hypertrophic pyloric stenosis in neonates. Instead, the newborn should be monitored for signs of infection and careful follow-up ensured.[7] SOR A
- Topical antibiotics are neither adequate nor necessary for treatment of gonococcal or chlamydia conjunctivitis when systemic antibiotics are used.[4,7] SOR A

PROGNOSIS

- Generally, neonatal conjunctivitis has a good prognosis if treated promptly and appropriately.[4,6]
- Without adequate treatment, neonatal conjunctivitis may result in corneal scarring and vision impairment. This is especially true of conjunctivitis caused by *N gonorrhoeae* or HSV infection.[3,4,6,7]

FOLLOW-UP

- Newborns born to mothers who have *Chlamydia* infection should be followed closely for signs of conjunctivitis and treated accordingly if they develop such manifestations.
- *C trachomatis* may also cause pneumonia in the neonatal period, with or without history of conjunctivitis. Chlamydial pneumonitis, characterized by cough and tachypnea, usually becomes apparent at 4 to 12 weeks of life.[1,7]

PATIENT EDUCATION

- Parents are encouraged to seek medical advice immediately if a newborn baby develops signs or symptoms of conjunctivitis.
- The diagnosis of chlamydial or gonococcal conjunctivitis in a newborn warrants screening and appropriate treatment of sexually transmitted infections in the mother and her sexual partner.[8]

73 ABDOMINAL WALL DEFECTS

Jose Lozada, MD
Anthony Stallion, MD

The normal abdominal wall is formed by infolding of the cranial, caudal, and two lateral embryonic folds. These folds form in the 4th week of development as a combination of the parietal layer of lateral plate mesoderm and overlying ectoderm. As they move ventrally to meet in the midline, rates of cell proliferation and fusion in the folds differ. This fusion process between the folds is complex, involving cell-to-cell adhesion, cell migration, and cell reorganization. Simultaneously, as the abdominal wall is forming, the rapid growth of the intestinal tract leads to its herniation through the umbilical ring into the yolk sac from the 6th to the 10th week of gestation. By the 10th to 12th week of gestation, the intestine returns to the abdominal cavity in a well-coordinated pattern. This results in normal intestinal rotation and fixation, followed by complete formation of the abdominal wall.[1]

Abnormal formation of the abdominal wall can result in omphalocele and possibly gastroschisis, which are discussed in succession.

GASTROSCHISIS

PATIENT STORY

A term newborn infant is found to have protrusion of the abdominal wall, involving the viscera (**Figure 73-1**). A prenatal diagnosis of gastroschisis had been made by ultrasound and the mother was referred to a high-risk obstetrical service for management. The infant was born via vaginal delivery and upon delivery was taken to the neonatal intensive care unit for immediate resuscitation and management. The family had met with the pediatric surgeon and neonatal intensive care team prior to the delivery. The infant underwent successful surgical repair for the defect. After a 5-week hospital course, the infant was discharged home with good bowel function.

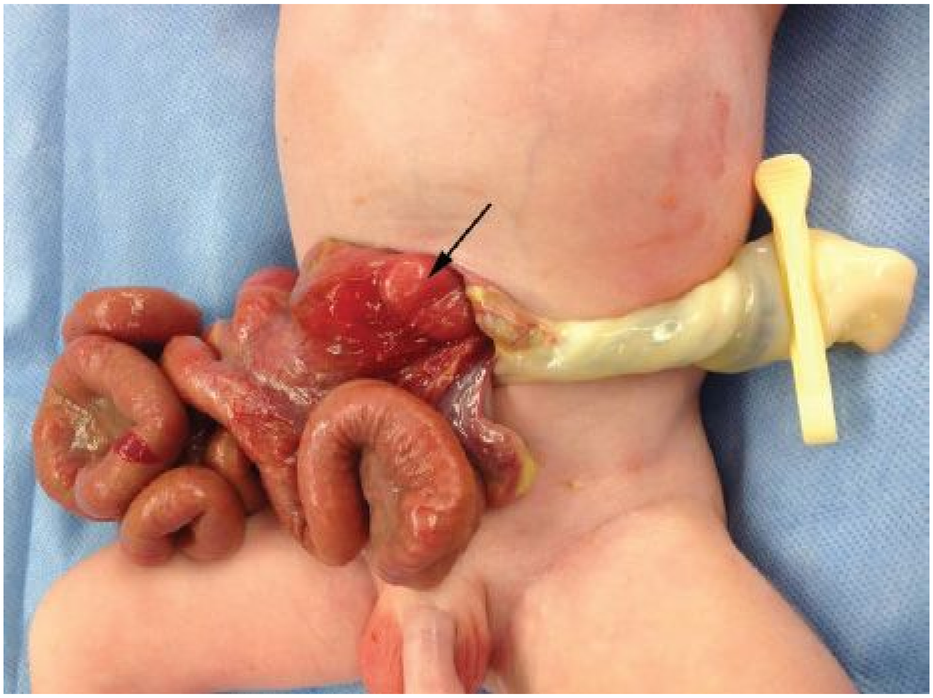

FIGURE 73-1 Newborn infant with gastroschisis. Note the evisceration occurring to the right of the umbilical cord. In addition to small intestine, his left testis (*arrow*) can also be appreciated as part of the exstrophy. (*Used with permission from Anthony Stallion, MD.*)

INTRODUCTION

Gastroschisis is a full-thickness defect in the abdominal wall, typically to the right of umbilical cord (**Figure 73-1**), where a variable amount of intestine and/or other organs may be herniated through the abdominal wall without a membrane or covering.[2,3]

EPIDEMIOLOGY

- The incidence of gastroschisis seems to be increasing worldwide and is approaching 3 to 4 per 10,000 births in endemic areas.[4]
- Recent epidemiologic studies have found a strong association between the occurrence of gastroschisis and young maternal age. However, a clear cause of gastroschisis has yet to be determined.[4,5]

ETIOLOGY AND PATHOPHYSIOLOGY

- The cause of a gastroschisis is unknown.
- Several theories have been proposed to explain the unique abdominal wall defect through which abdominal organs may eviscerate early in gestation.[6] These theories include:
  - Localized failure of mesoderm formation.
  - Rupture of the amnion at the umbilical ring.
  - Abnormal involution of the right umbilical vein.
  - Disruption of the right vitelline artery with subsequent localized body wall ischemia.
  - Abnormal body wall folding.
- Gastroschisis does not appear to be strongly associated with other congenital abnormalities. It is unclear if this represents evidence that gastroschisis is not a primary developmental defect.

RISK FACTORS

- Young maternal age.

DIAGNOSIS

PRENATAL DIAGNOSIS

- Abdominal wall defects are often diagnosed before birth by ultrasound. The specificity is greater than 95 percent, with sensitivity being more variable due to operator variability.[7]
- A study performed on pregnant women whose fetuses had known ventral wall defects found that there was an increase in serum alpha-fetoprotein levels.[8]

CLINICAL FEATURES

- About 10 percent of babies with gastroschisis will have intestinal stenosis or atresia likely stemming from vascular insufficiency to the bowel; this insufficiency could occur early at the time of gastroschisis development or later from volvulus or compression of the mesenteric vascular pedicle against a narrowing abdominal wall ring.
- Other associated anomalies, such as chromosomal abnormalities, are uncommon.[9,10]

DIFFERENTIAL DIAGNOSIS

- Omphalocele—see the following section.

MANAGEMENT

PRENATAL MANAGEMENT

- The most common associated risks for a fetus with gastroschisis include intrauterine growth retardation (IUGR), oligohydramnios, premature delivery, and fetal death.
- Because of these associated risks, the family should undergo high-risk obstetrics care connected to a specialized pediatric center to optimize the post-partum outcome.
- If prenatally diagnosed, the family should be introduced to the pediatric surgeon.
- While there are no current intrauterine interventions, this introduction allows the family to be counseled about the condition, its treatment and prognosis.

POST-PARTUM MANAGEMENT

- Initial airway, breathing, and circulation evaluation and intervention if necessary.
- Once this initial assessment and care has occurred, the next step involves placing the exposed viscera and entire lower half of the dried baby in a transparent plastic bag, commonly called a bowel bag. This allows the preservation of body heat and keeps the bowel moist. Care must be taken to support the bowel with moist gauze so that it does not fall to either side of the body and cause venous congestion and subsequent edema. This can hinder the ability to attain primary closure.
- A small hole can be made if necessary for a lower extremity to allow for intravenous access.
- Ensure appropriate gastric decompression.
- Given the risk of volume loss, aggressive hydration should be part of the initial management.

SURGERY

- If a primary closure is not possible, or if there are signs of bowel ischemia, a “silo” may be placed in the operating room (**Figure 73-2**). A “silo” is a tubular or inverted funnel-like structure with synthetic material to give temporary cover to the abdominal viscera and allow for serial reduction of the organs into the abdominal cavity. The “silo” protects the intestine and other viscera outside the abdomen while they are slowly reduced into the abdominal cavity with daily gentle pressure.

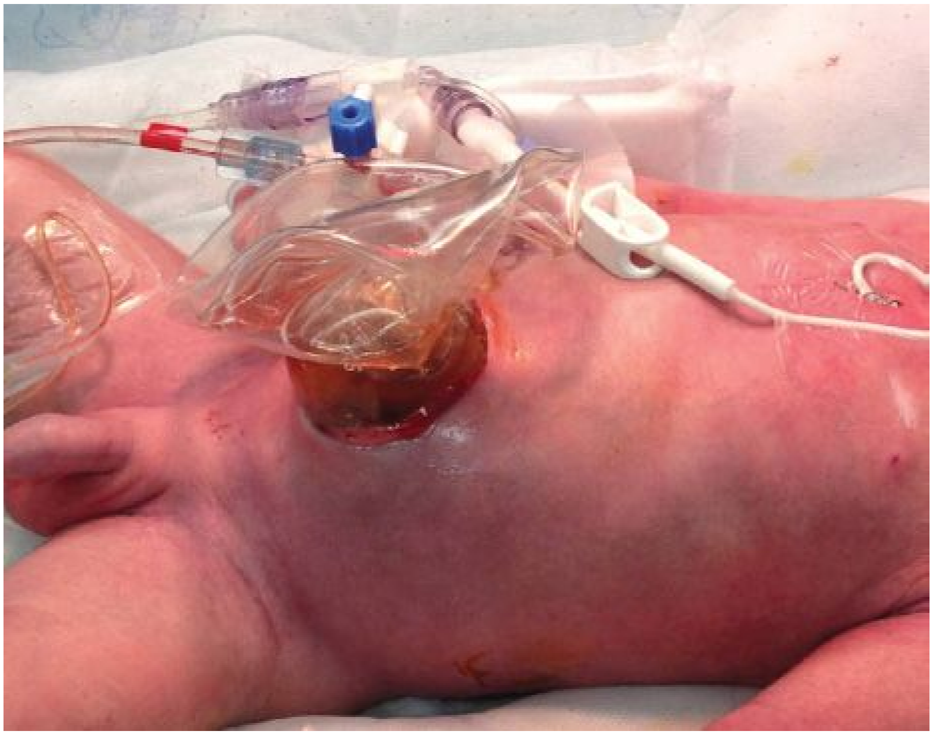

FIGURE 73-2 Intraoperative placed silo on same patient as **Figure 73-1**. (*Used with permission from Anthony Stallion, MD.*)

- This serial reduction of bowel has the goal of completely reducing the exposed viscera by the seventh to tenth day of life.
- Another approach that is being used more recently is the “pre-fashioned” or “pre-manufactured silo.” A pre-fashioned silo is a tubularized synthetic material that comes formed from the manufacturer and does not require any suturing and can be placed at the bedside.
- This is followed by operative closure of the abdominal wall primarily or with a synthetic patch to avoid excessive intra-abdominal pressure.

REFERRAL

Referral to high-risk obstetrics care connected to a specialized pediatric center and pediatric surgery is imperative.

PREVENTION AND SCREENING

- Abdominal wall defects are often diagnosed before birth by ultrasound.

PROGNOSIS

- The outcome of patients with gastroschisis depends in great part to the condition of the bowel, size of the defect, and ability to reduce the viscera in a timely fashion.
- Survival has been reported to be between 90 and 95 percent, with the main cause of death being bowel loss and intestinal necrosis.[11]
- The risk for necrotizing enterocolitis is high, manifested by pneumatosis intestinalis (gas in the bowel wall) on radiographic imaging. This may occur in the postoperative period when feedings are being advanced.[12]
- The hospitalization period is usually long. This is mainly due to delayed return of bowel function and advancing to full enteral feedings, which is usually a combination of oral and tube feedings. Many patients have some degree of difficulty nippling since they do not feed at birth and have a prolonged period without oral intake.
- Approximately 40 percent of patients are discharged within one month of surgical intervention, 36 percent between one to two months, and 25 percent greater than two months.[13]
- Overall, long-term gastrointestinal function is good. There are occasional patients with long-term intolerance of feedings, mainly due to

dysmotility.[14] There is also a reported 5 to 10 percent long-term risk of adhesive obstructions.[15]

OMPHALOCELE

PATIENT STORY

A diagnosis of omphalocele was made on fetal ultrasound in an infant who was delivered by Cesarean section at 37 weeks of gestation due to onset of labor. The newborn infant was noted to have a large midline abdominal wall defect with herniated intestines covered by a membrane. The umbilical vessels inserted directly into the membrane (**Figure 73-3**). The infant received immediate resuscitation including nasogastric compression and respiratory support. The infant’s work-up included a chest x-ray, cardiac echocardiogram, and renal ultrasound to rule out associated congenital anomalies. The results of all these studies were normal. The patient was taken electively 24 hours after birth for surgical repair. The repair required placement of a biosynthetic patch to prevent excessive intra-abdominal pressure with closure. The skin was able to be closed primarily. The patient’s postoperative course was uneventful except for a prolonged ileus. He was begun on enteral feeds on postoperative day #20. The patient reached full feeds on postoperative day #34 and was discharged home on all oral feedings on postoperative day #40.

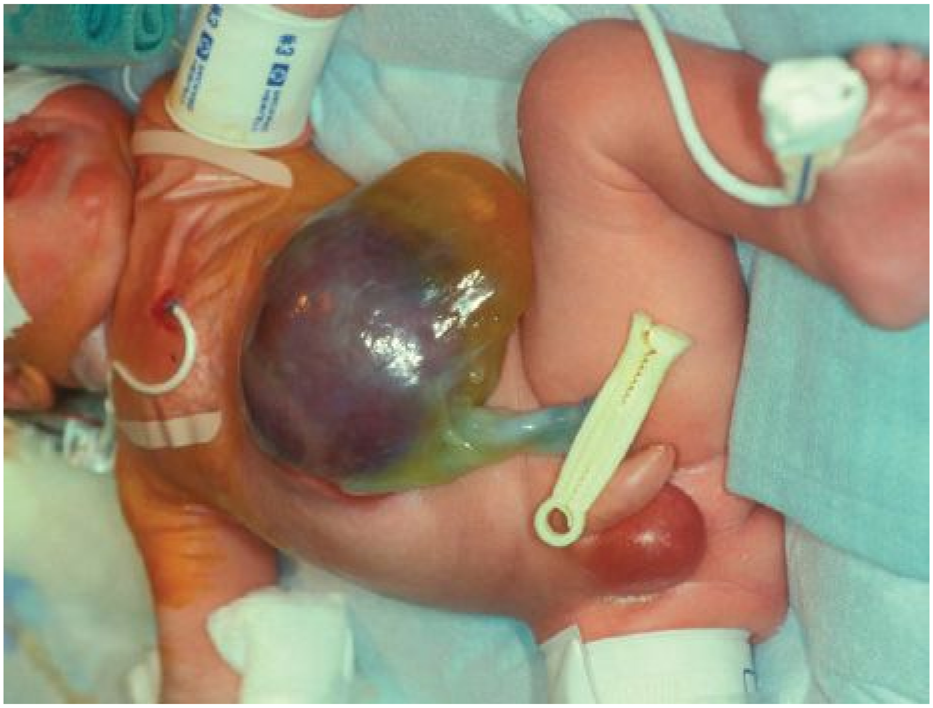

FIGURE 73-3 Newborn infant with an omphalocele. Note that the umbilical vessels insert directly into the membrane. (*Used with permission from Anthony Stallion, MD.*)

INTRODUCTION

An omphalocele is a midline abdominal wall defect of variable size in which the herniated viscera is covered by a membrane consisting of peritoneum on the inner surface, amnion on the outer surface, and Wharton’s jelly between the layers. The umbilical vessels insert directly into the membrane and not on the abdominal wall. This is a true midline developmental defect. There is failure of complete closure of the two cranio-caudal and two lateral folds not fully meeting in the midline. The defect may be centered in the upper, middle, or lower abdomen. The herniated viscera within the omphalocele may include any abdominal organ and is largely dependent on the defect size and location.

SYNONYMS

Exomphalos.

EPIDEMIOLOGY

- The incidence of omphalocele ranges between 1.5 and 3 per 10,000 births.
- Most cases are sporadic but there are rare familial cases of omphalocele.[16]

ETIOLOGY AND PATHOPHYSIOLOGY

- In omphalocele, the intestine that is physiologically herniated into the umbilical cord in the 6th to 10th weeks does not return to the abdominal cavity.
- The cause of this failure of intestinal return to the abdomen is unknown but is thought to be associated with defects in body wall folding.
- As this is a true developmental defect, there is a high association of associated congenital anomalies.
- When there is a predominately cranial fold deficit, the result is an epigastric omphalocele. This abnormality may be associated with additional cranial fold abnormalities, particularly midline developmental defects, including anterior diaphragmatic hernias, sternal clefts, pericardial defects, and cardiac defects (Pentalogy of Cantrell).
- When there is a predominately caudal fold deficit, the omphalocele may be associated with bladder or cloacal exstrophy (**Figure 73-4**) or other anorectal malformations.

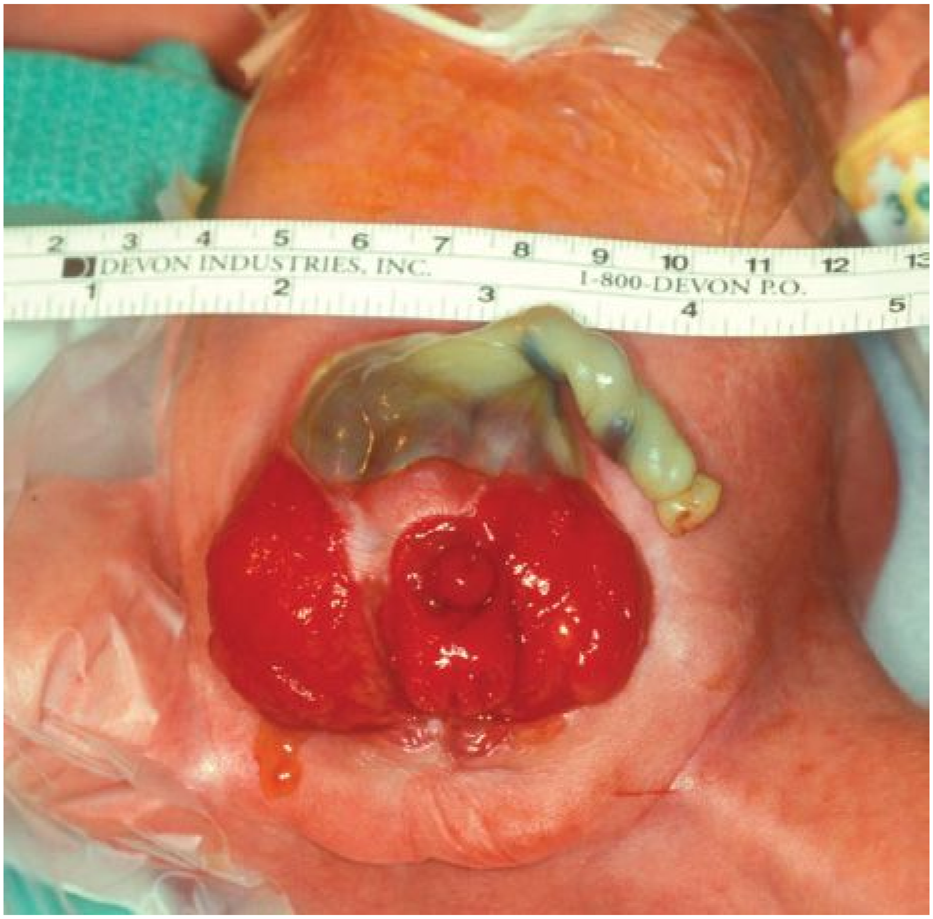

FIGURE 73-4 Omphalocele with predominately caudal fold deficit and an associated cloacal exstrophy. (*Used with permission from Anthony Stallion, MD.*)

DIAGNOSIS

PRENATAL DIAGNOSIS

- Similar to gastroschisis, prenatal ultrasound after the first trimester is the gold-standard for prenatal diagnosis with similar specificity and sensitivity.
- Elevated maternal serum AFP may alert the clinician performing the prenatal care that a referral for high level ultrasound is needed.

CLINICAL FEATURES

- Fifty to seventy percent of cases of omphalocele have an associated anomaly:[17]
  - Thirty percent of cases have associated chromosomal anomalies.
    - Trisomy 13, Patau syndrome.
    - Trisomy 14.
    - Trisomy 15.
    - Trisomy 18, Edwards syndrome.
    - Trisomy 21, Down syndrome.
  - Thirty to fifty percent have associated cardiac anomalies.
  - Syndromic anomalies may occur.
  - Beckwith-Wiedemann syndrome (10% of infants with omphalocele have this syndrome). This syndrome is an overgrowth syndrome that may present with macrosomia, macroglossia, visceromegaly, and renal abnormalities along with the omphalocele.
  - Pentalogy of Cantrell (omphalocele, anterior diaphragmatic hernias, sternal clefts, pericardial defects, and cardiac defects).
- Associated complications during pregnancy:
  - Intrauterine growth restriction (5 to 35%).
  - Premature delivery (5 to 60%).
  - Loss of pregnancy.

LABORATORY TESTING

- Chromosomal studies are warranted in all cases because of associated congenital anomalies.

IMAGING

- Ultrasound evaluation and fetal echocardiography for other structural defects is recommended.
- After delivery obtain an abdominal ultrasound and cardiac echocardiogram to confirm prenatal findings and rule out missed

anomalies.

DIFFERENTIAL DIAGNOSIS

- Gastroschisis—see the previous section.

MANAGEMENT

PRENATAL MANAGEMENT

- Once discovered by fetal ultrasound, further diagnostic evaluation should include:
  - Fetal ultrasound evaluation for other structural defects.
  - Fetal echocardiography.
  - Chromosome determination.
- There is no indication for early delivery, although caesarian section is recommended for infants with a large omphalocele to prevent sac rupture or dystocia during labor.

NEWBORN RESUSCITATION

- Initial ABC resuscitation.
- Placement of nasogastric tube for gastric decompression.

SURGERY

- If the covering sac is intact, there is no urgency to perform operative closure.

- If intact, a complete evaluation for associated defects should be done before any operative intervention. The sac should be supported or suspended to prevent venous congestion of the viscera, edema, or ischemia. This will aid in later attempts at reduction.
- With small defects, the membrane can be excised, and the defect closed primarily. Any membrane adherent to the liver may be left in place.
- Larger defects can be treated similarly to gastroschisis, with excision of the external membrane, followed by the placement of a “silo” with serial reduction of the abdominal viscera over 7 to 10 days.
- For very large defects relative to the size of the infant, there may be resulting loss of abdominal domain and reduction may not be possible. In this instance, the membrane may be treated with a topical agent such as silver sulfadiazine to promote desiccation, contraction and epithelialization of the membrane. The visceral contents may be slowly reduced with loose elastic bandages over time with delayed closure up to 2 years after initial treatment.[18]
- Also, long-term consideration can be given to placement of tissue expanders and eventual component separation to assist in eventual closure of the giant defects.

REFERRAL

Referral to high-risk obstetrics care connected to a specialized pediatric center with pediatric surgery is imperative.

PREVENTION AND SCREENING

- Prenatal ultrasound after the first trimester is the gold-standard for prenatal diagnosis.
- Elevated maternal serum AFP may also be useful.

PROGNOSIS

- Overall, outcomes of children after omphalocele repair will depend largely on the presence of other congenital anomalies, especially cardiac anomalies, and other comorbidities.

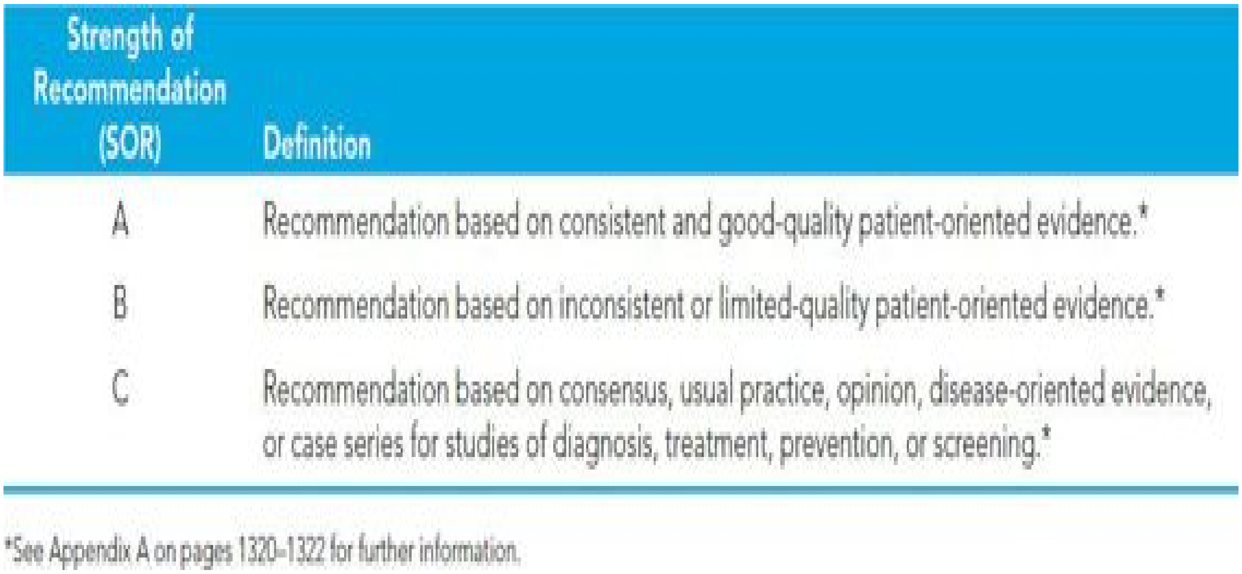
PART 12

ADOLESCENT PROBLEMS



Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1320–1322 for further information.

74 OVERVIEW OF VAGINITIS

E.J. Mayeaux, Jr., MD

PATIENT STORY

An 18-year-old female presented to her physician with vulvar and vaginal itching associated with a vaginal discharge. On examination, the patient is noted to have redness and excoriations on her vulva (**Figure 74-1**). She also had a thick white discharge was seen covering cervix and vaginal sidewallson speculum exam. The pH of the discharge was 4.2, and <10 percent of the epithelial cells on her wet prep were clue cells (**Figure 74-2**), but yeast and hyphae were noted. She was diagnosed with candida vulvovaginitis and was treated with oral fluconazole.

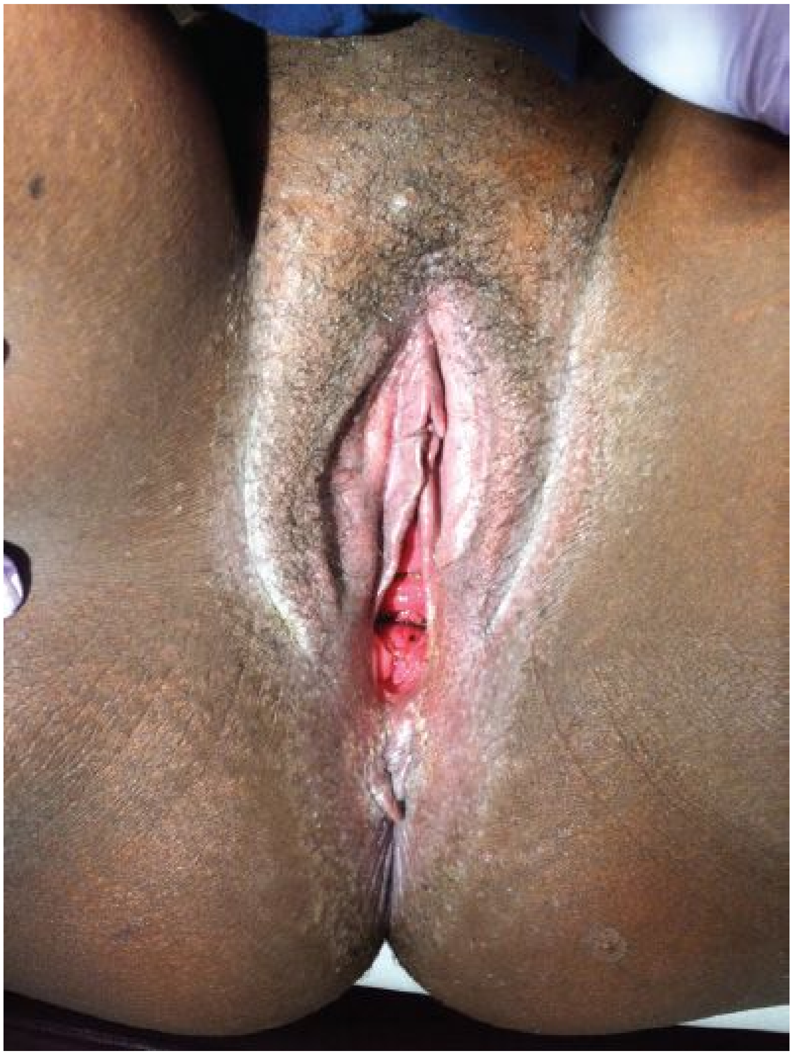


FIGURE 74-1 Candida vulvovaginitis in an 18-year-old female who complained of severe vaginal and vulvar itching. Her vulva demonstrated redness with excoriations. Note the satellite lesions near the borders of the inflamed areas. She was diagnosed with candida vulvovaginitis. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

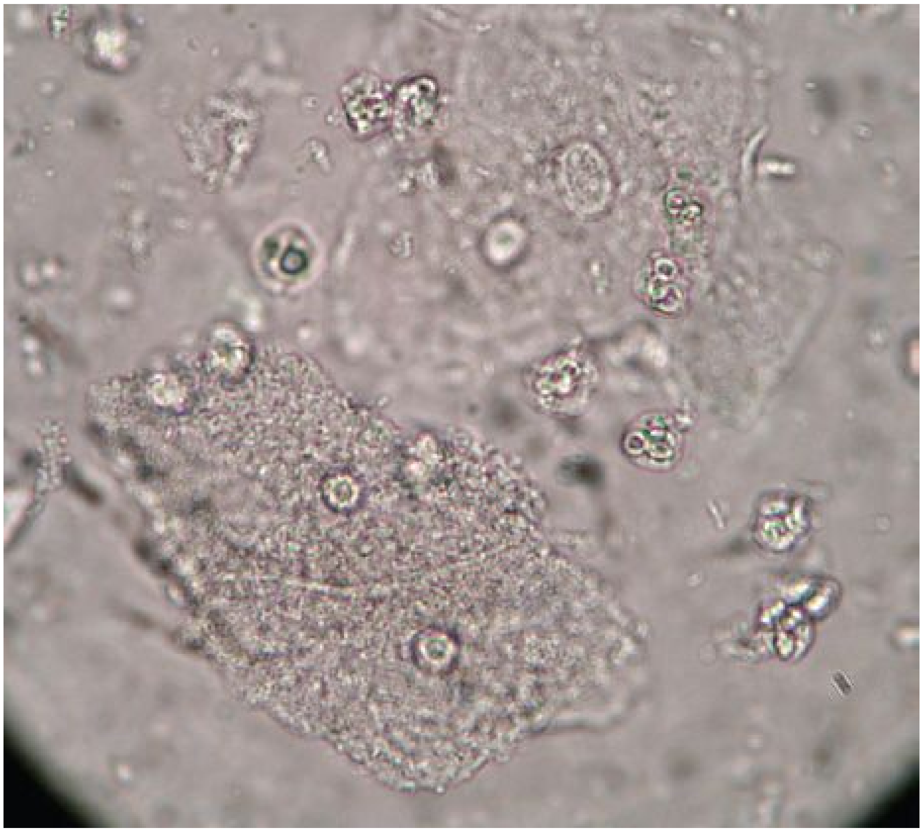

FIGURE 74-2 Clue cells on a wet mount of vaginal discharge in saline under high-power light microscopy. Note the presence of vaginal epithelial cells, smaller white blood cells (polymorphonucleocytes), and bacteria. The bacteria are the coccobacilli of *Gardnerella vaginalis* covering the cell membranes of the two vaginal epithelial cells near the lower end of the field. These are clue cells seen in patients with bacterial vaginosis. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Vaginal discharge is a frequent presenting complaint in primary care. The three most common causes in adolescents and adults are bacterial vaginosis, candidiasis, and trichomoniasis. Providers must refrain from "diagnosing" a vaginitis based solely on the color and consistency of the discharge, as this may lead to misdiagnosis and may miss concomitant infections.[1]

Vulvovaginal complaints in prepubertal children may be result from infection, congenital abnormalities, trauma, or dermatologic conditions. Vaginitis is the most commont gynecologic problem in prepubertal girls, often presenting with symptoms including vaginal discharge, erythema, soreness, pruritus, dysuria, or bleeding.[2]

Adolescence is a developmental period with rapid changes in physical characteristics, sexual development, emotional development, and sexual activity. These changes may result in potential increased risk for acquiring sexually transmitted diseases.

EPIDEMIOLOGY

The reported rates of chlamydia and gonorrhea are highest among females ages 15 to 19 years. Adolescents are at greater risk for sexually transmitted diseases (STDs) because they frequently have unprotected intercourse, are biologically more susceptible to infection, are often engaged in partnerships of limited duration, and face multiple obstacles to utilization of health care.[1]

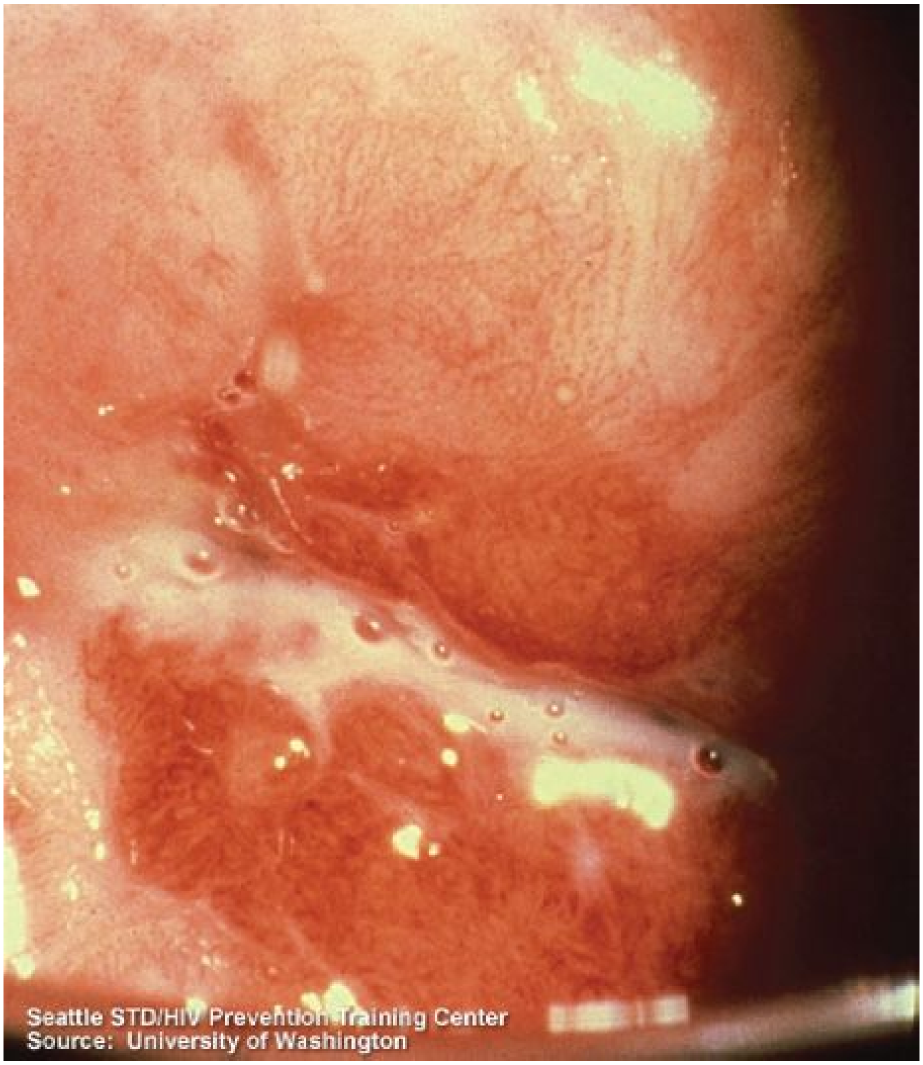
Cross-sectional data from the 2003 to 2004 US National Health and Nutrition Examination Survey (NHANES) shows 24 percent of female adolescents (aged 14 to 19 years) had laboratory evidence of infection with human papillomavirus (HPV, 18%), Chlamydia trachomatis (4%), Trichomonas vaginalis (3%), herpes simplex virus type 2 (HSV-2, 2%), or Neisseria gonorrhoeae. Among girls who reported ever having had sex, 40 percent had laboratory evidence of one of the four STDs, most commonly HPV (30%) and chlamydia (7%).[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- The quantity and quality of normal vaginal discharge in healthy adolescents vary. Physiologic leukorrhea refers to generally nonmalodorous, mucousy, white or yellowish vaginal discharge in the absence of a pathologic cause. It is not accompanied by signs and symptoms, such as pain, pruritus, burning, erythema, or tissue friability. However, slight malodor and irritative symptoms can be normal for some women at certain times.[4] Physiologic leukorrhea is usually a result of estrogen-induced changes in cervicovaginal secretions.

- Nonspecific vulvovaginitis accounts for 25 to 75 percent of vulvovaginitis in prepubertal girls.[5] Potential factors that increase their risk of vulvovaginitis in children include poor hygiene, lack of labial development, unestrogenized thin mucosa, more alkaline vaginal pH, bubble baths, deodorant soaps, obesity, and tight-fitting clothes.
- Foreign bodies in children can cause acute and chronic recurrent vulvovaginitis. Toilet paper is the most common foreign body found in the vaginas of children but small toys, hair bands, beads, and paper clips are also common.[6]
- Sexual abuse may also result in nonspecific vulvovaginitis. Not finding STDs does not rule out abuse.[7]
- Noninfectious causes of vaginitis include irritants (e.g., scented panty liners, spermicides, povidone-iodine, soaps and perfumes, and some topical drugs) and allergens (e.g., latex condoms, topical antifungal agents, and chemical preservatives) that produce hypersensitivity reactions.
- Before starting an examination, determine whether the patient douched recently, because this can lower the yield of diagnostic tests and increase the risk of pelvic inflammatory disease.[8] Patients who have been told not to douche will sometimes start wiping the vagina with soapy washcloths, which also irritates the vagina and cervix and may cause a discharge. Douching is associated with increases in bacterial vaginosis and acquisition of sexually transmitted infections when exposed. However, recent studies indicate that douching with plain water once a week or less did not disturb normal flora.[9,10]
- There are many causes of vaginitis. Infectious causes include bacterial vaginosis (40% to 50% of cases) (**Figure 74-2**), vulvovaginal candidiasis (20% to 25%) (**Figure 74-1**), and trichomonas (15% to 20%) (**Figure 74-3**).[11] Less common causes include atrophic vaginitis, cytolytic or desquamative inflammatory vaginitis, streptococcal vaginitis, ulcerative

vaginitis, and idiopathic vulvovaginal ulceration associated with HIV infection.



Seattle STD/HIV Prevention Training Center
Source: University of Washington

FIGURE 74-3 Colposcopic view of the cervix in a patient infected with trichomonas vaginalis. Note the frothy discharge with visible bubbles and the cervical erythema. (*Used with permission from Seattle STD/HIV Prevention Training Center, University of Washington*.)

- *Streptococcus pyogenes* is the most commonly identified pathogen in prepubertal girls occuring in about 20 percent of girls with vulvovaginitis.[7]
- Pinworms infestation can cause vulvar symptoms, especially itching (see Chapter 179, Intestinal Worms and Parasites). Children with recurrent

episodes of vulvar and/or perianal itching, especially when most symptomatic at night, should be examined for pinworms and possibly treated empirically.[7]

- In addition to classic STDs, *Mycoplasma genitalium* infections are increasingly recognized as causes of sexually transmitted discharge in adolescents and young adults.[12]
- More rare noninfectious causes include chemicals, allergies, hypersensitivity, contact dermatitis, trauma, postpuerperal atrophic vaginitis, erosive lichen planus, collagen vascular disease, Behçet syndrome, and pemphigus syndromes.

DIAGNOSIS

CLINICAL FEATURES

- Examine the external genitalia for irritation or discharge (**Figure 74-1**). Speculum examination is done to determine the amount and character of the discharge (**Figure 74-3**). A chlamydia and gonorrhea test should always be done in sexually active females with a vaginal discharge. Look closely at the cervix for discharge and signs of infection, dysplasia, or cancer (**Figures 74-3** and **74-4**). Bimanual examination may show evidence of cervical, uterine, or adnexal tenderness. **Table 74-1** shows diagnostic values for examination of vaginitis.

TABLE 74-1 Diagnostic Values for Vaginal Infections

Diagnostic Criteria	Normal	Bacterial Vaginosis	Trichomonas Vaginitis	Candida Vulvovaginitis
Vaginal pH	3.8 to 4.2	>4.5	4.5	<4.5 (usually)
Discharge	White, thin, flocculent	Thin, white, gray	Yellow, green, or gray, frothy	White, curdy, "cottage cheese"
Amine odor "whiff" test	Absent	Fishy	Fishy	Absent
Microscopic	Lactobacilli, epithelial cells	Clue cells, adherent cocci, no white blood cells	Trichomonads, white blood cells >10/hpf	Budding yeast, hyphae, Pseudohyphae

Used with permission from E.J. Mayeaux, Jr., MD.

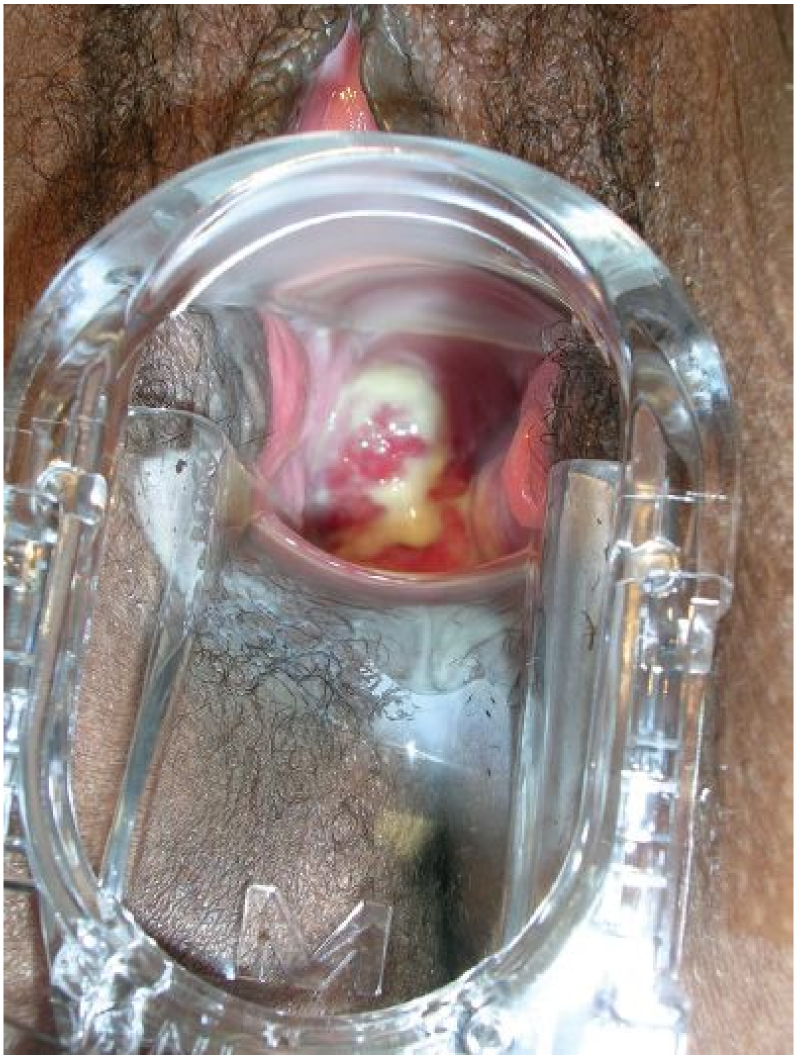


FIGURE 74-4 Speculum exam showing mucopurulent discharge with a friable appearing cervix in a patient with chlamydia cervicitis. (*Used with permission from Richard P. Usatine, MD.*)

- Vaginal pH testing can be helpful in the diagnosis of vaginitis. The pH can be checked by applying pH paper to the vaginal sidewall. Do not place the pH paper in contact with the cervical mucus. A pH above 4.5 is seen with menopausal patients, trichomonas infection, or bacterial vaginosis.
- Wet preps are obtained by applying a cotton-tipped applicator to the vaginal sidewall and placing the sample into normal saline. A drop of the suspension is then placed on a slide and examined for the presence and number of white blood cells (WBCs), trichomonads, candidal hyphae, or clue cells (**Figure 74-2**).
- A KOH prep is made by adding a drop of KOH solution to a drop of saline suspension of the discharge. The KOH lyses epithelial cells in 5 to 15 minutes (faster if the slide is warmed briefly) and allows easier visualization of candidal hyphae. The use of KOH with DMSO allows for quicker lyses of the epithelial cells and immediate examination of the smear.
- Another diagnostic procedure is the “whiff” test, which is performed by placing a drop of KOH on a slide of the wet prep and smelling for a foul, fishy odor. The odor is indicative of anaerobic overgrowth or infection. The “whiff” test is positive if the fishy amine odor is detected during the exam and it is then not necessary to add KOH and “whiff” again.

LABORATORY TESTING

- Nucleic acid amplification tests are highly sensitive tests for *Neisseria gonorrhoeae*, *Chlamydia*, and *Chlamydia trachomatis* that can be performed on genital specimens or urine. Urine screening for gonorrhea, chlamydia, or both using nucleic acid amplification test can be used successfully in difficult-to-reach adolescents.[13]
- Newer tests are available using nucleic acid detection for multiple pathogens that cause vaginal discharge. These have the advantages of much higher sensitivity and are not affected by delays in microscopic

assessment. They also do not require providers maintain microscopic proficiency testing. They take longer to perform than classic microscopic tests.[1]

MANAGEMENT

- Management is based on the identification of the causative agent.
- Management of vaginal irritants and allergens involves identifying and eliminating the offending agents. However, irritants and allergens can often be difficult to identify.
- Health food store lactobacilli are the wrong strain and do not adhere well to the vaginal epithelium. Ingestion of live-culture, nonpasteurized yogurt does not significantly change the incidence of candidal vulvovaginitis or bacterial vaginosis.[14]
- Treatment for physiologic leukorrhea is unnecessary.
- There are multiple recommendations for nonspecific vaginitis in children once a specific etiology has been excluded:
    - Avoid leotards and sleeper pajamas. Nightgowns allow air to circulate.
    - Use cotton underpants.
    - Double-rinse underwear after washing to avoid residual irritants. Do not use fabric softeners for underwear and swimsuits.
    - Avoid tights, leotards, and leggings for daytime use. Skirts and loose-fitting pants allow air to circulate.
    - Daily warm bathing for 10 to 15 minutes. Use soap to wash regions other than the genitals just before exiting tub. Rinse the genital area well and gently pat dry.
    - Do not use bubble baths or perfumed soaps.
    - If the vulvar area is irritated, cool compresses may relieve the discomfort.
    - Wet wipes can be used instead of toilet paper for wiping. Emollients may help protect skin.

  - Review hygiene with the child. Emphasize wiping front-to-back after bowel movements.
  - Avoid letting children sit in wet swimsuits for long periods of time after swimming.
- If symptoms persist beyond two to three weeks or recur, the possibility of a foreign body or specific infection should be examined.

MEDICATIONS

- Antibiotic therapy (amoxicillin PO; topical metronidazole; or topical clindamycin) may hasten the resolution of a purulent vaginal discharge that does not respond to hygiene measures and for which other diagnoses have been excluded.
- Occasionally, a short course of estrogen cream can thicken the vaginal mucosa and make it more resistant to recurrent nonspecific infections.
- A foreign body can often be removed with irrigation with warmed fluid. The introitus may be treated with a topical anesthetic agent such as Xylocaine jelly if necessary. Examination under sedation and/or anesthesia may be necessary for extraction of larger foreign bodies and those that cannot be removed with simple irrigation.[6]

75 MUCOSAL ULCERATIVE DISORDERS IN FEMALE ADOLESCENTS

Marjan Attaran, MD

Mucosal ulcerative disorders in adolescent females can be caused by sexually transmitted as well as nonsexually transmitted diseases. In this chapter, common mucosal ulcerative disorders are discussed sequentially and include:

1. Vulvar herpes simplex virus (HSV) infection
2. Syphilis in teenage females
3. Chancroid
4. Behcet Disease

VULVAR HERPES SIMPLEX

See Chapter 114, Herpes Simplex, for information on all types of herpes simplex infections.

PATIENT STORY

A 16-year-old girl presents with vulvar swelling, pain, and difficulty urinating. She admits to being sexually active. On examination, ulcerative lesions are noted on the inner aspects of the labia minora (**Figure 75-1**). She is treated with analgesics and oral acyclovir for presumed Herpes simplex virus type 2 (HSV-2). She is also tested for other STDs including blood tests for syphilis, HIV, and urine tests for gonorrhea and chlamydia. Her culture of the lesions is positive for HSV-2 as expected. Her other tests are all negative. Her lesions resolve after 2 weeks.

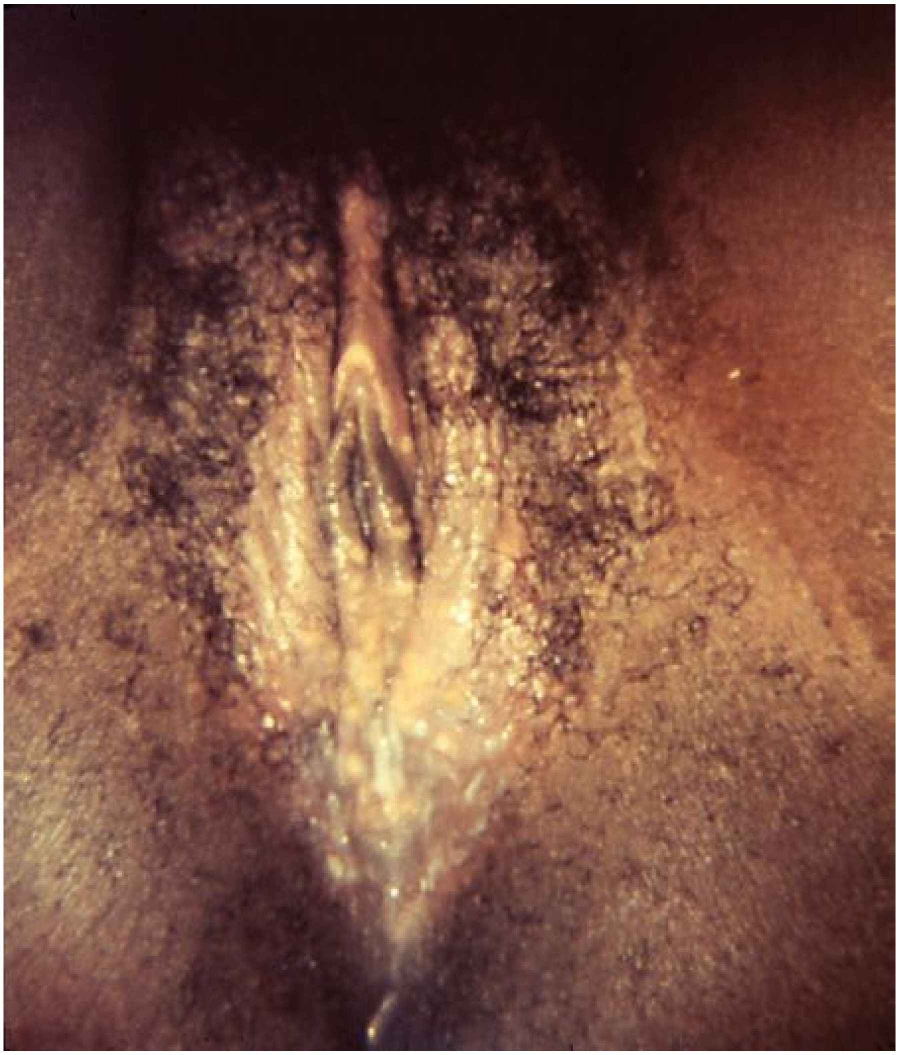

FIGURE 75-1 Tender ulcerative lesions on the vulva which are positive for herpes simplex virus infection. (*Used with permission from Centers for Disease Control/Susan Lindsley, MD.*)

INTRODUCTION

HSV-2 is a sexually transmitted infection that usually causes vesicles and ulcers in the genito-anal region. HSV-1 usually involves infections found extra-genitally. HSV-2 infections present with painful genital ulcerative lesions. HSV-1 can occur in the genito-anal region and HSV-2 can occur on the oral mucosa. There are many people with positive serologies for both types of herpes simplex that are not aware of having a “herpes infection” with symptoms.

EPIDEMIOLOGY

- The prevalence of HSV increases with age.[1–4]
- By age 15 years of age, 40 percent will be infected with HSV-1.[2]
- The prevalence of HSV-1 is greater than HSV-2 in most areas of the world and since HSV-2 is primarily sexually transmitted, it is not as common in children.
- Data from the Centers for Disease Control and Prevention (CDC) monitored through the National Health and Nutrition Examination Survey (NAHNES) found the overall prevalence of HSV-2 from 2005 to 2008 to be 16.2 percent; of those testing positive for HSV-2 infection, 81.1 percent said they had never been told by a doctor or health care professional that they had genital herpes.[2]
- In this study, seroprevalence increased with age, ranging from 1.4 percent among those aged 14 to 19 years to 26.1 percent among those aged 40 to 49 years.[2]
- HSV-2 seroprevalence is greater among women (20.9%) than men (11.5%).[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Genital herpes is usually caused by HSV-2 but may also be caused by HSV-1.

- Transmission occurs more commonly from an infected male to a female partner.
- Infection occurs as a result of exposure to mucosal tissue that has active lesions or as a result of exposure to the secretion of an individual who has active HSV infection.
- Incubation period is about 4 days but can range from 2 to 12 days.
- It may be divided into two categories: first episode versus recurrences. Patients experiencing their first outbreak may not have any antibodies to type 1 or 2 HSV or they may have an antibody to usually type 1.
- The virus usually remains in the sensory ganglia of the autonomic nervous system. Once triggered the virus can travel down the sensory nerve and reactivate the same region as the initial infection.

RISK FACTORS

- Found more commonly in females and African Americans.[2]
- Found more commonly in individuals with lower socioeconomic status.[1]

DIAGNOSIS

CLINICAL FEATURES

- Vesicles are noted on the labia minora and vestibule (**Figure 75-1**). Lesions may also be noted in the vagina and on the cervix.
- The vesicles are small, on an erythematous base, and rupture into painful shallow ulcerations.
- Skin lesions are usually preceded by prodromal symptoms that include: fever, malaise, burning, and paresthesia at the site, loss of appetite, and headaches. Lymphadenopathy may also be noted.

- Recurrences occur as a result of triggers such as stress, fatigue, and menstruation.

LABORATORY TESTING

- Viral culture may be obtained from an active lesion. In these cases, the base of the unroofed lesion must be swabbed vigorously. The cells are then evaluated for HSV infection.
- Direct fluorescent antibody (DFA)—This technique identifies the presence of viral antigens. It is rapid, sensitive, and relatively inexpensive. Tzanck smear-cells obtained from the base of a vesicle are stained and then assessed for multinucleated giant cells. This is not as specific as culture and DFA and only valuable if done by persons well trained in this testing.
- Polymerase chain reaction (PCR)—May be used to detect the presence of herpes virus DNA in the CSF when herpes encephalitis is suspected. It is used less often for genital herpes infections.
- Serologic assays—Used primarily for diagnosing recurrent infection. This is generally not helpful in acute diagnosis and management.

DIFFERENTIAL DIAGNOSIS

- Other sexually transmitted infections must be considered and include syphilis and chancroid.
- Other diagnoses to consider are candida infection, Behcet disease (as discussed in this chapter), lichen planus, lichen sclerosis, herpes zoster, and trauma. These entities can usually be distinguished based on their characteristic appearance and usual involvement in areas other than the genital tract.
- Prepubertal children who develop genital herpes must be evaluated for sexual abuse (see Chapter 9, Child Sexual Abuse).

MANAGEMENT

PREVENTION

- Patients must be educated about the mode of transmission and understand the concept of asymptomatic shedding.

MEDICATIONS

- Systemic antiviral drugs can modestly improve the signs and symptoms of herpes episodes when used to treat first clinical and recurrent episodes, or when used as daily suppressive therapy.[5]
- Antiviral drugs do not eradicate latent virus.
- Acyclovir, valacyclovir and famciclovir have been shown to provide clinical benefit for genital herpes.[5] SOR Ⓑ
- Oral acyclovir has been approved for use in children with primary genital HSV infection. The medication should be started within 6 days of onset of disease. Oral acyclovir may also be used in recurrent HSV within 2 days of onset.
- Recommended maximum dose is 80 mg/kg/day (1200 mg/day) for 7 to 10 days for a primary infection and 5 days for a recurrent infection.
- Supportive therapy may be necessary for control of pain associated with the lesions.
- At times chronic suppressive therapy may be necessary and may be more effective than episodic therapy for recurrent infection. The maximum dose is 1000 mg/day of acyclovir.

PROGNOSIS

- The treatment of genital herpes does not lead to cure.

PATIENT EDUCATION

- Patients have to be educated about the modes of transmission of herpes virus.
- Patients with active lesions need to avoid direct contact of their lesions with other individuals.
- Condoms should be used at all other times.
- They should be educated about the factors that may precipitate a recurrence.

SYPHILIS ON THE MUCOSAL SURFACES OF ADOLESCENT FEMALES

See Chapter 181, Syphilis, for information on all types of syphilis infections.

PATIENT STORY

A 16-year-old female noted several nonpainful bumps while shaving her vulvar area (**Figure 75-2**). She noted in the ensuing couple days that the surface of the some of the bumps eroded into ulcers. While this was not painful she was scared and presented to her physician for evaluation. She admitted to having had intercourse (unprotected) for the first time 6 weeks ago. The physician noted flat-topped raised plaques that could be condyloma lata or HPV. Her serum RPR test and confirmatory treponemal test were positive. She was treated with one dose of 2.4 million units of benzathine penicillin given intramuscularly. An HIV screen and an HIV DNA PCR were performed and fortunately, were negative.

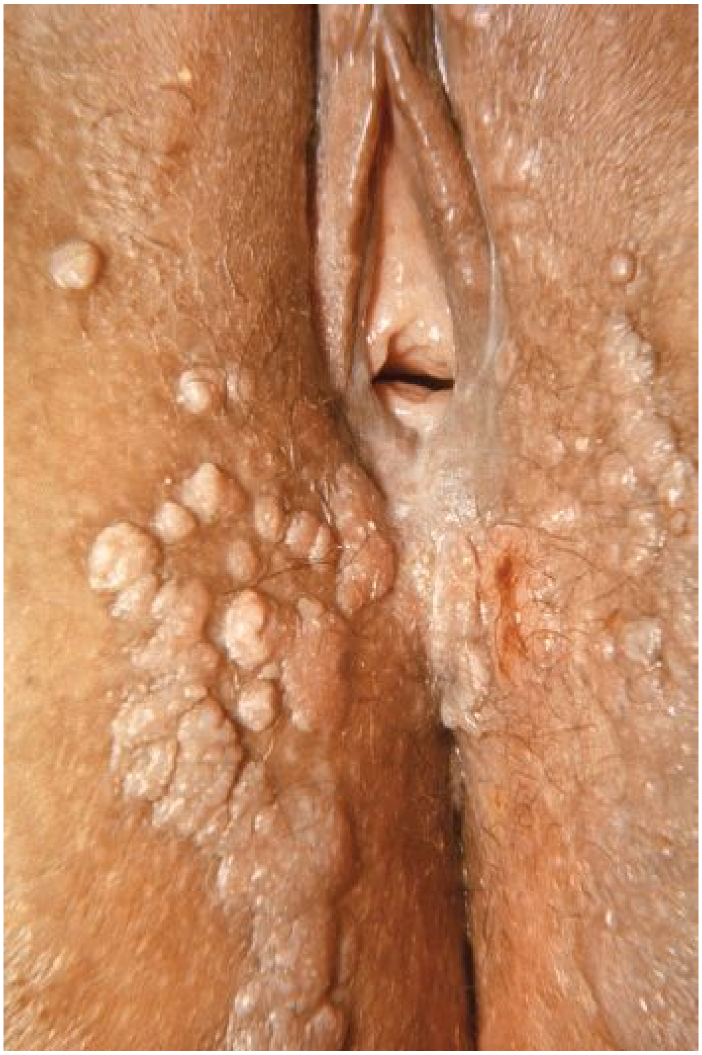

FIGURE 75-2 Condyloma lata lesions of secondary syphilis in a young female. (*Used with permission from Centers for Disease Control/Joyce Ayers, MD.*)

INTRODUCTION

Syphilis is an infection caused by the spirochete *Treponema pallidum*. It causes ulcerative lesions on the external genitalia.

EPIDEMIOLOGY

- The rate of syphilis in the US in 2011 was 1.0 case per 100,000 adult population.[6]
- The rate of primary and secondary syphilis in 15 to 19 year olds in the US in 2011 was 2.4 per 100,000 population.[6]

ETIOLOGY AND PATHOPHYSIOLOGY

- Acquired syphilis is transmitted by direct contact with syphilis lesions. The spirochete enters through areas of micro trauma in the mucous membranes.
- Syphilis is categorized as early (primary, secondary and early latent <2 years of infection) versus late (>2 years of infection).

RISK FACTORS

- Persons in correctional facilities.

- Males having sex with males.
- Persons having multiple sexual partners.
- Persons using drugs and alcohol and participating in commercial or coerced sex.

DIAGNOSIS

CLINICAL FEATURES

- The chancre is typically single, painless and appears round and firm and lasts for 3 to 6 weeks. There is associated lymphadenopathy.
- The appearance of the chancre marks the first stage of syphilis. It appears about 3 weeks after transmission. It heals with or without treatment.
- Multisystem involvement is noted in the second stage of syphilis. The patient experiences skin rashes and mucous membrane lesions. Sometimes condyloma lata (large raised, gray, or white lesions) may develop in areas such as the mouth, under arms and groin area (**Figure 75-3**).[7,8]

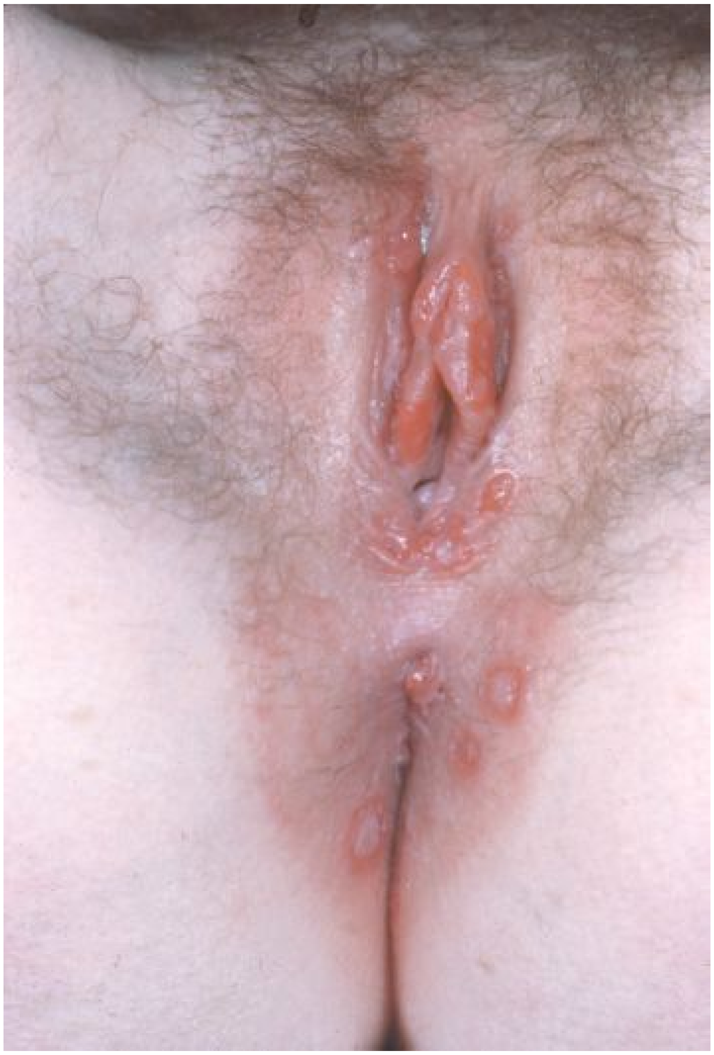

FIGURE 75-3 Condyloma lata lesions involving the vulva and anal region. (*Used with permission from Centers for Disease Control*.)

- Other symptoms of secondary syphilis include: fever, swollen lymph glands, sore throat, muscle aches, and fatigue.
- Late stage of syphilis occurs 10 to 20 years after the original infection and occurs in about 15 percent of people. During this time the disease will damage internal organs such as the brain, eyes, joints, and bones.

DISTRIBUTION

- Chancres occur on the external genitalia, vagina, anus, and/or the rectum. Chancres may also occur on the lips and the mouth.

LABORATORY TESTING

- Nontreponemal test-nonspecific.
    - These tests include VDRL and RPR. They are inexpensive screening tools but not very specific and can produce false positive results.[7]
- Treponemal tests-specific.
    - These tests are necessary to confirm the diagnosis of syphilis.
    - They include Fluorescent treponemal antibody absorbed test (FTA-ABS), *T. pallidum* particle agglutination assey (TP-PA), and treponemal enzyme immunoassay to detect IgG/IgM.[7]

DIFFERENTIAL DIAGNOSIS

- Must differentiate from HSV and chancroid—See these entities in this chapter.
- Lymphogranuloma venereum—Usually manifests with marked inguinal lymphadenopathy. A genital ulcer or papule may occur but often is not seen or missed.
- Granuloma inguinale (Donovanosis)—Very rare in the US. Endemic in some tropical and developing areas, including India; Papua, New Guinea; the Caribbean; central Australia; and southern Africa. Characterized by painless, slowly progressive ulcerative lesions in the genital tract or perineum without regional lymphadenopathy.

MANAGEMENT

MEDICATIONS

- A single intramuscular injection of Benzathine Penicillin G cures a patient with primary, secondary and early latent syphilis.[5] SOR Ⓐ

- Treatment kills the spirochete and prevents further damage.
- Patients who are allergic to penicillin may take doxycycline or tetracycline but the evidence for these treatments is not as firm as for penicillin.

PREVENTION AND SCREENING

- Abstain from intercourse until all the lesions have healed.
- Patients should be tested for other sexually transmitted diseases, especially HIV.
- Patients with syphilis must notify their partners so that they can be tested and treated.
- Consistent use of condoms can reduce the risk of acquiring syphilis.

PROGNOSIS

- Syphilis will not recur but being infected once does not protect one from getting reinfected.

PATIENT EDUCATION

The lesions of syphilis will resolve spontaneously but they must be treated to prevent progression of the infection.

PATIENT RESOURCES

CHANCROID

PATIENT STORY

An 18-year-old female recently returned from a trip to South America and noticed a red bump on her vulva that started one week ago. She is presenting now to her physician as it is quite painful and has an ulcer (**Figure 75-4**). She has had swelling in the inguinal region bilaterally and these areas are painful to her also. She denies any change in her vaginal discharge and states she has been sexually active in the past. A culture of the ulcer is negative for HSV and her syphilis serologies are negative. A diagnosis of probable Chancroid is made and she is treated with one gram of oral azithromycin. The lesions and inguinal lymphadenopathy resolve within 7 days.

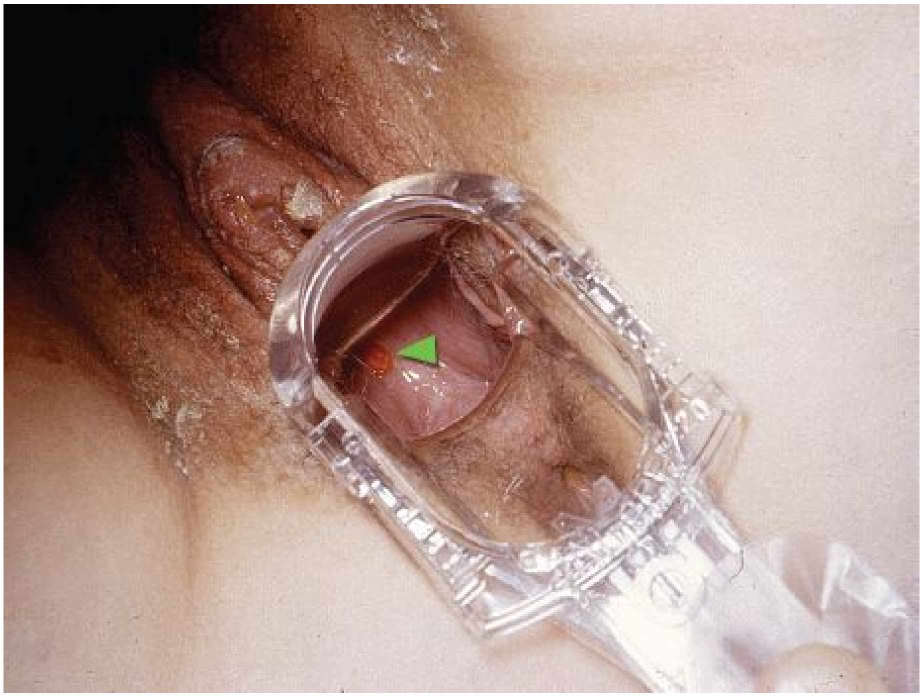

FIGURE 75-4 Chancroid ulcer on the posterior vaginal wall. (*Used with permission from Centers for Disease Control/Susan Lindsley, MD.*)

INTRODUCTION

Chancroid is an infection caused by *Haemophilus ducreyi*. It presents as genital ulceration that may be associated with regional lymphadenitis and bubo formation.

EPIDEMIOLOGY

- There has been a steady decline in the incidence of chancroid in the US since 1987. Since 2001, only sporadic cases have been reported. In 2010, 24 cases of chancroid were reported.[9]
- It is a major cause of genital ulceration in developing countries.
- Urban outbreaks are occasionally noted more in association with commercial sex work.
- It is more common in Africa, Asia, and Latin America.

ETIOLOGY AND PATHOPHYSIOLOGY

- Caused by *Haemophilus ducreyi*, a gram negative bacteria.[10]
- It is a sexually transmitted infection. Bacteria gain access to tissues from abrasions that occur during sexual intercourse.
- It may spread by auto-inoculation to other anatomical sites
- Its incubation time is 4 to 10 days.

- *H. ducreyi* produces a cytotoxin that causes cell injury and subsequent ulcer formation.

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis is suggested when the combination of painful genital ulcer is seen in conjunction with pustular inguinal lymphadenopathy.
- Lesions are 1 to 2 cm wide with a gray pustular base that bleeds with scraping.
- A definite diagnosis is made when *H. ducreyi* is isolated from the lesion.
- A probable diagnosis is made when:
    - One or more painful genital ulcers exist.
    - No evidence of syphilis 7 days after onset of ulcers (serologies negative).
    - Clinical presentation is typical of chancroid.
    - HSV testing is negative.

LABORATORY TESTING

- Difficult to culture *H. ducreyi*.
- Special culture media necessary to grow *H. ducreyi*.
- No FDA approved PCR test is available in the US.[11]
- Commercial laboratories do have PCR testing available.[12]

DIFFERENTIAL DIAGNOSIS

- HSV and syphilis should always be ruled out when ulcerative genital lesions are present. Note that the RPR is often negative when a syphilitic chancre first appears so repeating the RPR in 2 to 4 weeks may be needed if syphilis is being considered.
- Lymphogranuloma venereum—Usually manifests with marked inguinal lymphadenopathy. A genital ulcer or papule may occur but often is not seen or missed.
- Granuloma inguinale (Donovanosis)—Very rare in the US. Endemic in some tropical and developing areas, including India; Papua, New Guinea; the Caribbean; central Australia; and southern Africa. Characterized by painless, slowly progressive ulcerative lesions in the genital tract or perineum without regional lymphadenopathy.

MANAGEMENT

- Antimicrobial treatment is required to cure the infection, resolve the clinical symptoms, and prevent transmission to others.
- Medications
    - The CDC recommends one of the following regimens:[5]
    - Azithromycin, 1 gram in oral dose in a single dose.
    - Ceftriaxone 250 mg intramuscular dose.
    - Ciprofloxacin 500 mg twice a day for three days, orally (contraindicated in pregnancy).
    - Erythromycin 500 mg three times a day for 7 days.
- Surgery
    - Needle aspiration or incision and drainage of fluctuant slow healing buboes can be considered.[5] SOR Ⓒ
    - Incision and drainage of fluctuant buboes avoids the need for frequent aspirations and possible spontaneous rupture.

PREVENTION AND SCREENING

- All patients should receive health education including information on safe sex.[10]

PROGNOSIS

- Within 3 to 7 days of starting therapy, there should be improvement of ulcerative symptoms.
- The associated lymphadenitis and buboes may respond more slowly.
- If improvement is not seen then the diagnosis should be reconsidered. Co-infection with HIV or another STD such as syphilis should be considered.[11]
- Scarring may occur in advanced cases, despite appropriate therapy.

FOLLOW-UP

- Patients should be offered HIV testing at the time of the diagnosis and then follow-up HIV and serologic syphilis test three months later.

BEHCET DISEASE

PATIENT STORY

A 12-year-old nonsexually active girl presented to the pediatrician with vulvar pain that had begun 4 days prior to presentation. Examination revealed ulcerative lesions on both labia majora (**Figure 75-5**). HSV cultures and syphilis serologies were negative. The lesions resolved over several days. She returned one month later with a similar presentation. Behcet syndrome was suspected and she was referred to pediatric rheumatology.

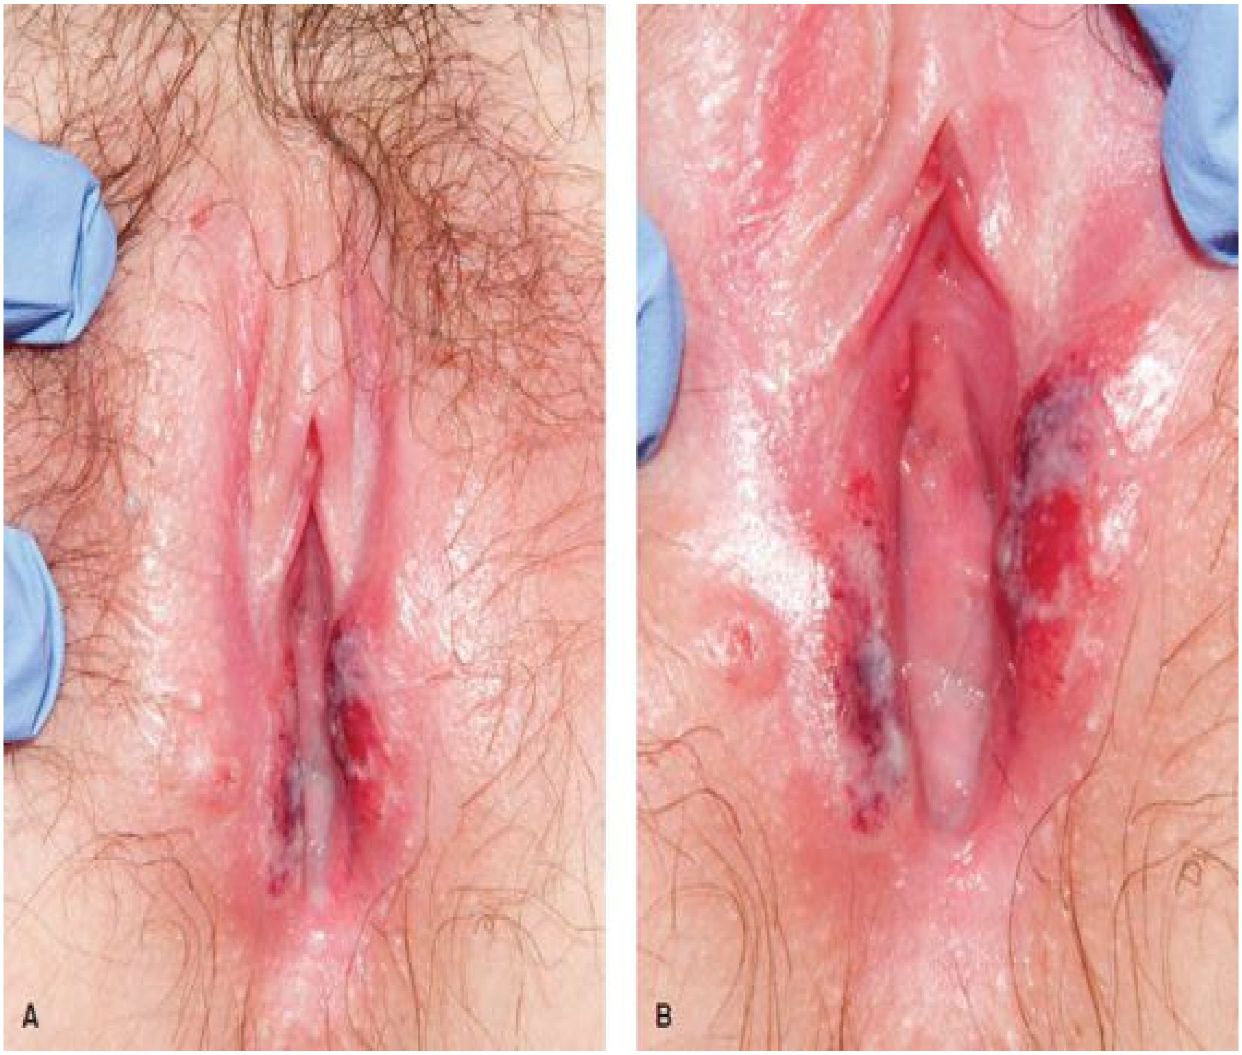

FIGURE 75-5 Bilateral ulcerative lesions in a 12-year-old girl with recurrent vulvar lesions on labia majora (**A**) and close-up view (**B**). The girl was found to have Behcet disease. (*Used with permission from Marjan Attaran, MD.*)

INTRODUCTION

This is a systemic inflammatory disorder that is characterized by recurrent oral, genital, and cutaneous mucosal lesions, often associated with uveitis.

EPIDEMIOLOGY

- The prevalence of Behcet disease (BD) in North America is 0.12 to 0.33 cases per 100,000 population.[13]
- A higher prevalence is noted from the Far East to the Mediterranean area and the Middle East Countries. Turkey reports the highest prevalence of BD.[14]
- Mean age of presentation is in the third and fourth decade of life. However, it has also been noted in children and adolescents.[15]

ETIOLOGY AND PATHOPHYSIOLOGY

- Pathogenesis of this disease is unknown.[13]
- An interaction of genetic, environmental, and immunologic factors may account for this disease.
- Genetic abnormalities may explain some cases of BD.[13]
- The most strongly associated genetic factor to BD is HLA-B51. But this accounts for less than 20 percent of the genetic risk.

- There is a possibility that an environmental factor triggers BD in patients with genetic susceptibility. These may be bacterial or viral in origin.
- Neutrophil activity is increased in BD.
- The major lymphocytes implicated in BD pathogenesis are T cells.
- Endothelial cell antibodies have been identified in BD individuals.

RISK FACTORS

- Males are more likely to have BD in the Middle East.
- Females have higher preponderance of BD in Japan.

DIAGNOSIS

The diagnosis depends on the existence of specific clinical features. There is no specific laboratory test. A major or minor aphthous oral ulceration should be noted at least three times in a 12 month period (see Chapter 40, Aphthous Ulcer). In addition the patient should experience two minor criteria, which may include eye lesions, skin lesions, genital lesions, and a positive pathergy test.[14] Pathergy is the appearance or worsening of lesions after trauma to the involved area. A pathergy skin test can be performed with a needle prick and the appearance of a pustule or papule surrounded by erythema 24 to 48 hours after the prick. This is characteristic but not pathognomonic for BD.

CLINICAL FEATURES

- Oral ulcers are usually the initial symptom. They may precede the other manifestations of BD by many years.
- The ulcer is described as a circular aphthous like ulcer with erythematous border and may be located on the buccal mucosa, lips, gingivae, soft palate, and pharynx.

- Genital ulcers are located on the vulva, vagina, cervix in women and prepuce and scrotum in men.
- Eighty percent of patients with BD will have skin lesions. These lesions include erythema nodosum, papulopustular lesions, and pseudofolliculitis.
- Ocular disease is noted in up to 70 percent of BD patients. Uveitis can be detected by an ophthalmologist using a slit lamp. Presenting complaints may be blurry vision and gravelly sensation in the eye.
- Arthritic symptoms may be noted in half of the BD patients.
- Less common associations are thrombophlebitis and gastrointestinal problems. BD can affect arteries and veins and mucosal ulcers can occur anywhere along the gastrointestinal tract.
- The central nervous system may become involved in a small percentage of patients.

LABORATORY TESTING

- Evaluation of the inflammatory cells within a BD lesion usually reveals neutrophils, CD4+ T cells, and cytotoxic cells.

DIFFERENTIAL DIAGNOSIS

- Recurrent aphthous ulcers—Not associated with any systemic manifestations (see Chapter 40, Aphthous Ulcers).
- Recurrent HSV infections—Usually not associated with systemic manifestations except for the primary event, and have classic vesicular lesions (see Chapter 39, Herpes Simplex Gingivostomatitis and Chapter 114, Herpes Simplex).
- Syphilis or chancroid—See discussion in this chapter and Chapter 181, Syphilis.
- Inflammatory bowel disease—May initially present with mucosal ulcerative lesions, but in time develop gastrointestinal symptoms (see

Chapter 59, Inflammatory Bowel Disease).

- Reactive arthritis—Usually accompanied by urethritis and conjunctivitis.
- Immunobullous skin disorders—Usually more widespread and have bullous rather than ulcerative lesions (see Chapters 155 to 157).

MANAGEMENT

NONPHARMACOLOGIC

- There are no controlled studies in the pediatric population evaluating treatment of BD.[16,17]
- Sitz baths can help clean the lesions in the external genitalia.

MEDICATIONS

- Mouth washes with sucralfate suspension, or topical and/or corticosteroids may be helpful. SOR Ⓒ
- A short course of oral corticosteroids is often used for acute ulceration and provides fast relief of symptoms. SOR Ⓒ
- Long-term colchicine is often used to decrease the frequency of the episodes and the severity of symptoms. SOR Ⓒ
- Non-steroidal anti-inflammatory medications may be helpful to control the arthritis and arthralgia when used in combination with colchicine. SOR Ⓒ

REFERRAL

- BD is a multisystem disease that requires a multidisciplinary approach. Referral to rheumatology and ophthalmology should be strongly considered.

- Referral to ophthalmology early is critical to diminishing the morbidity associated with the eye involvement of BD.

PROGNOSIS

- BD is a chronic relapsing disease that will need continued monitoring.
- The ulcerative lesions may continue to recur.
- Patients must be monitored for any systemic manifestations of the disease as this may lead to increased morbidity and mortality.

76 BACTERIAL VAGINOSIS

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 17-year-old pregnant teen reports some vaginal itching and odor associated with a thin discharge. There is no associated pain. She is unmarried and has had three lifetime sexual partners. On examination, her discharge is visible (**Figure 76-1**). It is thin and off-white. Wet prep examination shows that more than 50 percent of the epithelial cells are clue cells (**Figure 76-2**). Tests for STDs are all negative. The patient is treated with oral metronidazole 500 mg bid for 7 days with good results.

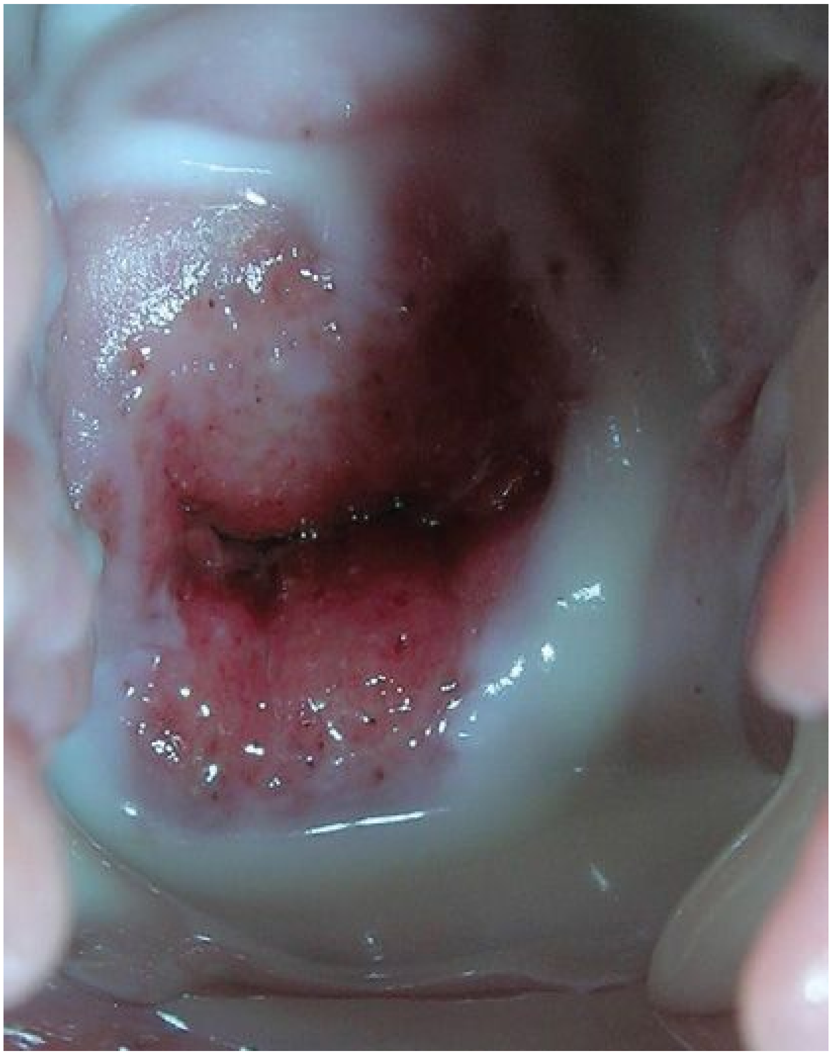

FIGURE 76-1 Bacterial vaginosis in 17-year-old pregnant teen with homogeneous, thin white vaginal discharge. She reports some vaginal itching and odor. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

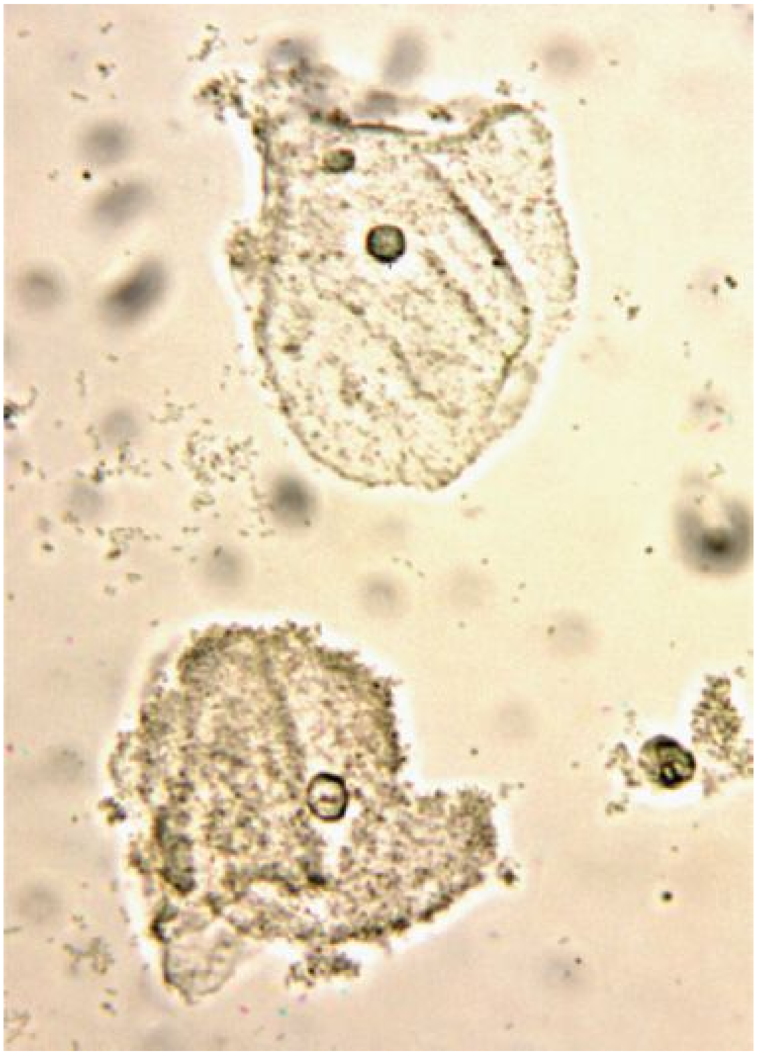

FIGURE 76-2 Clue cell and bacteria seen in bacterial vaginosis. The lower cell is a clue cell covered in bacteria while the upper cell is a normal epithelial cell. Light microscope under high power. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

INTRODUCTION

Bacterial vaginosis (BV) is a clinical syndrome resulting from alteration of the vaginal ecosystem. It is called a vaginosis, not a vaginitis, because the tissues themselves are not actually infected, but only have superficial involvement. Women with BV are at increased risk for the acquisition of

HIV, *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and herpes simplex virus (HSV)-2, and they have increased risk of complications after gynecologic surgery.[1]

BV is associated with adverse pregnancy outcomes, including premature rupture of membranes, preterm labor, preterm birth, intraamniotic infection, and postpartum endometritis. However, the only established benefit of BV therapy in pregnant women is the reduction of symptoms and signs of vaginal infection.[1]

SYNONYMS

- Vaginal bacteriosis.
- *Corynebacterium* vaginosis/*vaginalis*/*vaginitis*.
- *Gardnerella vaginalis*/vaginosis.
- *Haemophilus vaginalis*/vaginitis.
- Nonspecific vaginitis.
- Anaerobic vaginosis.

EPIDEMIOLOGY

- BV is estimated to be the most prevalent cause of vaginal discharge or malodor in women presenting for care in the US. However, more than 50 percent of women with BV are asymptomatic.[1] It accounts for more than 10 million outpatient visits per year.[2] The worldwide prevalence is unknown.

ETIOLOGY AND PATHOPHYSIOLOGY

- Hydrogen peroxide-producing *Lactobacillus* is the most common organism composing normal vaginal flora after puberty.[1] In BV, normal vaginal lactobacilli are replaced by high concentrations of anaerobic bacteria such as *Mobiluncus*, *Prevotella*, *Gardnerella*, *Bacteroides*, and *Mycoplasma* species.[1,2]
- The hydrogen peroxide produced by the *Lactobacillus* may help in inhibiting the growth of atypical flora.
- The odor of BV is caused by the aromatic amines produced by the altered bacterial flora in the vagina. These aromatic amines include putrescine and cadaverine—aptly named to describe their foul odor.

RISK FACTORS

- Multiple male or female partners.[1,3]
- A new sex partner.[1]
- Douching.[4]
- Lack of condom use.[1]
- Lack of vaginal lactobacilli.[1]
- Prior BV infection.[1]

DIAGNOSIS

CLINICAL FEATURES

- Symptomatic patients present with an unpleasant, “fishy smelling” discharge that is more noticeable after coitus (the basic pH of seminal fluid is like doing the whiff test with KOH). There may be pruritus but not as often as seen with *Candida* vaginitis. The physical examination should include inspection of the external genitalia for irritation or discharge. Speculum examination is done to determine the amount and character of the discharge. A nucleic acid amplification test for *N. gonorrhoeae*, *Chlamydia*, and/or *C. trachomatis* (or similar test) should be performed on genital specimens (urethral or cervical) or urine.

- BV is usually clinically diagnosed by finding three of the following four signs and symptoms:
    - Homogeneous, thin, white discharge that smoothly coats the vaginal walls (**Figures 76-3** and **76-4**).
    - Presence of clue cells on microscopic examination (**Figure 76-2**).
    - pH of vaginal fluid >4.5.
    - A fishy odor of vaginal discharge before or after addition of 10 percent KOH (i.e., the whiff test).[1]

LABORATORY TESTING

- Vaginal pH testing can be very helpful in the diagnosis of vaginitis. The normal vaginal pH is usually 3.5 to 4.5. A pH above 4.5 is seen with menopausal patients, *Trichomonas* infection, or BV. A small piece of pH paper is touched to the vaginal discharge during the exam or on the speculum. Do not test a wet-prep sample if saline has been added because the saline alters the pH.
- Wet preps are obtained using a cotton-tipped applicator applied to the vaginal sidewall, placing the sample of discharge into normal saline (not water). Observe for clue cells, number of white blood cells, trichomonads, and candidal hyphae. Clue cells are squamous epithelial cells whose borders are obscured by attached bacteria. More than 20 to 25 percent of epithelial cells seen in BV should be clue cells (**Figure 76-2**).

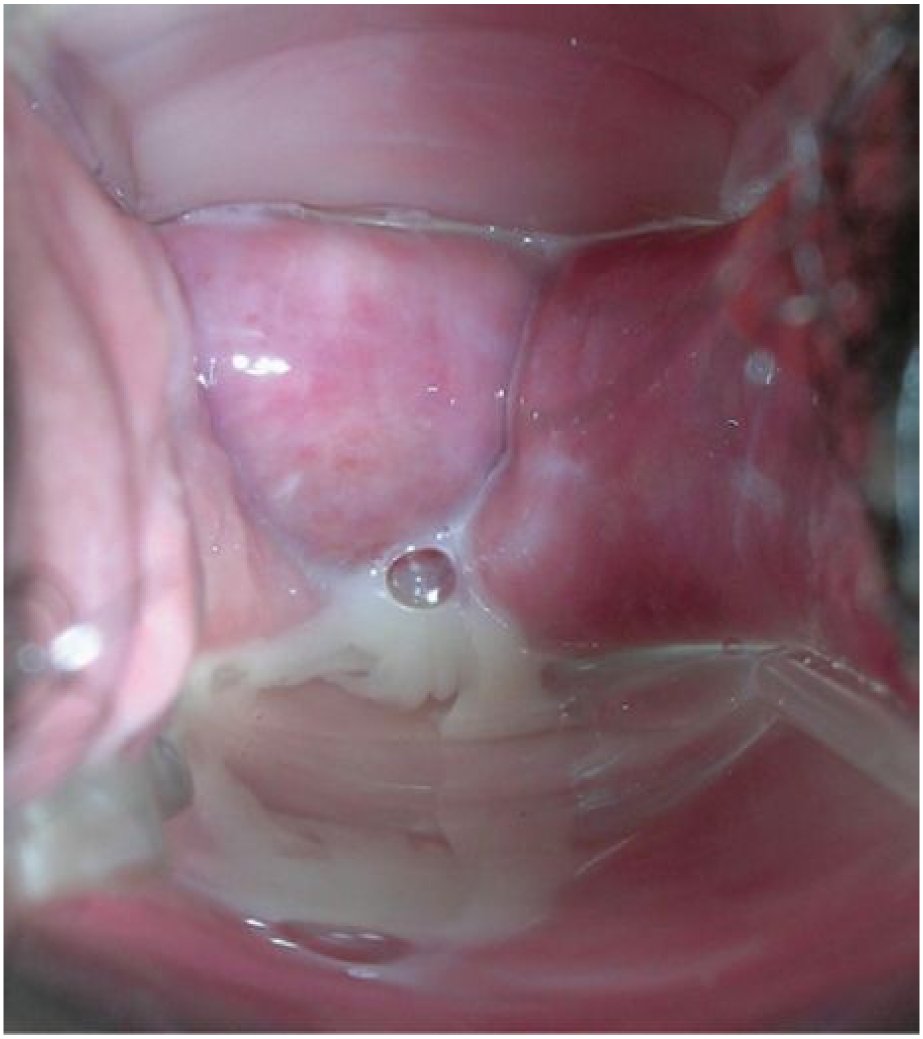

FIGURE 76-3 A homogeneous, off-white creamy malodorous discharge that adheres to the vaginal walls and pools in the vaginal vault in a woman with bacterial vaginosis. (*Used with permission from Richard P. Usatine, MD.*)

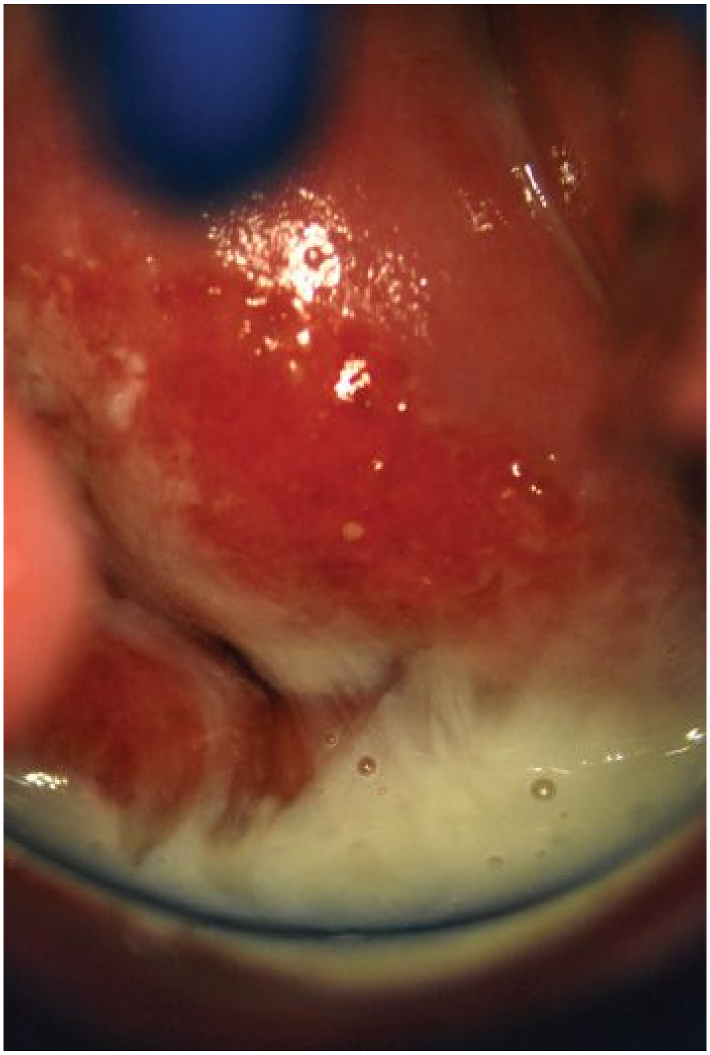

FIGURE 76-4 Bacterial vaginosis seen on the cervix with a white homogeneous discharge. Note the lack of clumping or “cottage-cheese” appearance usually found with *Candida* infections. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

- A proline aminopeptidase test card (Pip Activity Test Card), a DNA probe-based test for high concentrations of *G. vaginalis* (Affirm VP III), and the OSOM BVBLUE test have shown acceptable performance characteristics compared with Gram stain (gold standard).[1] However, they are more costly than traditional testing.
- Although a test card is available for the detection of elevated pH and trimethylamine, it has low sensitivity and specificity and is not recommended by the Centers for Disease Control and Prevention (CDC).[1]

- Culture of *G. vaginalis* is not recommended as a diagnostic tool because it is not specific.
- Pap tests are not useful for the diagnosis of BV because of their low sensitivity.[1]

DIFFERENTIAL DIAGNOSIS

- *Trichomonas* also may have the odor of aromatic amines and, therefore, easily confused with BV at first glance. Look for the strawberry cervix on examination and moving trichomonads on the wet prep (Chapter 78, Trichomonas Vaginitis).
- *Candida* vaginitis tends to present with a cottage-cheese-like discharge and vaginal itching (Chapter 77, *Candida* Vulvovaginitis).
- Gonorrhea and chlamydia should not be missed in patients with vaginal discharge. Consider testing for these sexually transmitted diseases (STDs) based on patients’ risk factors and the presence of purulence clinically and white blood cells on the wet prep (Chapter 79, Chlamydia Cervicitis).

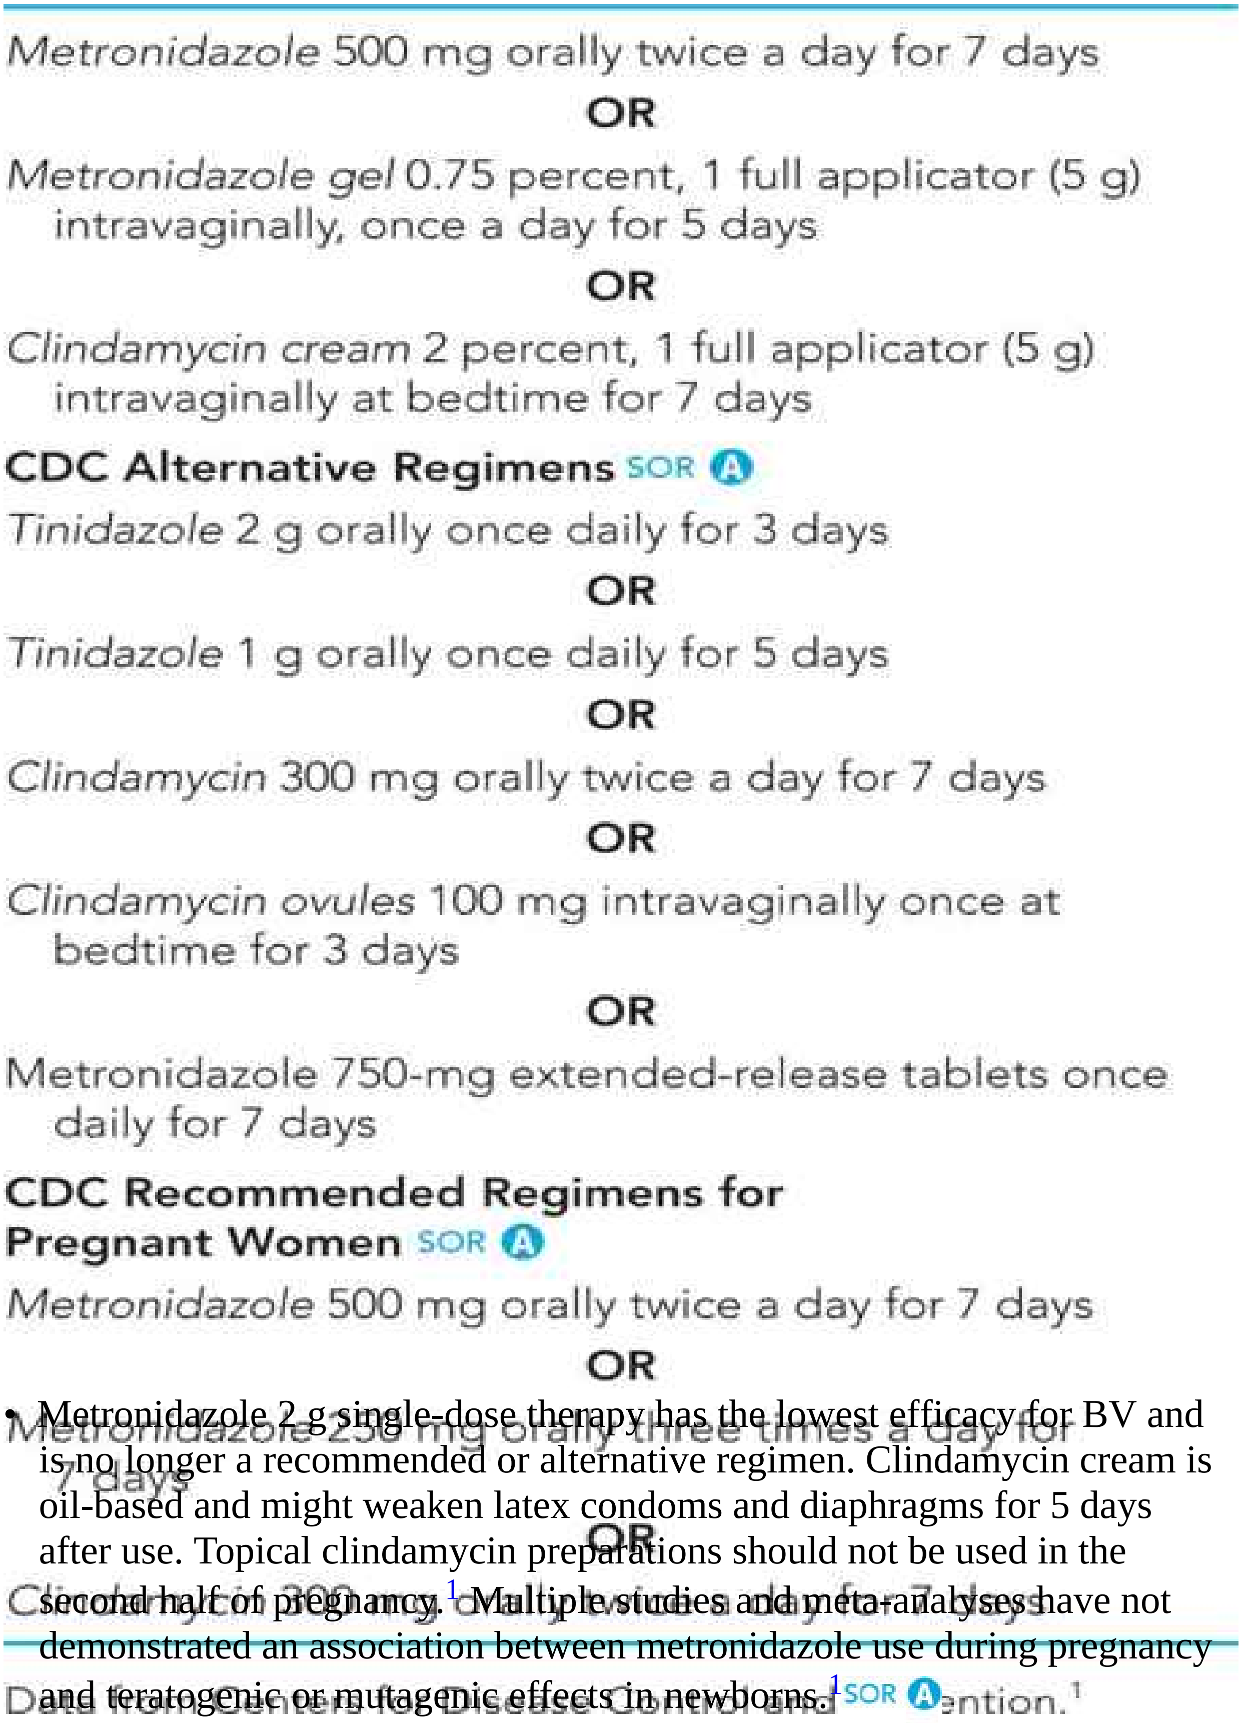
MANAGEMENT

- Treatment is recommended for women with symptoms.
- Treatment of male sex partners has not been beneficial in preventing the recurrence of BV.[1] SOR Ⓐ

MEDICATIONS

- The established benefits of therapy for BV in nonpregnant women are to (**a**) relieve vaginal symptoms and signs of infection and (**b**) reduce the risk for infectious complications after abortion or hysterectomy.[1] SOR Ⓐ Other potential benefits might include a reduction in risk for other sexually transmitted infections (STIs).[1] SOR Ⓑ **Table 76-1** shows CDC recommended treatments.

TABLE 76-1 CDC Recommended Regimens SOR Ⓐ



Metronidazole 500 mg orally twice a day for 7 days

OR

Metronidazole gel 0.75 percent, 1 full applicator (5 g) intravaginally, once a day for 5 days

OR

Clindamycin cream 2 percent, 1 full applicator (5 g) intravaginally at bedtime for 7 days

CDC Alternative Regimens SOR A

Tinidazole 2 g orally once daily for 3 days

OR

Tinidazole 1 g orally once daily for 5 days

OR

Clindamycin 300 mg orally twice a day for 7 days

OR

Clindamycin ovules 100 mg intravaginally once at bedtime for 3 days

OR

Metronidazole 750-mg extended-release tablets once daily for 7 days

CDC Recommended Regimens for Pregnant Women SOR A

Metronidazole 500 mg orally twice a day for 7 days

OR

Metronidazole 250 mg orally three times a day for 7 days

OR

Clindamycin 300 mg orally twice a day for 7 days

Data from Centers for Disease Control and Prevention.[1]

- Metronidazole 2 g single-dose therapy has the lowest efficacy for BV and is no longer a recommended or alternative regimen. Clindamycin cream is oil-based and might weaken latex condoms and diaphragms for 5 days after use. Topical clindamycin preparations should not be used in the second half of pregnancy.[1] Multiple studies and meta-analyses have not demonstrated an association between metronidazole use during pregnancy and teratogenic or mutagenic effects in newborns.[1] SOR A

- The only established benefit of therapy for BV in pregnant women is to relieve vaginal symptoms and signs of infection.[1] SOR Ⓐ Additional potential benefits of therapy include (**a**) reducing the risk for infectious complications associated with BV during pregnancy and (**b**) reducing the risk for other infections (e.g., other STDs or HIV). Multiple studies and meta-analyses have not demonstrated an association between metronidazole use during pregnancy and teratogenic or mutagenic effects in newborns.[5]
- One randomized trial for persistent BV indicated that metronidazole gel 0.75 percent twice per week for 6 months after completion of a recommended regimen was effective in maintaining a clinical cure for 6 months.[6] SOR Ⓑ
- Limited data suggest that oral nitroimidazole followed by intravaginal boric acid and suppressive metronidazole gel for those women in remission might be an option in women with recurrent BV. SOR Ⓑ[7]
- Intravaginal clindamycin cream has been associated with adverse outcomes if used in the latter half of pregnancy.[1]

COMPLEMENTARY AND ALTERNATIVE THERAPY

- Extended ingestion of live culture, nonpasteurized yogurt may theoretically increase colonization by lactobacilli and decrease the episodes of BV.[8] SOR Ⓒ However, health food store lactobacilli are the wrong strain and are not well retained by the vagina.
- The efficacy of exogenous lactobacillus recolonization with probiotic lactobacilli vaginal gelatin capsules has been reported in two small trials.[9,10]

PREVENTION

- Avoidance of risk factors is recommended, although asymptomatic BV is common.
- The evidence is insufficient to assess the impact of screening for BV in pregnant women at high risk for preterm delivery.[1]

FOLLOW-UP

- Follow-up visits are unnecessary in nonpregnant women if symptoms resolve.[1]
- Treatment of BV in asymptomatic pregnant women who are at high risk for preterm delivery might prevent adverse pregnancy outcomes. Therefore, a follow-up evaluation 1 month after completion of treatment should be considered to evaluate whether therapy was effective.[1] SOR C
- If symptoms do recur, consider a treatment regimen different from the original regimen to treat recurrent disease.[1] SOR C

PATIENT EDUCATION

- Avoid consuming alcohol during treatment with metronidazole and for 24 hours thereafter. Women should be advised to return for additional therapy if symptoms recur because recurrence of BV is not unusual.

77 CANDIDA VULVOVAGINITIS

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

An 18-year-old woman presents with severe vaginal and vulvar itching and a thick white discharge. **Figure 77-1** shows the appearance of her vulva with redness and excoriations. Note the satellite lesions near the borders of the inflamed areas. Her pelvic examination demonstrated a thick adherent discharge on the vaginal wall and cervix (**Figure 77-2**) that is consistent with an active candida infection. Treatment with a prescription anti-candida drug was successful.

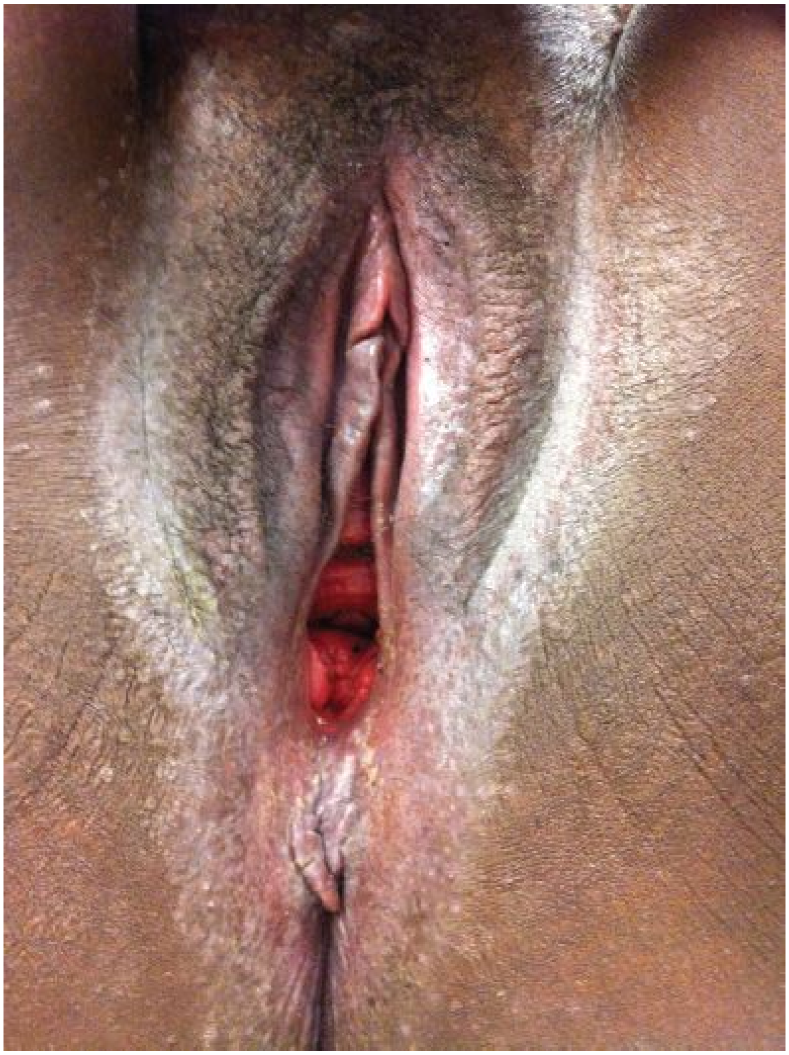

FIGURE 77-1 Candida vulvovaginitis in an 18-year-old who complained of severe vaginal and vulvar itching. She had erythema and excoriations of the vulva. Note the satellite lesions near the borders of the inflamed areas. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

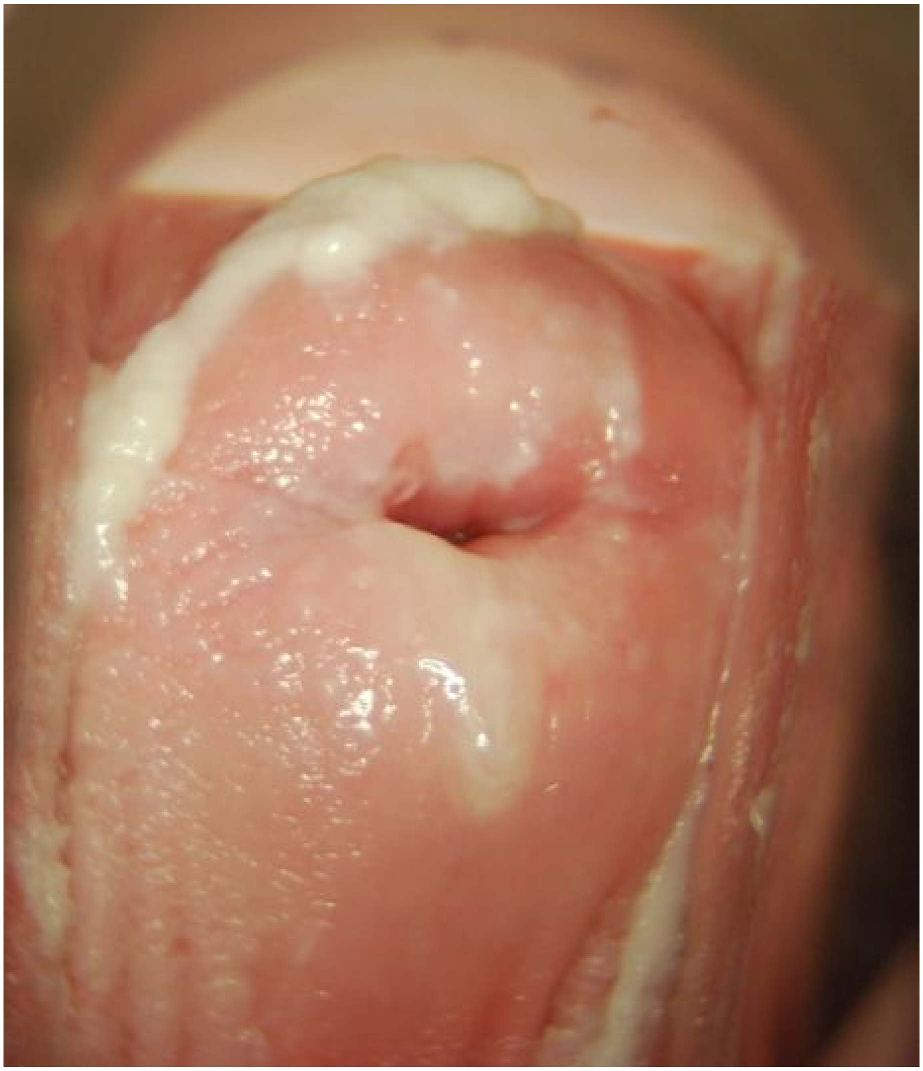

FIGURE 77-2 *Candida* vaginitis. Note the thick white adherent “cottage-cheese-like” discharge. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

INTRODUCTION

Vulvovaginal candidiasis (VVC) is a common fungal infection in women of childbearing age. Pruritus is accompanied by a thick, odorless, white vaginal discharge. VVC is not a sexually transmitted disease. On the basis of clinical presentation, microbiology, host factors, and response to therapy, VVC can be classified as either uncomplicated or complicated.[1] Uncomplicated VVC is characterized by sporadic or infrequent symptoms, mild-to-moderate symptoms, and the patient is nonimmunocompromised. Complicated VVC is characterized by recurrent (four or more episodes in 1 year) or severe VVC, non-*albicans* candidiasis, or the patient has uncontrolled diabetes, debilitation, or immunosuppression.[1]

SYNONYMS

Yeast vaginitis, yeast infection, candidiasis, moniliasis.

EPIDEMIOLOGY

- Candida (**Figure 77-3**) is usually not isolated in prepubertal girls except when predisposing factors, such as a recent course of antibiotics, diabetes, or the wearing of diapers are present.[2]

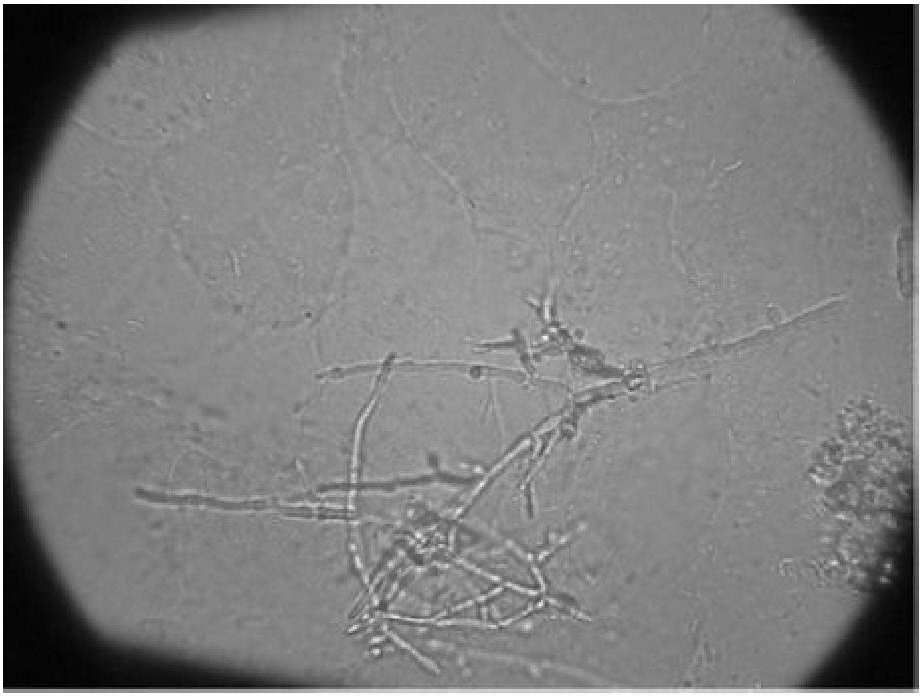

FIGURE 77-3 Wet mount with KOH showing *Candida albicans* in a teen with *Candida* vaginitis. Seen under high power demonstrating branching

pseudohyphae and budding yeast. (*Used with permission from Richard P. Usatine, MD.*)

- VVC accounts for approximately 1/3 of vaginitis cases.[1]
- *Candida* species are part of the lower genital tract flora in 20 to 50 percent of healthy asymptomatic women.[3]
- Seventy-five percent of all women in the US will experience at least one episode of VVC. Of these, 40 to 45 percent will have two or more episodes within their lifetime.[4] Approximately 10 to 20 percent of women will have complicated VVC that necessitates diagnostic and therapeutic considerations.
- It is a frequent iatrogenic complication of antibiotic treatment, secondary to altered vaginal flora.
- Approximately half of all women experience multiple episodes, and up to 5 percent experience recurrent disease.[1]
- Recurrent vulvovaginal candidiasis (RVVC) is defined as four or more episodes of symptomatic VVC in 1 year. It affects a small percentage of women (<5%).[5] Recurrent yeast vaginitis is usually caused by relapse, and less often by reinfection. Recurrent infection may be caused by *Candida* recolonization of the vagina from the rectum.[6]

ETIOLOGY AND PATHOPHYSIOLOGY

- Most vulvovaginal Candidiasis is caused by *Candida albicans* (**Figure 77-3**).[1,7] *Candida glabrata* now causes a significant percentage of all *Candida* vulvovaginal infections. This organism is resistant to the nonprescription imidazole creams. It can mutate out of the activity of treatment drugs much faster than *albicans* species.[8]
- The disease is suggested by pruritus in the vulvar area, together with erythema of the vagina and vulva (**Figures 77-1** and **77-2**). The familiar reddening of the vulvar tissues is caused by an ethanol by-product of the *Candida* infection. This ethanol compound also produces pruritic

symptoms. A scalloped edge with satellite lesions is characteristic of the erythema on the vulva.

- VVC can occur concomitantly with sexually transmitted diseases (STDs).
- The pathogenesis of recurrent VVC is poorly understood, and most women with these recurrences have no apparent predisposing or underlying conditions.[1]

RISK FACTORS[9,10]

- Diabetes mellitus, especially with higher A1C values.
- Recent antibiotic use.
- Increased estrogen levels.
- Immunosuppression.
- Contraceptive devices (vaginal sponges, diaphragms, and intrauterine devices).
- Genetic susceptibility.
- Behavioral factors—VVC may be linked to orogenital and, less commonly, anogenital sex.
- Wearing diapers.
- Spermicides are **not associated** with *Candida* infection.
- There is no high-quality evidence showing a link between VVC and hygienic habits or wearing tight or synthetic clothing.

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis is usually suspected by characteristic findings (**Figures 77-1** and **77-2**). Typical symptoms include pruritus, vaginal soreness, dyspareunia, and external dysuria. Typical signs include vulvar edema, fissures, excoriations, or thick, curdy vaginal discharge.[1]

LABORATORY TESTING

- Vaginitis solely caused by *Candida* generally has a normal vaginal pH of less than 4.5.
- The wet prep, KOH smear, or Gram stain may demonstrate yeast and/or pseudohyphae (**Figures 77-3** and **77-4**). Wet preps may also demonstrate white blood cells, trichomonads, candidal hyphae, or clue cells.
- The KOH prep is made by adding a drop of KOH solution to a drop of saline suspension of the discharge. The KOH lyses epithelial cells in 5 to 15 minutes (faster if the slide is warmed) and allows easier visualization of candidal hyphae or yeast.[1] Swartz-Lamkins stain (potassium hydroxide, a surfactant, and blue dye) may facilitate diagnosis by staining the yeast organisms a light blue.[11]

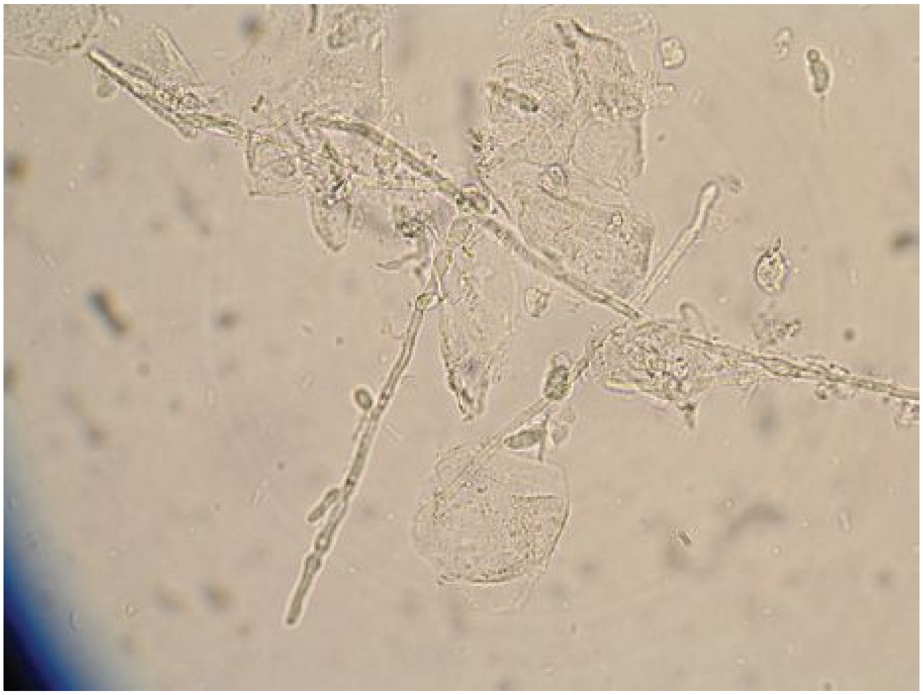

FIGURE 77-4 Wet mount with saline showing *Candida* in a teen with *Candida* vaginitis. Note how the branching pseudohyphae and budding yeast can be seen even though the epithelial cells have not been lysed by KOH. (*Used with permission from Richard P. Usatine, MD.*)

- Rapid antigen testing is also available for *Candida*. The detection of vaginal yeast by rapid antigen testing is feasible for office practice and more sensitive than wet mount. A negative test result, however, was not found to be sensitive enough to rule out yeast and avoid a culture.[7] SOR Ⓐ
- Fungal culture with Sabouraud agar, Nickerson medium, or Microstix-*Candida* medium should be considered in patients with symptoms and a negative KOH because *C. glabrata* does not form pseudohyphae or hyphae and is not easily recognized on microscopy. If the wet mount is negative and *Candida* cultures cannot be done, empiric treatment can be considered for symptomatic women with any sign of VVC on examination.[1] SOR Ⓒ Asymptomatic women should not be cultured as 10 to 20 percent of women harbor *Candida* sp. and other yeasts in the vagina.[1] SOR Ⓐ
- Vaginal cultures should be obtained from patients with RVVC to confirm the clinical diagnosis and to identify unusual species, including non-*albicans* species, particularly *C. glabrata* (*C. glabrata* does not form pseudohyphae or hyphae and is not easily recognized on microscopy).[1] SOR Ⓑ *C. glabrata* and other non-*albicans Candida* species are observed in 10 to 20 percent of patients with RVVC.[1]
- Given the frequency at which RVVC occurs in the immunocompetent healthy population, the occurrence of RVVC alone should not be considered an indication for HIV testing.[1] SOR Ⓒ

DIFFERENTIAL DIAGNOSIS

- Trichomoniasis can be confused with candidiasis because patients may report itching and a discharge in both diagnoses. Look for the strawberry cervix on examination and moving trichomonads on the wet prep (Chapter 78, Trichomonas Vaginitis).

- Bacterial vaginosis can be confused with candidiasis because patients may report a discharge and an odor in both diagnoses. The odor is usually much worse in bacterial vaginosis and the quality of the discharge can be different. The wet prep should allow for differentiation between these two infections (Chapter 76, Bacterial Vaginosis).
- Gonorrhea and *Chlamydia* should not be missed in patients with vaginal discharge. Consider testing for these STDs based on patients’ risk factors and the presence of purulence clinically and white blood cells on the wet prep (Chapter 79, Chlamydia Cervicitis).
- Cytolytic vaginosis, or Döderlein cytolysis, can be confused with candidiasis. Cytolytic vaginosis is produced by a massive desquamation of epithelial cells related to excess lactobacilli in the vagina. The signs and symptoms are similar to *Candida* vaginitis, except no yeast are found on wet prep. The wet prep will show an overgrowth of lactobacilli. The treatment is to discontinue all antifungals and other agents or procedures that alter the vaginal flora.

MANAGEMENT

NONPHARMACOLOGIC

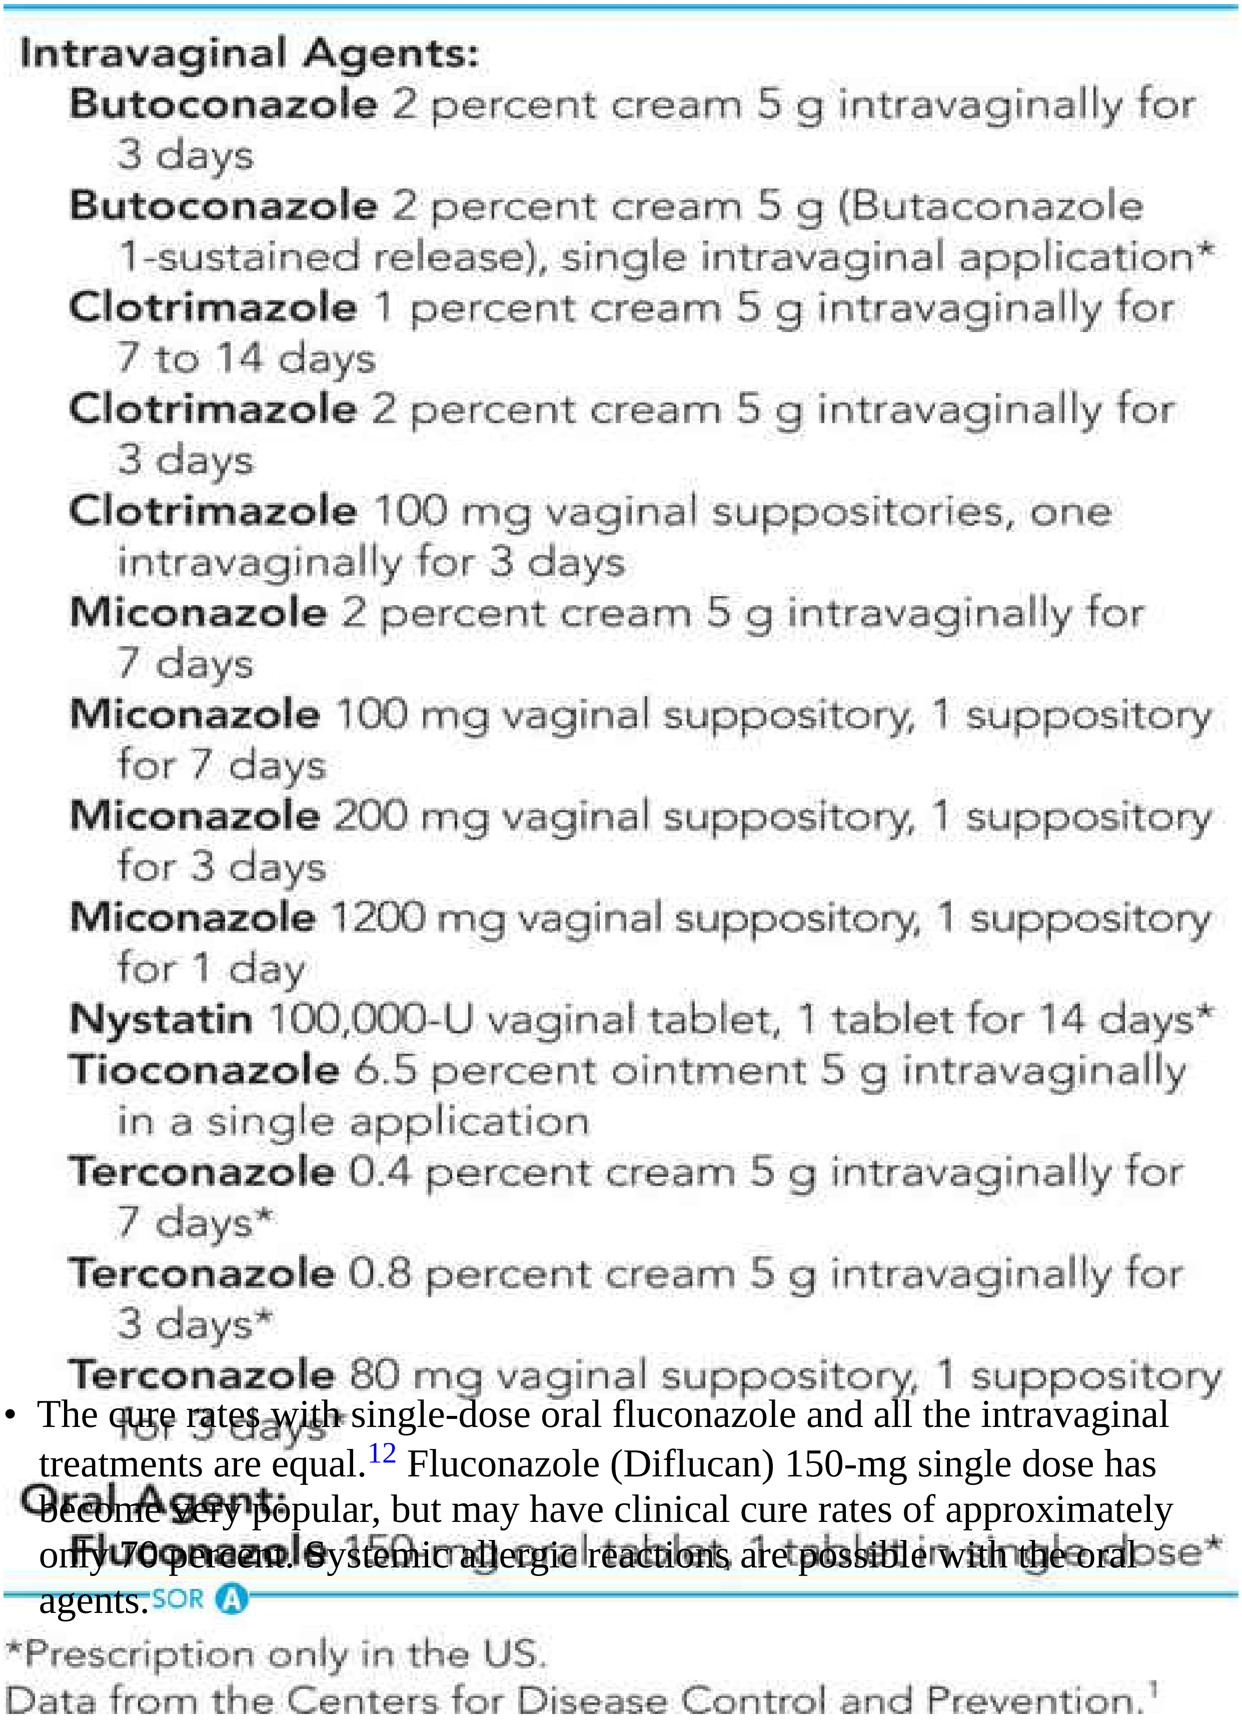
- VVC is not usually acquired through sexual intercourse; treatment of sex partners is not recommended but may be considered in women who have recurrent infection. Some male sex partners might have balanitis (Chapter 136, Candidiasis) and might benefit from treatment.[1] SOR Ⓐ
- Any woman whose symptoms persist after using a nonprescription preparation or who has a recurrence of symptoms within 2 months should be evaluated with office-based testing as they are not necessarily more capable of diagnosing themselves even with prior diagnosed episodes of

VVC and delay in the treatment of other vulvovaginitis etiologies can result in adverse clinical outcomes.[1] SOR Ⓐ

MEDICATIONS

- Women with typical symptoms and a positive test result should receive treatment. Short-courses of topical formulations effectively treat uncomplicated VVC (**Table 77-1**).[1] SOR Ⓐ Topical azole drugs are more effective than nystatin, and result in clinical cure and negative cultures in 80 to 90 percent of patients who complete therapy. The creams and suppositories in **Table 77-1** are oil-based and might weaken latex condoms and diaphragms.[1] SOR Ⓐ

TABLE 77-1 Centers for Disease Control and Prevention Recommended Treatment Regimens



Intravaginal Agents:

Butoconazole 2 percent cream 5 g intravaginally for 3 days

Butoconazole 2 percent cream 5 g (Butaconazole 1-sustained release), single intravaginal application*

Clotrimazole 1 percent cream 5 g intravaginally for 7 to 14 days

Clotrimazole 2 percent cream 5 g intravaginally for 3 days

Clotrimazole 100 mg vaginal suppositories, one intravaginally for 3 days

Miconazole 2 percent cream 5 g intravaginally for 7 days

Miconazole 100 mg vaginal suppository, 1 suppository for 7 days

Miconazole 200 mg vaginal suppository, 1 suppository for 3 days

Miconazole 1200 mg vaginal suppository, 1 suppository for 1 day

Nystatin 100,000-U vaginal tablet, 1 tablet for 14 days*

Tioconazole 6.5 percent ointment 5 g intravaginally in a single application

Terconazole 0.4 percent cream 5 g intravaginally for 7 days*

Terconazole 0.8 percent cream 5 g intravaginally for 3 days*

Terconazole 80 mg vaginal suppository, 1 suppository for 3 days*

Oral Agent:

Fluconazole 150 mg oral tablet, 1 tablet in single dose*

*Prescription only in the US.

Data from the Centers for Disease Control and Prevention.[1]

- The cure rates with single-dose oral fluconazole and all the intravaginal treatments are equal.[12] Fluconazole (Diflucan) 150-mg single dose has become very popular, but may have clinical cure rates of approximately only 70 percent. Systemic allergic reactions are possible with the oral agents. SOR A

- The oral agents fluconazole, ketoconazole, and itraconazole also appear to be effective.[1] SOR Ⓑ
- VVC frequently occurs during pregnancy. Only topical azole therapies, applied for 7 days, are recommended for use among pregnant women.[1] SOR Ⓒ
- The optimal treatment of non-*albicans* VVC remains unknown. Options include longer duration of therapy (7 to 14 days) with topical therapy or a 100-mg, 150-mg, or 200-mg oral dose of fluconazole every third day for a total of 3 doses.[1] SOR Ⓒ
- Severe VVC (i.e., extensive vulvar erythema, edema, excoriation, and fissure formation) is associated with lower clinical response rates in patients treated with short courses of topical or oral therapy. Either 7 to 14 days of topical azole or 150 mg of fluconazole in two sequential doses (second dose 72 hours after initial dose) is recommended.[1] SOR Ⓒ

COMPLEMENTARY AND ALTERNATIVE THERAPY

- If recurrence VVC occurs, 600 mg of boric acid in a gelatin capsule is recommended, administered vaginally once daily for 2 weeks. This regimen has clinical and mycologic eradication rates of approximately 70 percent.[1] SOR Ⓑ
- *Lactobacillus acidophilus* does not adhere well to the vaginal epithelium, and it does not significantly change the incidence of candidal vulvovaginitis.[6,13]
- There is no evidence from randomized trials that other complementary and alternative (CAM) therapies, such as garlic, tea tree oil, yogurt, or douching, are effective for the treatment or prevention of VVC caused by *C. albicans*.[14,15]

PREVENTION

MAINTENANCE REGIMENS

- Oral fluconazole (i.e., 100 mg, 150 mg, or 200 mg dose) weekly for 6 months is the first line of treatment. If this regimen is not feasible, some specialists recommend topical clotrimazole 200 mg twice a week, clotrimazole (500 mg dose vaginal suppositories once weekly), or other topical treatments used intermittently.[1] SOR Ⓒ
- Suppressive maintenance antifungal therapies are effective in reducing RVVC.[1] SOR Ⓐ However, 30 to 50 percent of women will have recurrent disease after maintenance therapy is discontinued. Routine treatment of sex partners is controversial. *C. albicans* azole resistance is rare in vaginal isolates, and susceptibility testing is usually not warranted for individual treatment guidance.

PROGNOSIS

- Women with underlying debilitating medical conditions (e.g., those with uncontrolled diabetes or those receiving corticosteroid treatments) do not respond as well to short-term therapies. Efforts to correct modifiable conditions should be made, and more prolonged (i.e., 7 to 14 days) conventional antimycotic treatment is necessary.[1] SOR Ⓒ
- Symptomatic VVC is more frequent in HIV-seropositive women and correlates with severity of immunodeficiency. In addition, among HIV-infected women, systemic azole exposure is associated with the isolation of non–*C. albicans* species from the vagina. According to the available data, therapy for VVC in HIV-infected women should not differ from that for seronegative women.[1] SOR Ⓒ

FOLLOW-UP

- Patients should be instructed to return for follow-up visits only if symptoms persist or recur within 2 months of onset of initial symptoms.[1]

PATIENT EDUCATION

- Studies show that women who were previously diagnosed with VVC are not necessarily more likely to be able to diagnose themselves.[1] Any woman whose symptoms persist after using an nonprescription preparation, or who has a recurrence of symptoms within 2 months, should be evaluated with office-based testing. Explain that unnecessary or inappropriate use of nonprescription preparations can lead to a delay in the treatment of other vulvovaginitis etiologies, which can result in adverse clinical outcomes.[1]

78 *TRICHOMONAS* VAGINITIS

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 17-year-old teen presents with a vaginal itching, odor, and discharge for several weeks. She has one partner who is asymptomatic. Speculum examination shows a cervix (**Figure 78-1**) with a copious foamy white discharge with a fishy odor. Wet mount shows trichomonads swimming in saline (**Figures 78-2** and **78-3**). The trichomonads are larger than white blood cells (WBCs) and have visible flagella and movement. She is diagnosed with trichomoniasis and treated with 2 g of metronidazole in a single dose. The patient is tested for other sexually transmitted diseases (STDs) and her partner is treated with the same regimen.

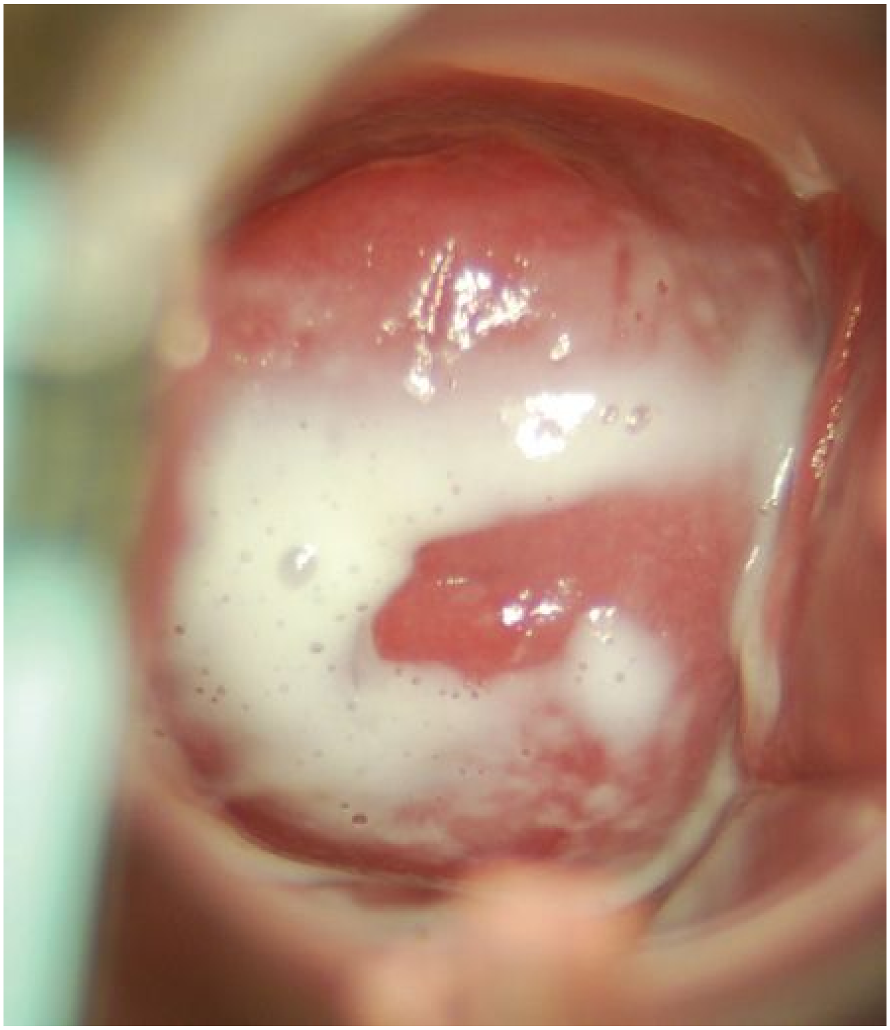

FIGURE 78-1 *Trichomonas* infection seen on the cervix. There is a thick foamy off-white discharge. (*Used with permission from Richard P. Usatine, MD.*)

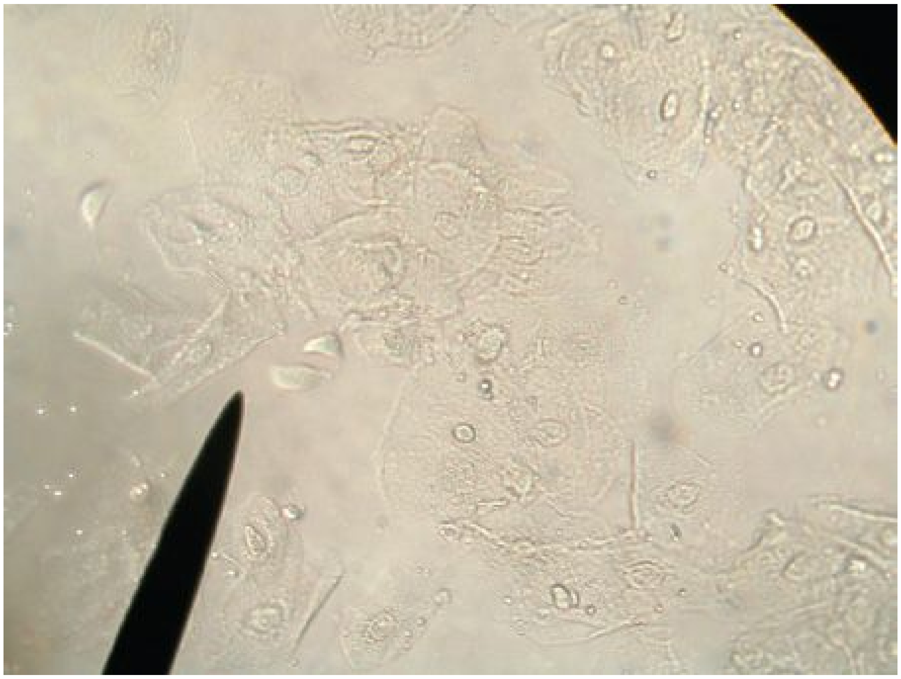

FIGURE 78-2 Wet mount showing *Trichomonas* in saline under low power. There are two visible trichomonads to the right and above the tip of the pointer. The largest cells are vaginal epithelial cells with visible nuclei. (*Used with permission from Richard P. Usatine, MD.*)

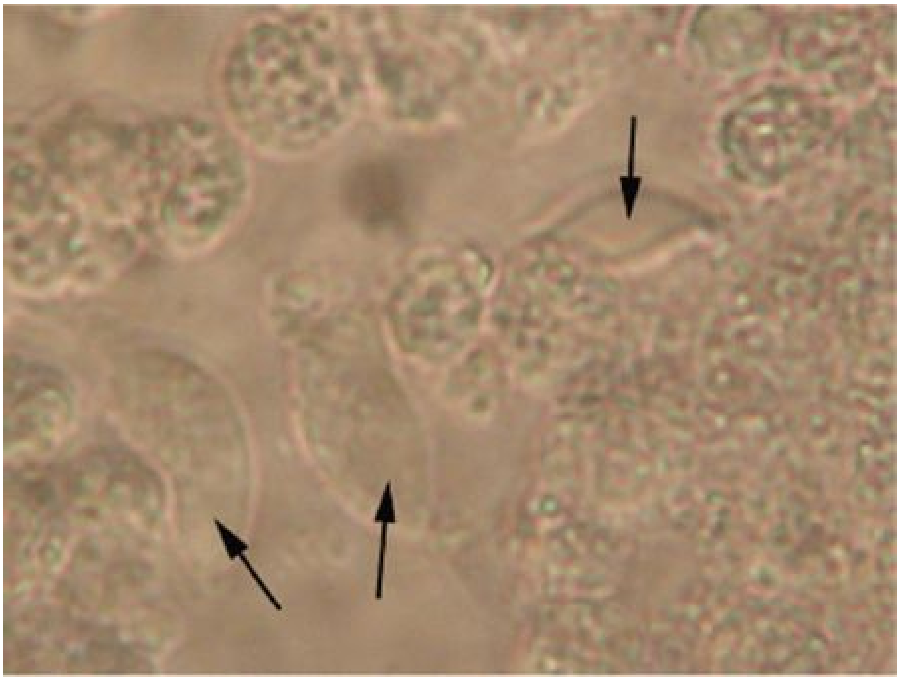

FIGURE 78-3 Wet mount showing *Trichomonas* (*arrows*) in saline under high power. The smaller more granular cells are white blood cells. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Trichomonas vaginitis is a local infection caused by the protozoan *Trichomonas vaginalis* that is associated with vaginal discharge and irritation. The patient often has an itch and an odor along with the discharge but may be asymptomatic.

SYNONYMS

Trichomoniasis, trich, tricky monkeys.

EPIDEMIOLOGY

- An estimated 3 to 5 million cases of trichomoniasis occur each year in the US.[1]
- The worldwide prevalence of trichomoniasis is estimated to be 180 million cases per year; and these cases account for 10 to 25 percent of all vaginal infections.[2]
- Cross-sectional data from the 2003 to 2004 US National Health and Nutrition Examination Survey (NHANES) shows 3 percent of female adolescents (aged 14 to 19 years) had laboratory evidence of infection with Trichomonas vaginalis.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- *Trichomonas* infection is caused by the unicellular protozoan *T. vaginalis*.[4]
- The majority of men (90%) infected with *T. vaginalis* are asymptomatic, but many women (50%) report symptoms.[5]
- The infection is predominantly transmitted via sexual contact. The organism can survive up to 48 hours at 10°C (50°F) outside the body, making transmission from shared undergarments or from infected hot spas possible although extremely unlikely.
- *Trichomonas* infection is associated with low-birth-weight infants, premature rupture of membranes, and preterm delivery in pregnant patients.[6]
- In a person coinfected with HIV, the pathology induced by *T. vaginalis* infection can increase HIV shedding. *Trichomonas* infection may also act to expand the portal of entry for HIV in an HIV-negative person. Studies from Africa have suggested that *T. vaginalis* infection may increase the rate of HIV transmission by approximately twofold.[7]

RISK FACTORS[3]

- New or multiple partners.
- A history of STDs.
- Exchanging sex for payment or drugs.
- Injection drug use.

DIAGNOSIS

CLINICAL FEATURES

- The physical examination should include inspection of the external genitalia for irritation or discharge (**Figures 78-1** and **78-5**). Speculum examination is done to determine the amount and character of the discharge and to look for the characteristic strawberry cervix (**Figures 78-4**). This strawberry pattern is caused by inflammation and punctate hemorrhages on the cervix.

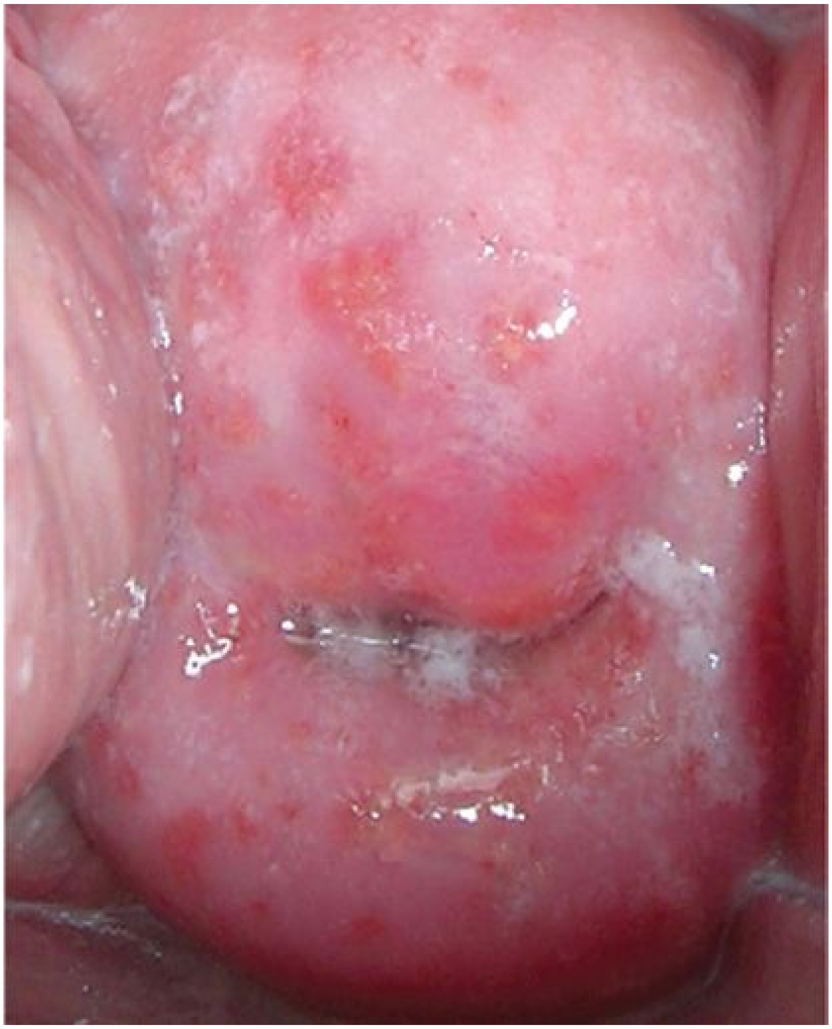

FIGURE 78-4 Close-up of strawberry cervix in a *Trichomonas* infection demonstrating inflammation and punctate hemorrhages. (*Used with permission from Richard P. Usatine, MD.*)

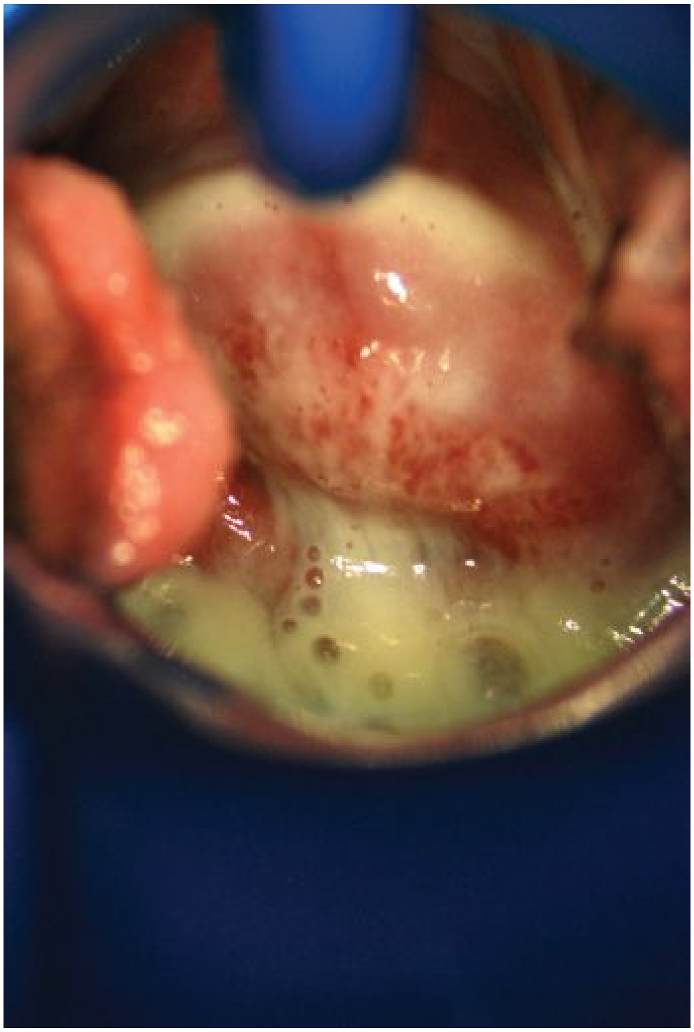

FIGURE 78-5 Speculum examination demonstrating the thick yellow-green discharge that may be seen in *Trichomonas* infection. The discharge can also be frothy white. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

- Typically, women with trichomoniasis have a diffuse, malodorous, yellow-green discharge (**Figure 78-5**) with vulvar irritation.[4] Vaginal and vulvar itching and irritation are common.
- It should be determined whether the patient douched recently, because this can lower the yield of diagnostic tests. Patients who have been told not to douche will sometimes start wiping the vagina with soapy washcloths to “keep clean” as an alternative. This greatly irritates the vagina and cervix, lowers test sensitivity, and may cause a discharge.

TYPICAL DISTRIBUTION

- In women, *Trichomonas vaginalis* may be found in the vagina, urethra, and paraurethral glands of infected women. Other sites include the cervix and Bartholin and Skene glands.

LABORATORY TESTING

- Because of the high prevalence of trichomoniasis, testing should be performed in women seeking care for vaginal discharge. Screening should be considered for women with risk factors.[4]
- Wet preps are obtained using a cotton-tipped applicator applied to the vaginal side-wall, placing the sample of discharge into normal saline (not water). A drop of the suspension is then placed on a slide, covered with a coverslip, and carefully examined with the low-power and high-dry objective lenses. Under the microscope, observe for motile trichomonads, which are often easy to visualize because of their lashing flagella (**Figure 78-2**).
- Wet prep has a sensitivity of only approximately 60 to 70 percent and requires immediate evaluation of wet preparation slide for optimal results.[4] One study found that 20 percent of samples for wet prep became negative by 10 minutes, 35 percent samples by 30 minutes, and 78 percent by two hours. They concluded that in order to maximize the sensitivity of this test, all specimens should be examined immediately after they are taken.[8]
- The OSOM Trichomonas Rapid Test and the Affirm VP III are FDA-cleared for trichomoniasis in women. Both tests are performed on vaginal secretions at the point of care and have a sensitivity greater than 83 percent and a specificity greater than 97 percent. The results of the OSOM Trichomonas Rapid Test are available in approximately 10 minutes, and results of the Affirm VP III are available within 45 minutes. False-positive tests might occur, especially in populations with a low prevalence of disease.[4]
- An FDA-approved polymerase chain reaction (PCR) assay for detection of gonorrhea and chlamydial infection (Amplicor, manufactured by Roche

Diagnostic Corp.) has been modified to test for *T. vaginalis* in vaginal or endocervical swabs and in urine from women and men, with sensitivity ranges from 88 to 97 percent and specificity from 98 to 99 percent.[9]

- APTIMA *T. vaginalis* Analyte Specific Reagents (ASR; manufactured by Gen-Probe, Inc.) also can detect *T. vaginalis* RNA using the same instrumentation platforms available for the FDA-cleared APTIMA Combo2 assay for diagnosis of gonorrhea and chlamydial infection. Published validation studies found sensitivity ranging from 74 to 98 percent and specificity from 87 to 98 percent.[10]
- A vaginal pH above 4.5 is seen with menopausal patients, *Trichomonas* infection, or bacterial vaginosis.[5]
- Culture is a sensitive and highly specific method of diagnosis. In women in whom trichomoniasis is suspected but not confirmed by microscopy, vaginal secretions should be cultured for *T. vaginalis*.[4]
- A nucleic acid amplification test for *Neisseria gonorrhoeae*, and/or *Chlamydia trachomatis* should be performed on all patients with *Trichomonas*.
- Although trichomonas may be detected on Pap testing, the sensitivity is low and Pap testing is not indicated in adolescents unless they are HIV infected.[11]

DIFFERENTIAL DIAGNOSIS

- Bacterial vaginosis and *Trichomonas* may have the odor of aromatic amines, and therefore may easily be confused with each other. Look for clue cells and trichomonads on the wet prep to differentiate between the two (Chapter 76, Bacterial Vaginosis).
- *Candida* vaginitis tends to present with a cottage-cheese-like discharge and vaginal itching (Chapter 77, Candida Vaginitis).
- Gonorrhea and *Chlamydia* and should not be missed in patients with vaginal discharge. Consider testing for these STDs based on patients’ risk

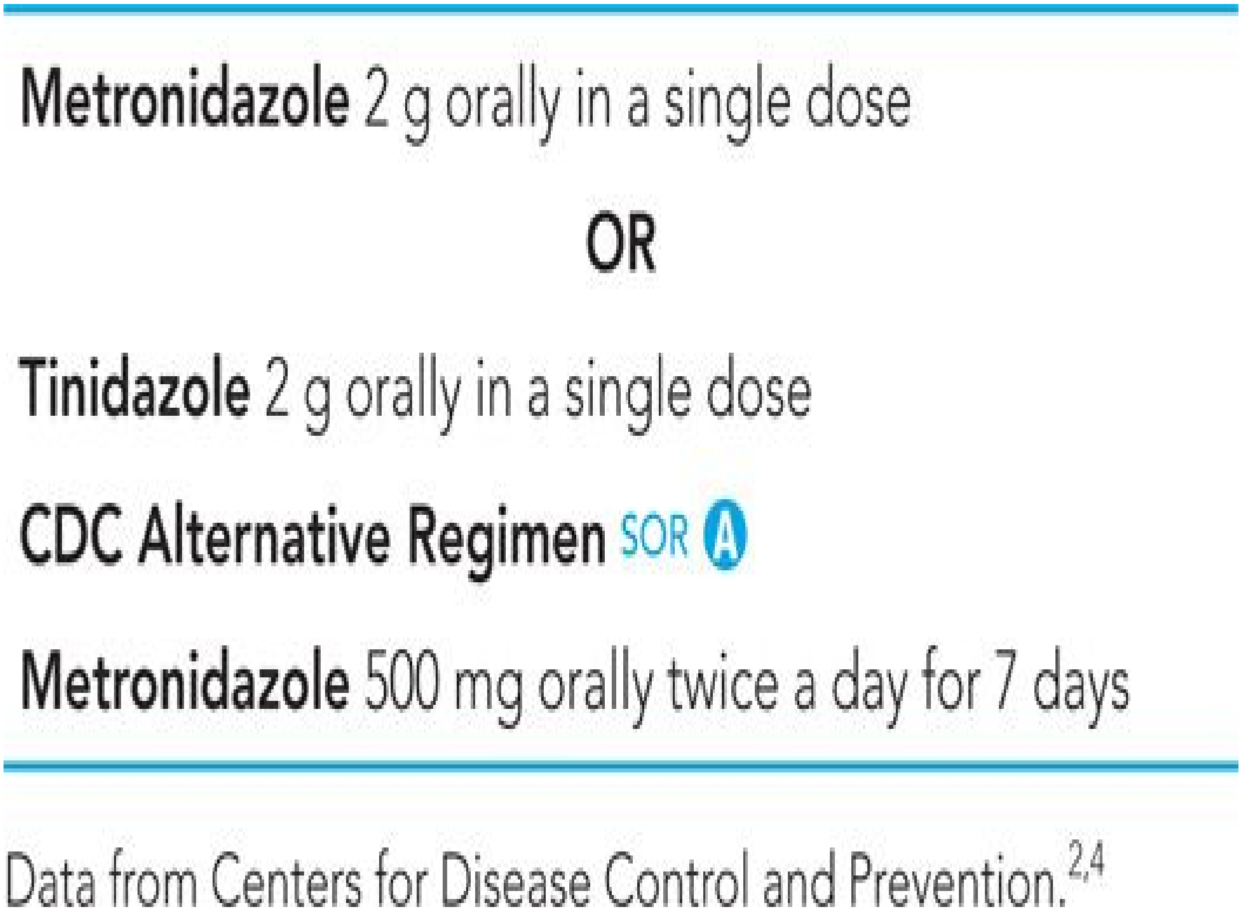
factors and the presence of purulence clinically and WBCs on the wet prep (Chapter 79, Chlamydia Cervicitis).

MANAGEMENT

MEDICATIONS

- **Table 78-1** shows treatments for *T. vaginalis* infections. Metronidazole 2 g orally as a single dose or 500 mg bid for 7 days (including pregnant patients) are the best treatments by Cochrane analysis.[12] SOR Ⓐ

TABLE 78-1 Centers for Disease Control and Prevention Recommended Regimens for Pregnant and Nonpregnant Patients. SOR Ⓐ



Metronidazole 2 g orally in a single dose

OR

Tinidazole 2 g orally in a single dose

CDC Alternative Regimen SOR Ⓐ

Metronidazole 500 mg orally twice a day for 7 days

Data from Centers for Disease Control and Prevention.[2,4]

- Tinidazole (Tindamax), a second-generation nitroimidazole, is indicated as a one-time dose of 2 g for the treatment of trichomoniasis (including metronidazole-resistant trichomoniasis).[4] SOR A It is effective therapy in nonresistant and resistant *T. vaginalis*.[13,14] The contraindications (including ethyl alcohol [ETOH]) to the use of tinidazole are similar to those for metronidazole.
- Pregnant women may be treated with 2 g of metronidazole in a single dose. Metronidazole is pregnancy category B. Vaginal trichomoniasis is associated with adverse pregnancy outcomes, particularly premature rupture of membranes, preterm delivery, and low birth weight. Unfortunately, data do not suggest that metronidazole treatment results in a reduction in perinatal morbidity and treatment may even increase prematurity or low birth weight.[4] Treatment of *T. vaginalis* might relieve symptoms of vaginal discharge in pregnant women and might prevent respiratory or genital infection of the newborn and further sexual transmission. The Centers for Disease Control and Prevention (CDC) recommends that clinicians counsel patients regarding the potential risks and benefits of treatment during pregnancy.[4]
- Some strains of *T. vaginalis* can have diminished susceptibility to metronidazole. Low-level metronidazole resistance has been identified in 2 to 5 percent of cases of vaginal trichomoniasis. These infections should respond to tinidazole or higher doses or longer durations of metronidazole. High-level resistance is rare.[15]
- Metronidazole gel is 50 percent less efficacious for the treatment of trichomoniasis than oral preparations and is not recommended.[4]

PREVENTION

- Patients should be instructed to avoid sex until they and their sex partners are cured (i.e., when therapy has been completed and patient and partner[s] are asymptomatic).[4]
- Spermicidal agents such as nonoxynol-9 reduce the rate of transmission of *Trichomonas*.[16]

- The risk of acquiring infection can be reduced by consistent use of condoms and limiting the number of sexual partners.

FOLLOW-UP

- Because of the high rate of reinfection among patients in whom trichomoniasis was diagnosed, rescreening at 3 months following initial infection can be considered for sexually active women.[4]

PATIENT EDUCATION

- Sexual partners of patients with *Trichomonas* should be treated. Patients can be sent home with a dose for a partner when it is believed that the partner will not come in on his own.

79 CHLAMYDIA CERVICITIS

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 16-year-old girl presents to clinic with a complaint of vaginal discharge. She has only one sexual partner but is unsure if her partner may have had other sexual contacts. On physical examination, there is ectopy and some mucoid discharge (**Figure 79-1**). The cervix bled easily while obtaining discharge and cells for a wet mount and genetic probe test. The wet mount showed many white blood cells (WBCs) but no visible pathogens. The patient was treated with 1 g of azithromycin taken in front of a clinic nurse. She was tested for HIV, syphilis, Trichomonas, GC, and Chlamydia and given a follow-up appointment in 1 week. The genetic probe test was positive for *Chlamydia* and all the other examinations were negative. This information was given to the patient on her return visit and safe sex was discussed.

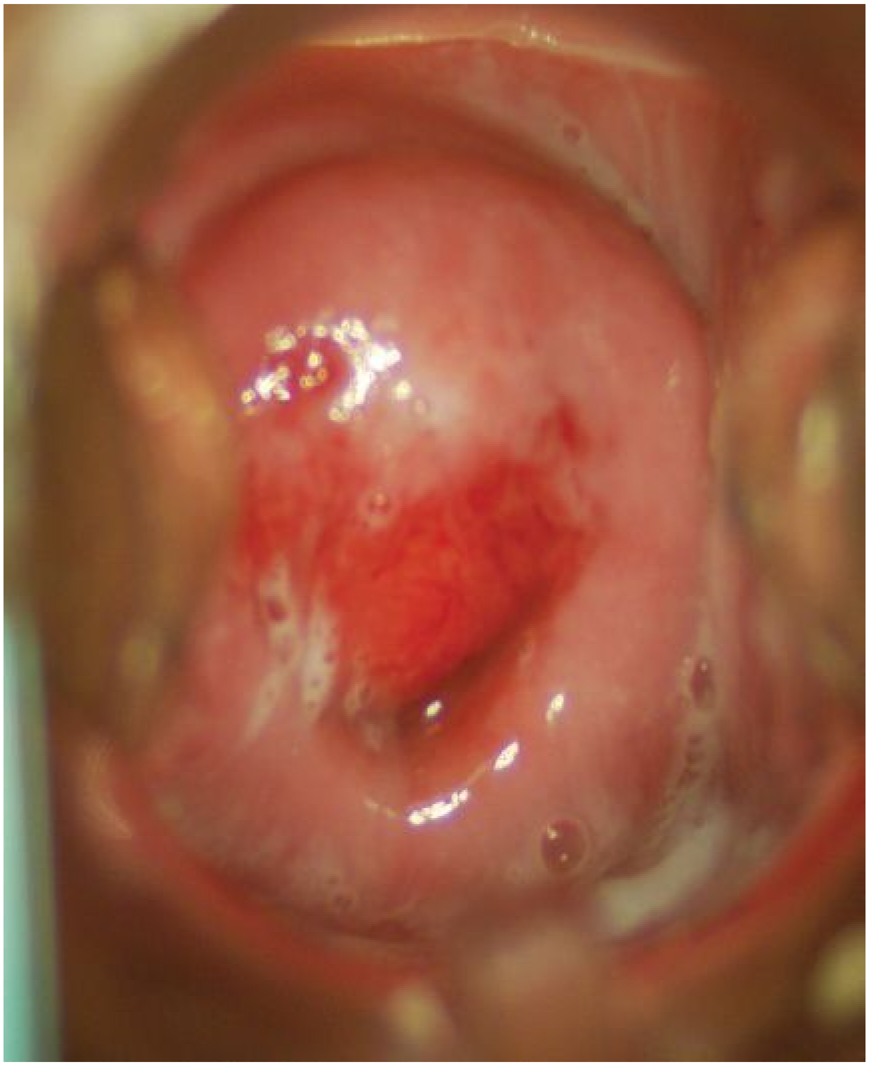

FIGURE 79-1 Chlamydial cervicitis with ectopy, mucoid discharge, and irritation in a 16-year-old girl. The cervix is inflamed and friable. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

INTRODUCTION

Chlamydia trachomatis causes genital infections that can result in pelvic inflammatory disease (PID), ectopic pregnancy, and infertility. Asymptomatic infection is common among both men and women so health care providers must rely on screening tests to detect disease. The Centers for Disease Control and Prevention (CDC) recommends annual screening of all sexually active women ages 25 years and younger, and of older women with risk factors, such as having a new sex partner or multiple sex partners.[1]

EPIDEMIOLOGY

- A very common STD, *Chlamydia* is the most frequently reported infectious disease in the US (excluding human papillomavirus [HPV]).[1] An estimated 1.2 million cases are reported to the CDC annually in the US.[2]
- The World Health Organization (WHO) estimates there are 140 million cases of Chlamydia trachomatis infection worldwide every year.[3]
- The CDC estimates screening and treatment programs can be conducted at an annual cost of $175 million. Every dollar spent on screening and treatment saves $12 in complications that result from untreated *Chlamydia*.[4]
- It is common among sexually active adolescents and young adults.[5] As many as 1 in 10 adolescent girls tested for *Chlamydia* is infected. Based on reports to the CDC provided by states that collect age-specific data, teenage girls have the highest rates of chlamydial infection. In these states, 15- to 19-year-old girls represent 46 percent of infections and 20- to 24-year-old women represent another 33 percent.[4]
- Cross-sectional data from the 2003-2004 US National Health and Nutrition Examination Survey (NHANES) shows 4 percent of female adolescents (aged 14 to 19 years) had laboratory evidence of infection with Chlamydia trachomatis.[6]

ETIOLOGY AND PATHOPHYSIOLOGY

- *C. trachomatis* is a small Gram-negative bacterium with unique biologic properties among living organisms. *Chlamydia* is an obligate intracellular parasite that has a distinct life-cycle consisting of two major phases: The small elementary bodies attach and penetrate into cells, and the metabolically active reticulate bodies that form large inclusions within cells.

- It has a long growth cycle, which explains why extended courses of treatment are often necessary. Immunity to infection is not long-lived, so reinfection or persistent infection is common.
- The infection may be asymptomatic and the onset often indolent. Symptoms of infection when present in women are most commonly abnormal vaginal discharge, vaginal bleeding (including after intercourse), and dysuria. Only 2 to 4 percent of infected men reported any symptoms.[7]
- It can cause cervicitis, endometritis, PID, infertility, perihepatitis (Fitz-Hugh-Curtis syndrome) urethritis, and epididymitis. It may produce poor neonatal outcomes including premature rupture of membranes, preterm labor, low birth weight, and infant death, conjunctivitis, and pediatric pneumonia.[8] Of exposed babies, 50 percent develop conjunctivitis and 10 to 16 percent develop pneumonia.[1] Perinatal *Chlamydia* is the leading cause of infectious blindness in the world, which is particularly worrisome since adolescents are at increased risk for infection and have more barriers to health care screening.[9]
- *Chlamydia* infections may lead to reactive arthritis, which presents with arthritis, conjunctivitis, and urethritis. Past or ongoing *C. trachomatis* infection may be a risk factor for ovarian cancer.[10,11]
- Up to 40 percent of women with untreated *Chlamydia* will develop PID. Undiagnosed PID caused by *Chlamydia* is common. Of those with PID, 20 percent will become infertile; 18 percent will experience debilitating, chronic pelvic pain; and 9 percent will have a life-threatening tubal pregnancy. Tubal pregnancy is the leading cause of first-trimester, pregnancy-related deaths in American women.[4]

RISK FACTORS[1,2,12]

- Adolescents and young adults.
- Nonwhite populations.
- Multiple and new sexual partners.
- Poor socioeconomic conditions.
- Single marital status.
- Nonbarrier contraceptive use.
- History of prior STD.

DIAGNOSIS

CLINICAL FEATURES

- The cervix is inflamed, friable, and may bleed easily with manipulation. The cervix may show ectopy (columnar cells on the ectocervix). The discharge is usually mucoid or mucopurulent (**Figure 79-1** to **79-3**).[8]

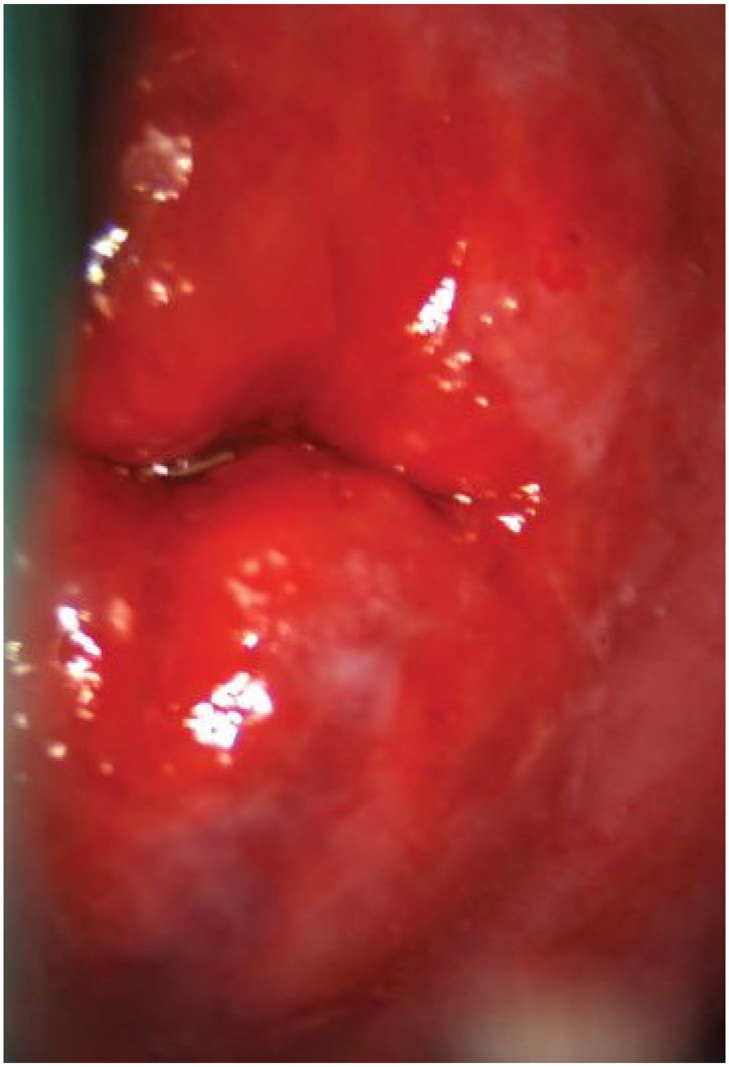

FIGURE 79-2 This patient presented with spotting after intercourse. She has cervicitis with ectopy, friability, and bleeding. NAAT was positive for Chlamydia. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

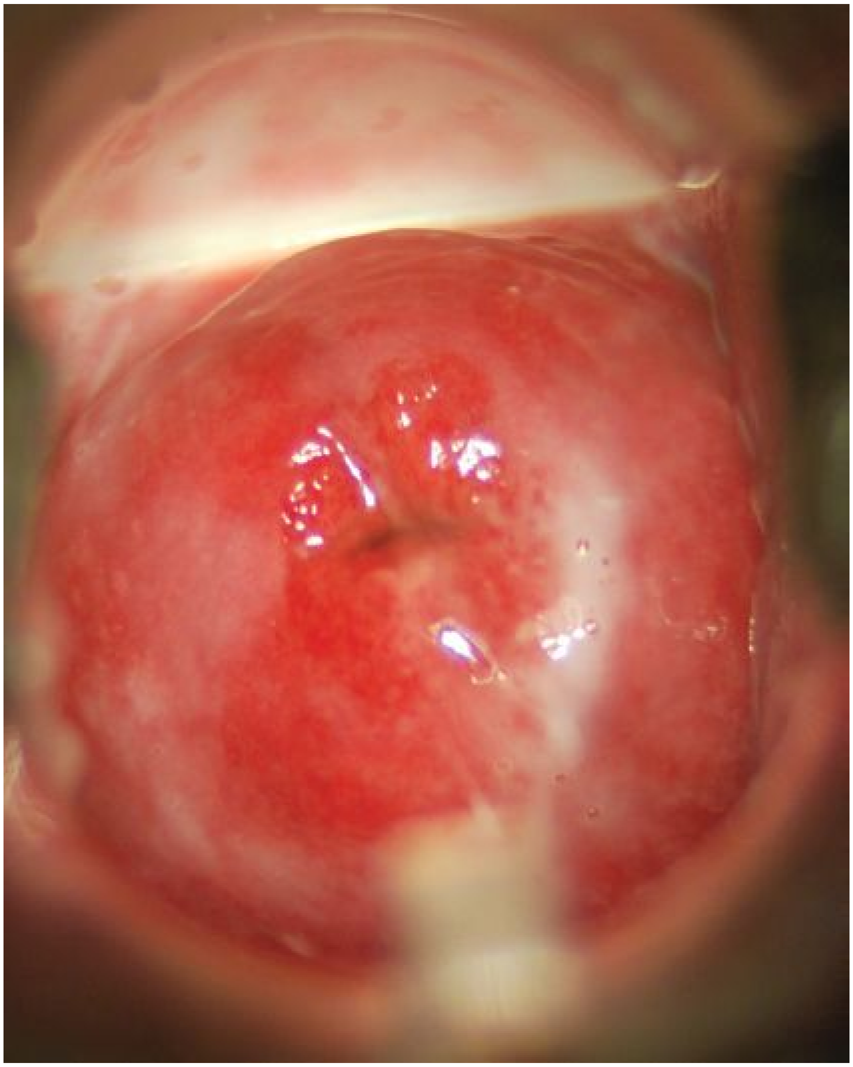

FIGURE 79-3 Chlamydia cervicitis that presented with a mild discharge. A NAAT test was positive for Chlamydia. The rest of her work-up was negative. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

- Persons who have receptive anal intercourse can acquire a rectal infection, which presents as anal pain, discharge, or bleeding. Persons who engage in oral sex can acquire a pharyngeal infection, which may present as an irritated throat.[8]
- Swab test—A white cotton-tip applicator is placed in the endocervical canal and removed to view. A visible mucopurulent discharge constitutes a positive swab test for *Chlamydia* (**Figure 79-4**). This is not specific for *Chlamydia* as other genital infections can cause a mucopurulent discharge, and is not recommended for diagnosis.

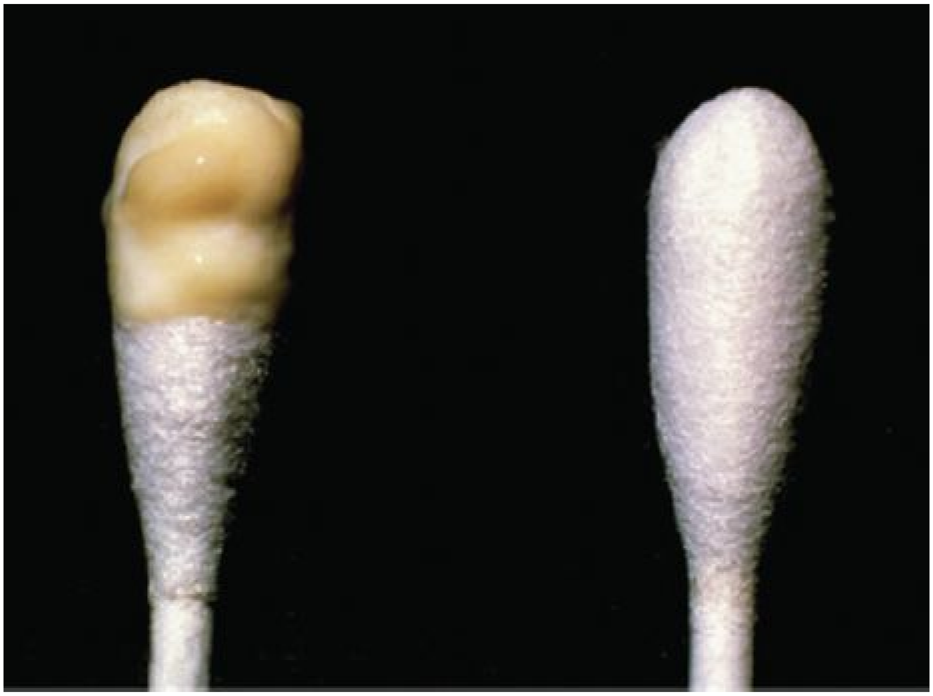

FIGURE 79-4 Mucopurulent discharge on the left swab from a cervix infected with *Chlamydia* (positive swab test). (*Used with permission from Connie Celum and Walter Stamm, Seattle STD/HIV Prevention Training Center, University of Washington*.)

LABORATORY TESTING

- A significant proportion of patients with *Chlamydia* are asymptomatic, providing a reservoir for infection. All pregnant women and sexually active women younger than 25 years of age should be screened with routine examinations. A wet prep is usually negative for other organisms. Only WBCs and normal flora are seen.
- *Chlamydia* cannot be cultured on artificial media because it is an obligate intracellular organism. Tissue culture is required to grow the live organism. When testing for *Chlamydia*, a wood-handled swab must not be used, as substances in wood may inhibit *Chlamydia* organism. Culture has sensitivity of 70 to 100 percent and a specificity of almost 100 percent, which makes it the gold standard.[1]
- The enzyme-linked immunosorbent assay (ELISA) technique (Chlamydiazyme) has a sensitivity of 70 to 100 percent and a specificity

of 97 to 99 percent.[5] Fluorescein-conjugated monoclonal antibodies test (MicroTrak) has a sensitivity of 70 to 100 percent and a specificity of 97 to 99 percent.[5]

- *C. trachomatis* can be detected using nucleic acid amplification techniques (NAATs) on swabs or voided urine specimens. These tests are often used for testing to detect gonorrhea and *Chlamydia*. Nucleic acid amplification tests have been used successfully in difficult-to-reach adolescents ("street kids") as well as in pediatric emergency departments and school-based settings.[13,14] Screening in school-based settings was associated with significant reduction in *Chlamydia* rates during a 1-year period. Self-collected vaginal swab specimens perform at least as well as with other approved specimens using NAATs.[15] NAATs can be performed on endocervical, urethral, vaginal, pharyngeal, rectal, or urine samples. The accuracy of NAATs on urine samples has been found to be nearly identical to that of samples obtained directly from the cervix.[16]
- Rectal and oropharyngeal *C. trachomatis* infection in persons engaging in anal or oral intercourse can be diagnosed by testing at the site of exposure. Although not FDA-cleared for this use, NAATs have demonstrated improved sensitivity and specificity compared with culture for the detection at rectal sites,[17] and at oropharyngeal sites in men.[18]
- Certain NAATs have been FDA-cleared for use on liquid-based cytology specimens, although test sensitivity using these specimens might be lower.[19]
- Persons who undergo testing for *Chlamydia* should be tested for other STDs as well.[1]

DIFFERENTIAL DIAGNOSIS

- Gonorrhea frequently coexists with *Chlamydia* and should be tested for when a patient is thought to have *Chlamydia*. The discharge of gonorrhea may be more purulent but this is not always the case.

- Bacterial vaginosis—The aromatic amine odor and clue cells help to distinguish between these infections (Chapter 76, Bacterial Vaginosis).
- Trichomoniasis—Look for the strawberry cervix and *Trichomonas* on the wet prep. There may also be a positive whiff test (see Chapter 78, Trichomonas Vaginitis).

MANAGEMENT

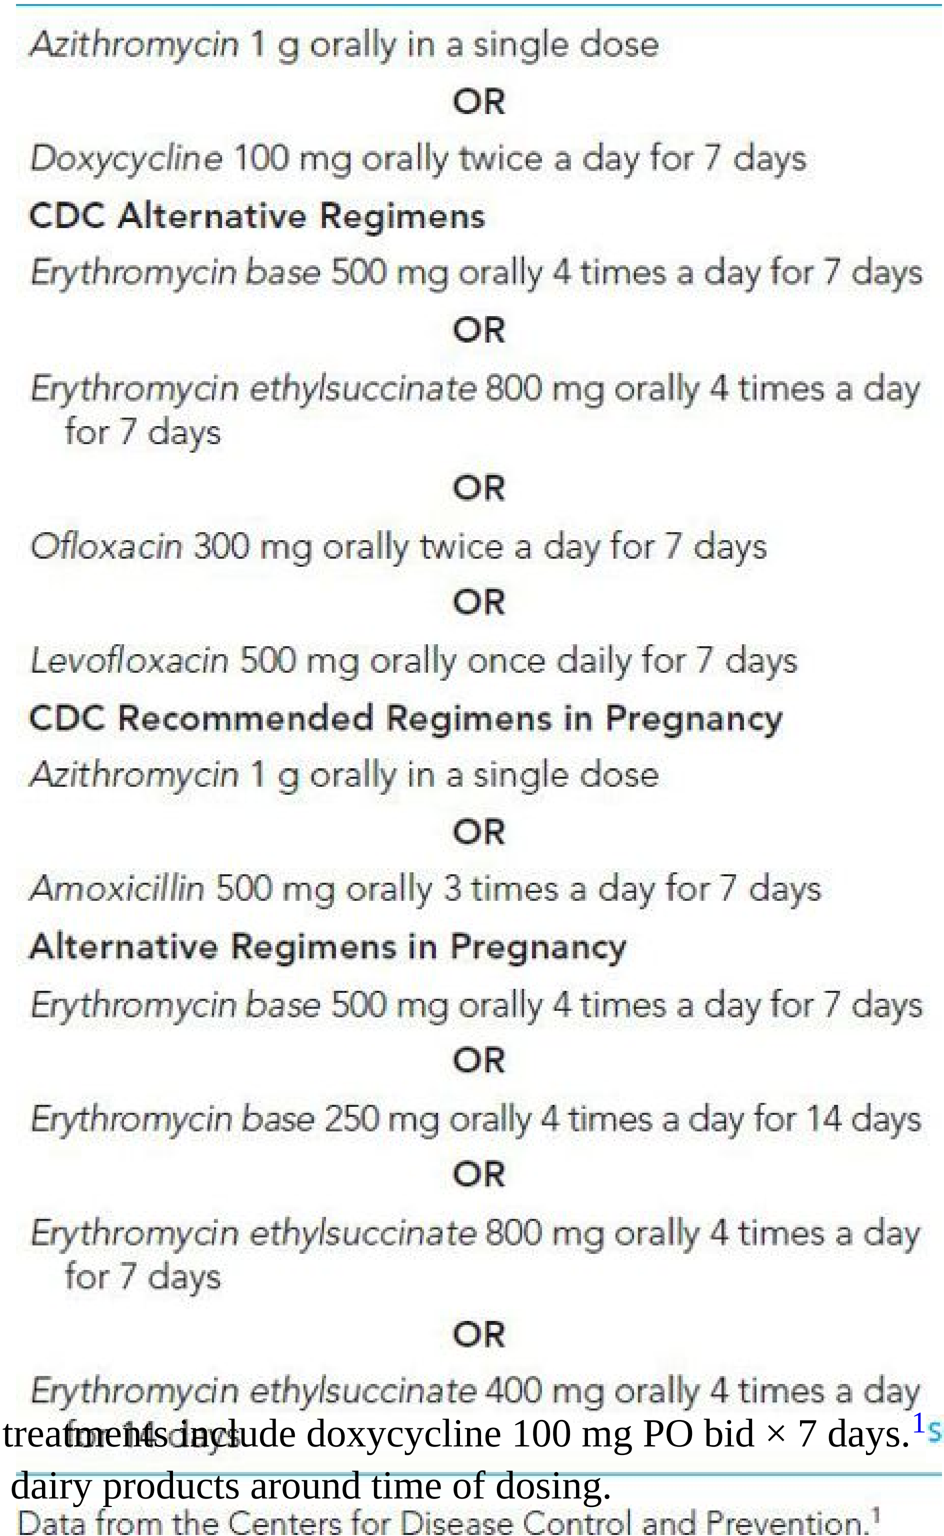
NONPHARMACOLOGIC

- Patients diagnosed with *Chlamydia* cervicitis should be tested for other STDs.[1]

MEDICATIONS

- **Table 79-1** shows CDC recommended treatments for *Chlamydia*. Azithromycin (Zithromax) 1000 mg one-time dose is easy and may be directly observed in the clinic.[1] SOR Ⓐ It is the first-line therapy for *Chlamydia* during pregnancy.

TABLE 79-1 Centers for Disease Control and Prevention Recommended Regimens SOR Ⓐ



Azithromycin 1 g orally in a single dose

OR

Doxycycline 100 mg orally twice a day for 7 days

CDC Alternative Regimens

Erythromycin base 500 mg orally 4 times a day for 7 days

OR

Erythromycin ethylsuccinate 800 mg orally 4 times a day for 7 days

OR

Ofloxacin 300 mg orally twice a day for 7 days

OR

Levofloxacin 500 mg orally once daily for 7 days

CDC Recommended Regimens in Pregnancy

Azithromycin 1 g orally in a single dose

OR

Amoxicillin 500 mg orally 3 times a day for 7 days

Alternative Regimens in Pregnancy

Erythromycin base 500 mg orally 4 times a day for 7 days

OR

Erythromycin base 250 mg orally 4 times a day for 14 days

OR

Erythromycin ethylsuccinate 800 mg orally 4 times a day for 7 days

OR

Erythromycin ethylsuccinate 400 mg orally 4 times a day for 14 days

Data from the Centers for Disease Control and Prevention.[1]

- Other treatments include doxycycline 100 mg PO bid × 7 days.[1] SOR A Avoid dairy products around time of dosing.
- Erythromycin might be less efficacious than either azithromycin or doxycycline, mainly because of the frequent occurrence of GI side effects that can lead to nonadherence.

- Ofloxacin (Floxin) 300 mg po bid × 7 days is an alternative that should be taken on an empty stomach.[1] SOR Ⓐ It is contraindicated in children or pregnant and lactating women, but may also cover *Neisseria gonorrhoeae* infection. Levofloxacin 500 mg orally for 7 days is another fluoroquinolone alternative.[1] SOR Ⓐ
- A metaanalysis of 12 randomized clinical trials of azithromycin versus doxycycline for the treatment of genital chlamydial infection demonstrated that the treatments were equally efficacious, with microbial cure rates of 97 and 98 percent, respectively.[20]
- Partners need treatment. If concerns exist that sex partners will not seek evaluation and treatment, then delivery of antibiotic therapy (either a prescription or medication) to their partners is an option.[1]
- Medications for chlamydial infections should be dispensed on site and the first dose directly observed to maximize medication adherence.[1]

REFERRAL OR HOSPITALIZATION

- With evidence of complications such as a tuboovarian abscess or severe PID.

PREVENTION

- Individuals who are sexually active should be aware of the risk of STDs and that ways of avoiding infection include mutual monogamy and appropriate barrier protection.

PROGNOSIS

- Treatment failures with full primary therapies are quite rare. Reinfection is very common and is related to nontreatment of sexual partners or acquisition from a new partner.

FOLLOW-UP

- Test-of-cure (repeat testing 3 to 4 weeks after completing therapy) is not recommended for persons treated with the recommended or alterative regimens, unless therapeutic compliance is in question, symptoms persist, or reinfection is suspected. However, test of cure is recommended in pregnant women.[1] If chlamydia is detected during the first trimester, repeat testing for reinfection should also be performed within three to six months, or in the third trimester.[1] Men and nonpregnant women should be retested at three months. If this is not possible, clinicians should retest the patient to screen for reinfection when he or she next presents for medical care within 12 months after treatment.[1]

PATIENT EDUCATION

- To minimize transmission, persons treated for *Chlamydia* should be instructed to abstain from sexual intercourse for 7 days after single-dose therapy or until completion of a 7-day regimen.
- To minimize the risk for reinfection, patients also should be instructed to abstain from sexual intercourse until all of their sex partners are treated.[1]

80 BREAST MASSES IN ADOLESCENTS

Katherine B. Lee, MD

PATIENT STORY

A 13-year-old girl is brought to her pediatrician by her mother because of a left breast mass, which she has noted for the past month. The lump has been very painful and “changed” in color (**Figure 80-1**). Her mother is concerned about the size of the lump, having seen it only three days prior to her visit. The patient reached menarche at age 12 years and is not taking any medications. She has never been pregnant. The diagnosis of giant fibroadenoma was suspected and the girl is referred to a breast surgeon. Given the size of the lesion, and severe asymmetry, it was advised that she have an excision of this mass with reconstruction to achieve a better cosmetic result. She underwent surgical excision of the mass, which confirmed a giant fibroadenoma. After the procedure, her breasts appeared symmetrical and she healed very well. There is concern that her left reconstruction may need to be revised in the future as her other breast will mature appropriately for her age. This will need to be followed into adulthood.

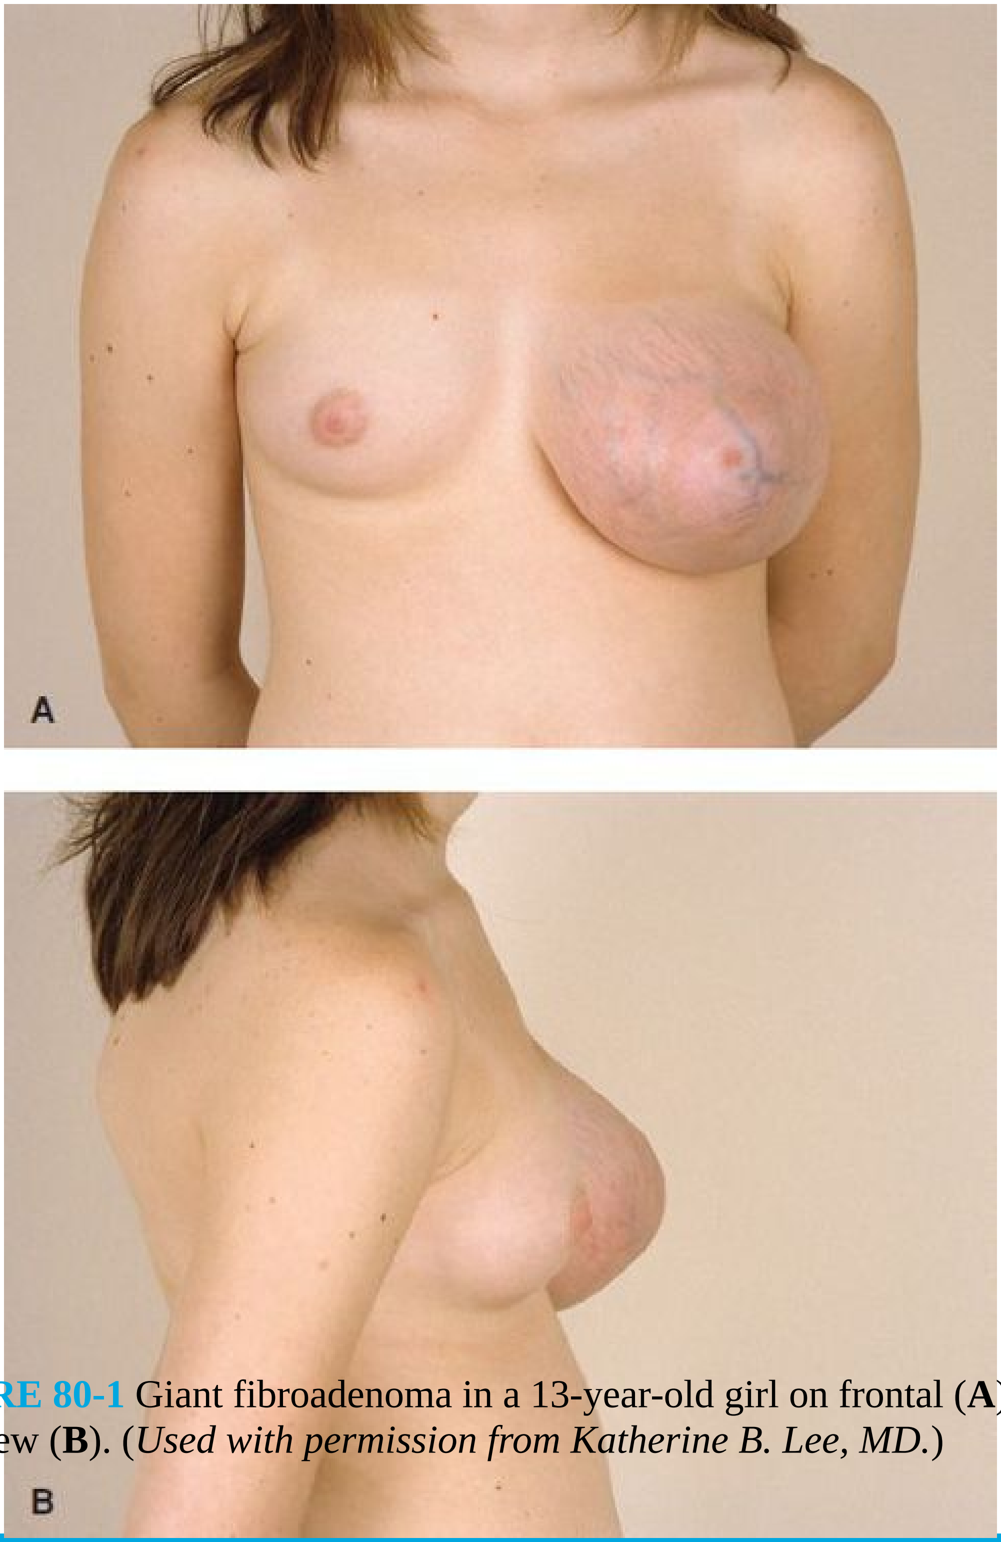

FIGURE 80-1 Giant fibroadenoma in a 13-year-old girl on frontal (**A**) and side view (**B**). (*Used with permission from Katherine B. Lee, MD.*)

INTRODUCTION

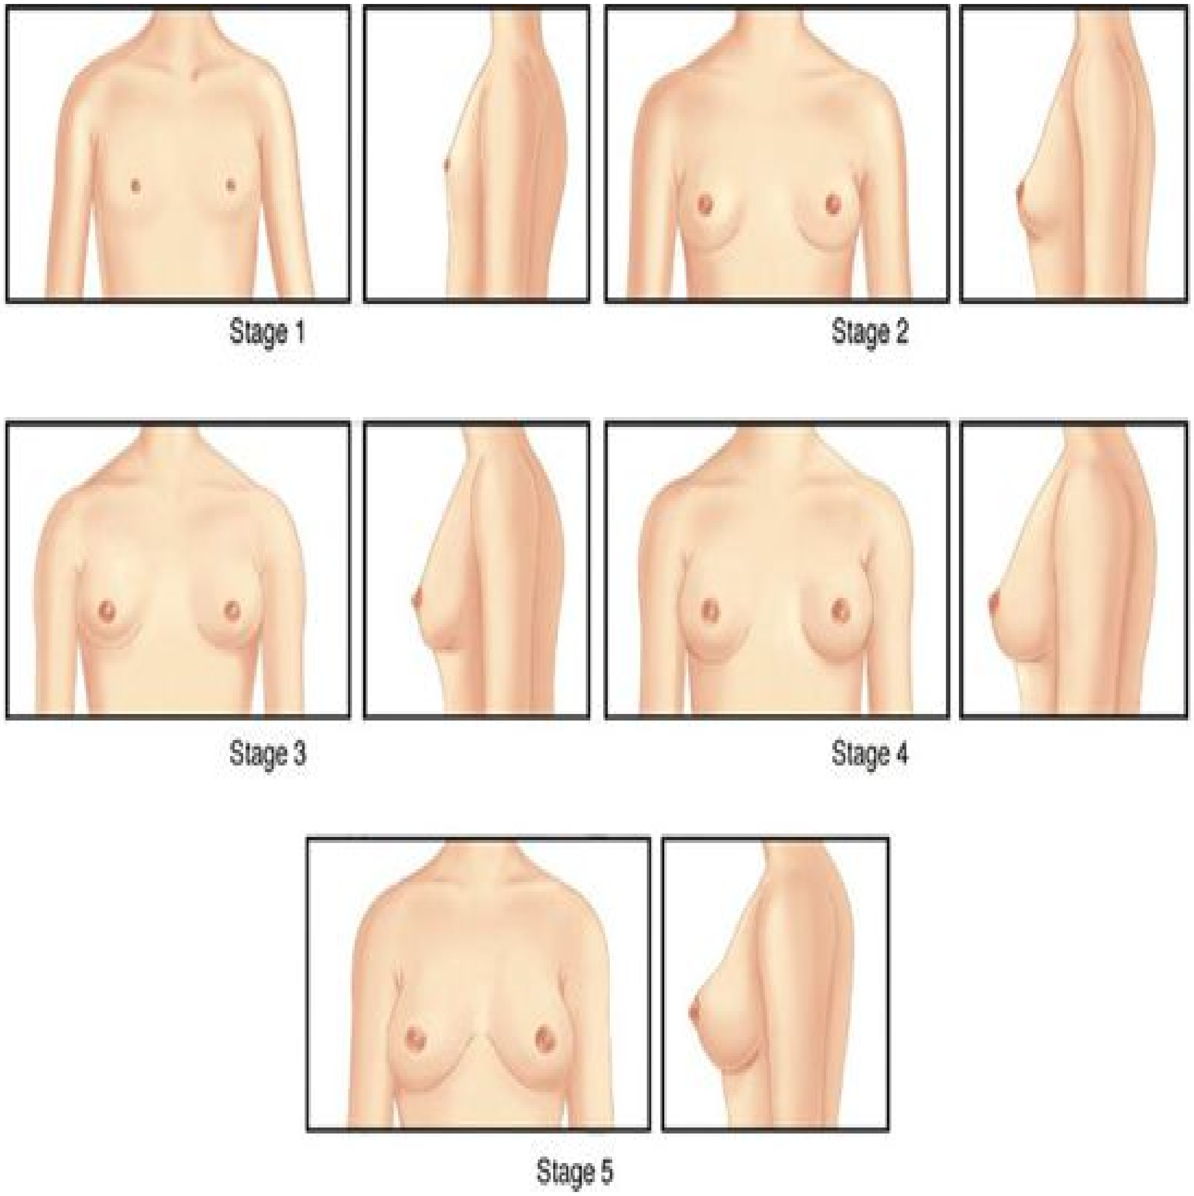
Breast masses in female adolescents can range from normal breast tissue to cysts to fibroadenomas to malignancies. The most common cause of breast masses in adolescent girls is a fibroadenoma, which is a benign, well circumscribed lesion composed of abundant stromal and epithelial components. Despite the benign nature of fibroadenomas, accurate diagnosis and management will help alleviate significant fears that are associated with these lesions.

EPIDEMIOLOGY

- Fibroadenomas are the most common breast lesions in adolescent girls.[1,2]
- These occur in about 10 percent of all women, and have a peak incidence in the second and third decades of life.
- Fibrocystic changes of the breast are common in adolescents, although the exact prevalence is not known.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Female adolescents usually go through breast development and growth during puberty (**Figure 80-2**). Knowledge of normal development is important in the diagnosis of breast masses in adolescents.



Stage 1	Preadolescent: juvenile breast with elevated papilla and small flat areola.
Stage 2	The breast bud forms under the influence of hormonal stimulation. The papilla and areola elevate as a small mound, and the areolar diameter increases.
Stage 3	Continued enlargement of the breast bud further elevates the papilla. The areola continues to enlarge; no separation of breast contours is noted.
Stage 4	The areola and papilla separate from the contour of the breast to form a secondary mound.
Stage 5	Mature: areolar mound recedes into the general contour of the breast; papilla continues to project.

FIGURE 80-2 Tanner staging of breast development. (*Used with permission from Greydanus DE, Pratt HD. Adolescent growth and development, and sport participation. In: Patel DR, Greydanus DE, Baker RJ, eds*. Pediatric Practice: Sports Medicine. *New York, NY: McGraw-Hill; 2009:18. www.accesspediatrics.com*).

- Pathology of the lesion determines the type of lesion: Cysts are fluid filled masses. Fibroadenomas are fibroepithelial lesions which are filled with numerous cells.

- Fibrocystic changes are thought to result from an imbalance between estrogen and progesterone.
- Women who have fibroadenomas do not appear to have an increased risk of developing breast cancer; however, it is important to note that about 2 percent of carcinomas arise in a fibroadenoma. For this reason, fibroadenomas are usually followed to assure stability over time. Growth beyond 5 cm is consistent with a giant fibroadenoma.
- Fibroadenomas are very responsive to hormonal changes and enlarge during pregnancy or prior to the menses.

RISK FACTORS

- Women in their 20s to 30s are at higher risk, although fibroadenomas are the most common causes of breast lesions in adolescents.
- Hormone exposure such as pregnancy or use of birth control pills.
- Having previous fibroadenomas make women susceptible to having more in the future.
- The role of caffeine as a risk factor for fibroadenomas is not clear.[3–5]

DIAGNOSIS

A careful history and physical examination is the first step in the diagnosis of breast lesions in adolescents. Most often, observation of the mass for one to two menstrual cycles will aid in the diagnosis and help rule out more serious causes. In equivocal cases, ultrasonography and/or needle aspiration are helpful.

CLINICAL FEATURES

- Fibroadenomas may be painful but most often are asymptomatic.
- The lesion size can be quite small (1cm) to several centimeters in diameter (as in the patient in the vignette).
- Most fibroadenomas are mobile, have a rubbery consistency, and are well circumscribed.
- Fibroadenomas may affect the contour of the breast (**Figure 80-3**).

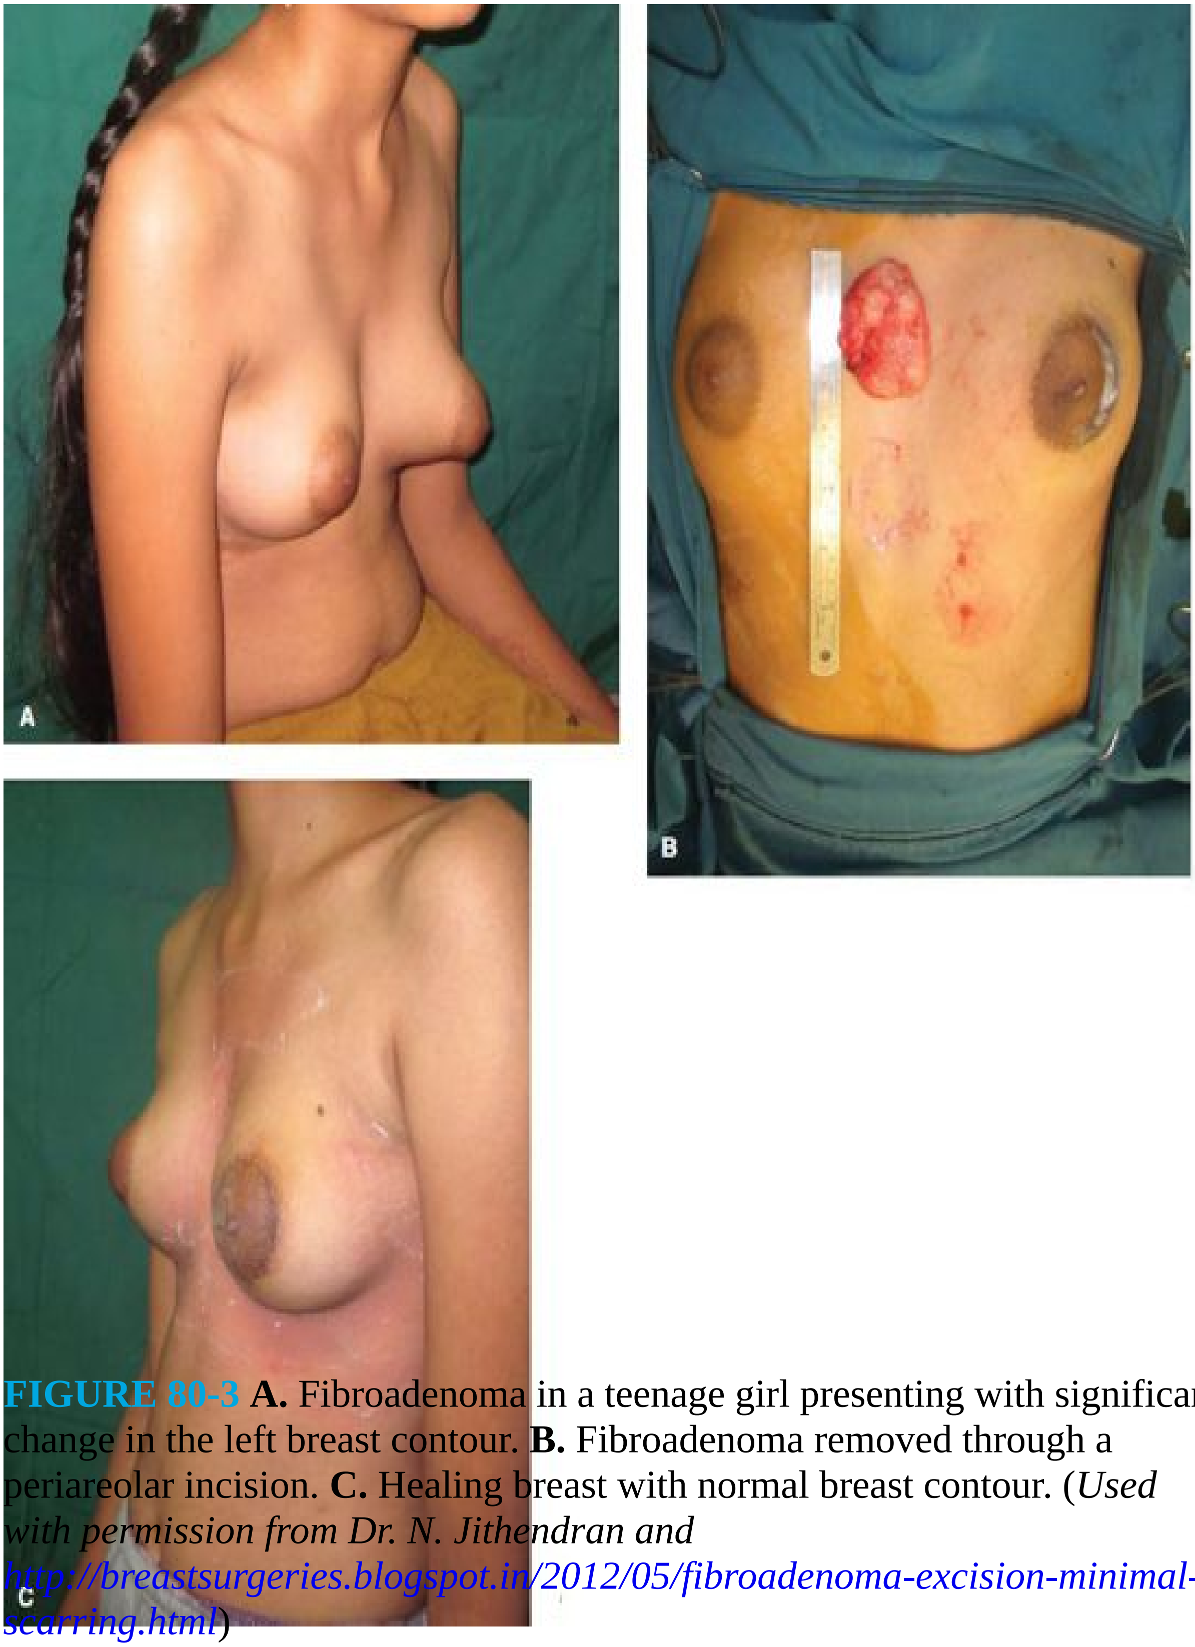


FIGURE 80-3 **A.** Fibroadenoma in a teenage girl presenting with significant change in the left breast contour. **B.** Fibroadenoma removed through a periareolar incision. **C.** Healing breast with normal breast contour. (*Used with permission from Dr. N. Jithendran and http://breastsurgeries.blogspot.in/2012/05/fibroadenoma-excision-minimal-scarring.html*)

- May occur recurrently or found as multiple masses.

DISTRIBUTION

- Can occur in any quadrant, but most frequently found in the upper, outer quadrant of the breast.

LABORATORY TESTING

- If the diagnosis is in question, the most definitive way of making the diagnosis is to sample the lesion via excision or core biopsy.
- Histology reveals proliferating stroma.

IMAGING

- Imaging is usually not necessary, but can help to differentiate cystic from solid masses if the lesion persists for more than two menstrual cycles.
- Ultrasonography of the breast is the modality of choice and will show a well circumscribed hypoechoic mass.[6,7]
- Mammography is not helpful in the diagnosis because of the large amount of glandular tissue in adolescents, which makes interpretation of the study difficult.[8]

DIFFERENTIAL DIAGNOSIS

- Breast bud—Breast tissue development can also be confused for an abnormality on examination. It is important to not confuse normal breast bud tissue for an abnormal mass (Figure 80-2).
- Simple cyst—Usually distinguished clinically and disappear over weeks to months.
- Fibroadenoma (Giant)—Greater than 5cm in size and may compress or replace normal breast tissue. Dilated superficial veins often visible (**Figure 80-1**).

- Breast abscess/mastitis—Often associated with overlying mastitis and/or purulent nipple discharge (**Figures 80-4** and **80-5**).
- Phyllodes tumor—A rare primary tumor, which is usually benign, but capable of a wide range of biologic behavior. A biopsy (tissue) is needed to definitely differentiate from fibroadenoma.

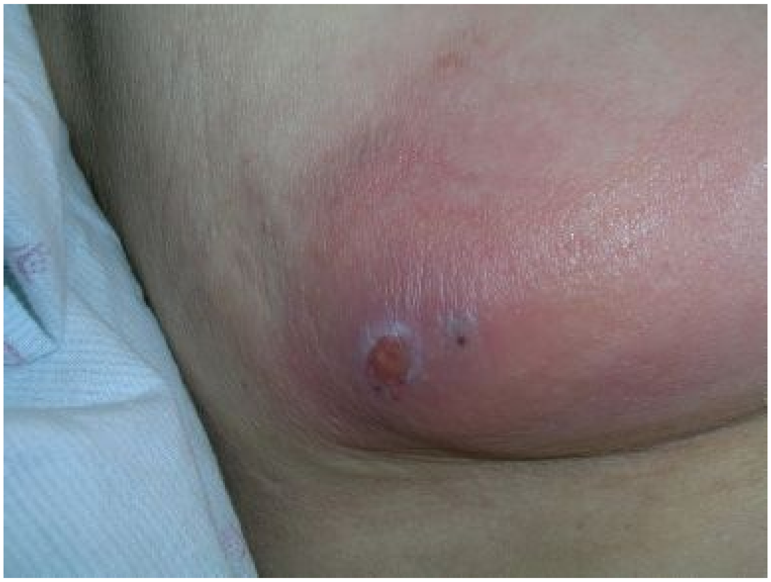

Figure 80-4 Breast abscess with surrounding cellulitis. (*Used with permission from Richard P. Usatine, MD.*)

- Breast cancer—Exceedingly rare in the adolescent population. Characterized by a firm, irregular mass.
- Other malignancies such as breast sarcoma—Very rare and characterized by a firm irregular mass that does not change with menstrual cycle.

MANAGEMENT

- The treatment of fibroadenomas in adolescent patients is generally conservative, observing and watching diligently as opposed to surgical excision.[8]

- Observation of the mass for one or two menstrual cycles is the most common approach if the history is typical for fibrocystic changes or a fibroadenoma.
- Asymptomatic solid masses measuring less than 5 cm and consistent with fibroadenomas can be observed.

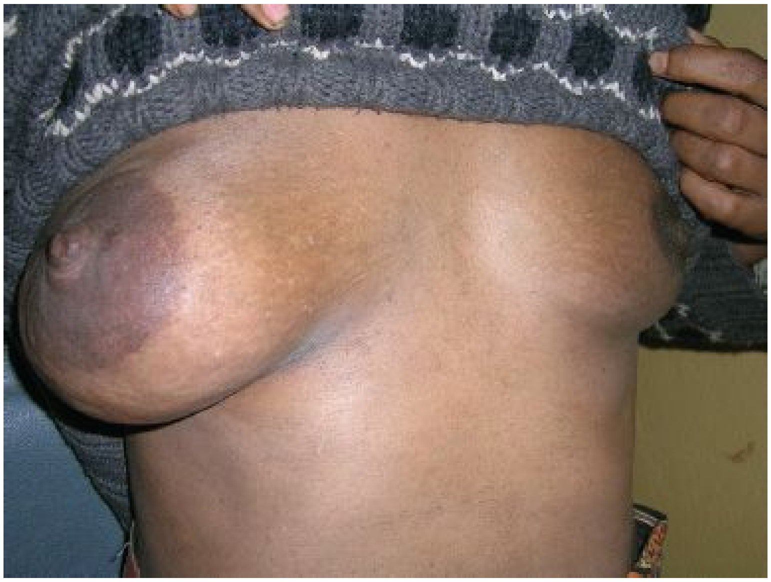

Figure 80-5 Postpartum mastitis with massive swelling of the involved breast. (*Used with permission from Richard P. Usatine, MD.*)

- When the mass regresses, observation at 3 to 4 months intervals is appropriate. If the lesion persists over this time period, an ultrasound can be obtained, and if completely consistent with fibroadenoma, can be observed without biopsy unless there are extenuating concerns.[9,10]

SURGERY

- Persistent cystic lesions can be evaluated by needle aspiration, although this is rarely required in adolescents.
- Surgical resection of solid masses may be warranted for nonmobile, hard, enlarging, associated with skin changes, or those associated with significant anxiety for the patients and their parents. SOR Ⓒ

- Giant fibroadenomas should be excised given their large size, severe asymmetry, compression of normal breast tissue and to rule out l tumors.[1,8,11] SOR Ⓒ

REFERRAL

- Removal of the lesion by a breast surgeon along with reconstruction with plastic surgery (**Figure 80-3**).

PREVENTION AND SCREENING

- No known interventions can prevent the development of a fibroadenoma, but a core biopsy is advised if there is question as to the diagnosis or if there is a concern for a phyllodes tumor.
- An ultrasound of the lesion should be performed to aid in the diagnosis.

PROGNOSIS

- Most fibroadenomas in adolescents decrease in size and eventually resolve completely.[12]
- For giant fibroadenomas, the prognosis is good as long as complete excision is achieved.

FOLLOW-UP

- Follow-up and reassurance are paramount in the management of fibroadenomas in adolescents.

PATIENT EDUCATION

- Reassurance as to benign nature of fibroadenomas is very important.
- Reassurance as to the rarity of breast cancer in adolescents is also important.

81 COMPLICATIONS OF TATTOOS AND PIERCINGS

Edward A. Jackson, MD
Richard P. Usatine, MD

PATIENT STORY

A teenager presents with itching and swelling along the area of a recent tattoo on the lower leg. She notes that the area has become swollen and is itching and draining (**Figure 81-1**). On examination there is swelling over the areas of red dye usage. The pediatrician recognized this as an allergy to the red dye and noted that there were signs of excoriations and some crusting. This was secondary to the scratching that broke the skin and allowed for a secondary infection to begin. The physician treated the secondary infection with oral cephalexin and referred the patient to dermatology for consideration of intralesional steroid treatment of the red dye allergy.

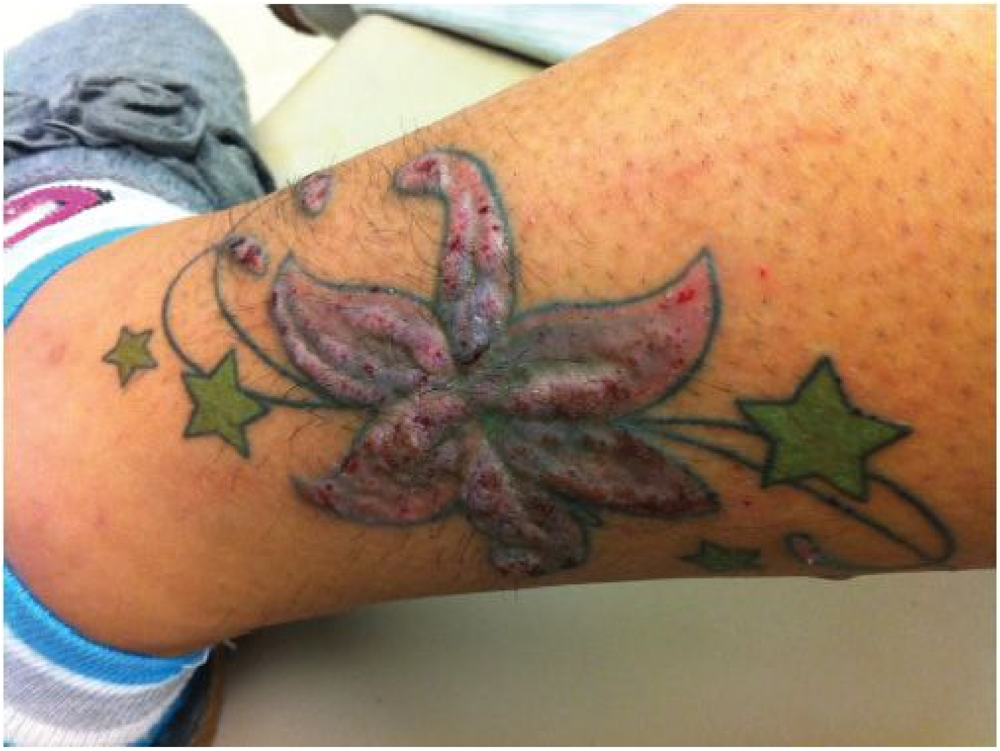

Figure 81-1 Allergic reaction to the red pigment in a tattoo on the lower leg of a teenage girl. (*Used with permission from Jonathan Karnes, MD.*)

A teenager presents with a tender red lump around an embedded neck piercing (**Figure 81-2A**). The physician notes that there is a granuloma around the piercing site on the left. The patient requests removal of this piercing which is performed in the office. Four months later a new granuloma forms around the piercing on the right neck (**Figure 81-2B**). The patient requests removal of the second piercing and acknowledges that it is not a good idea for her to get any additional piercings.

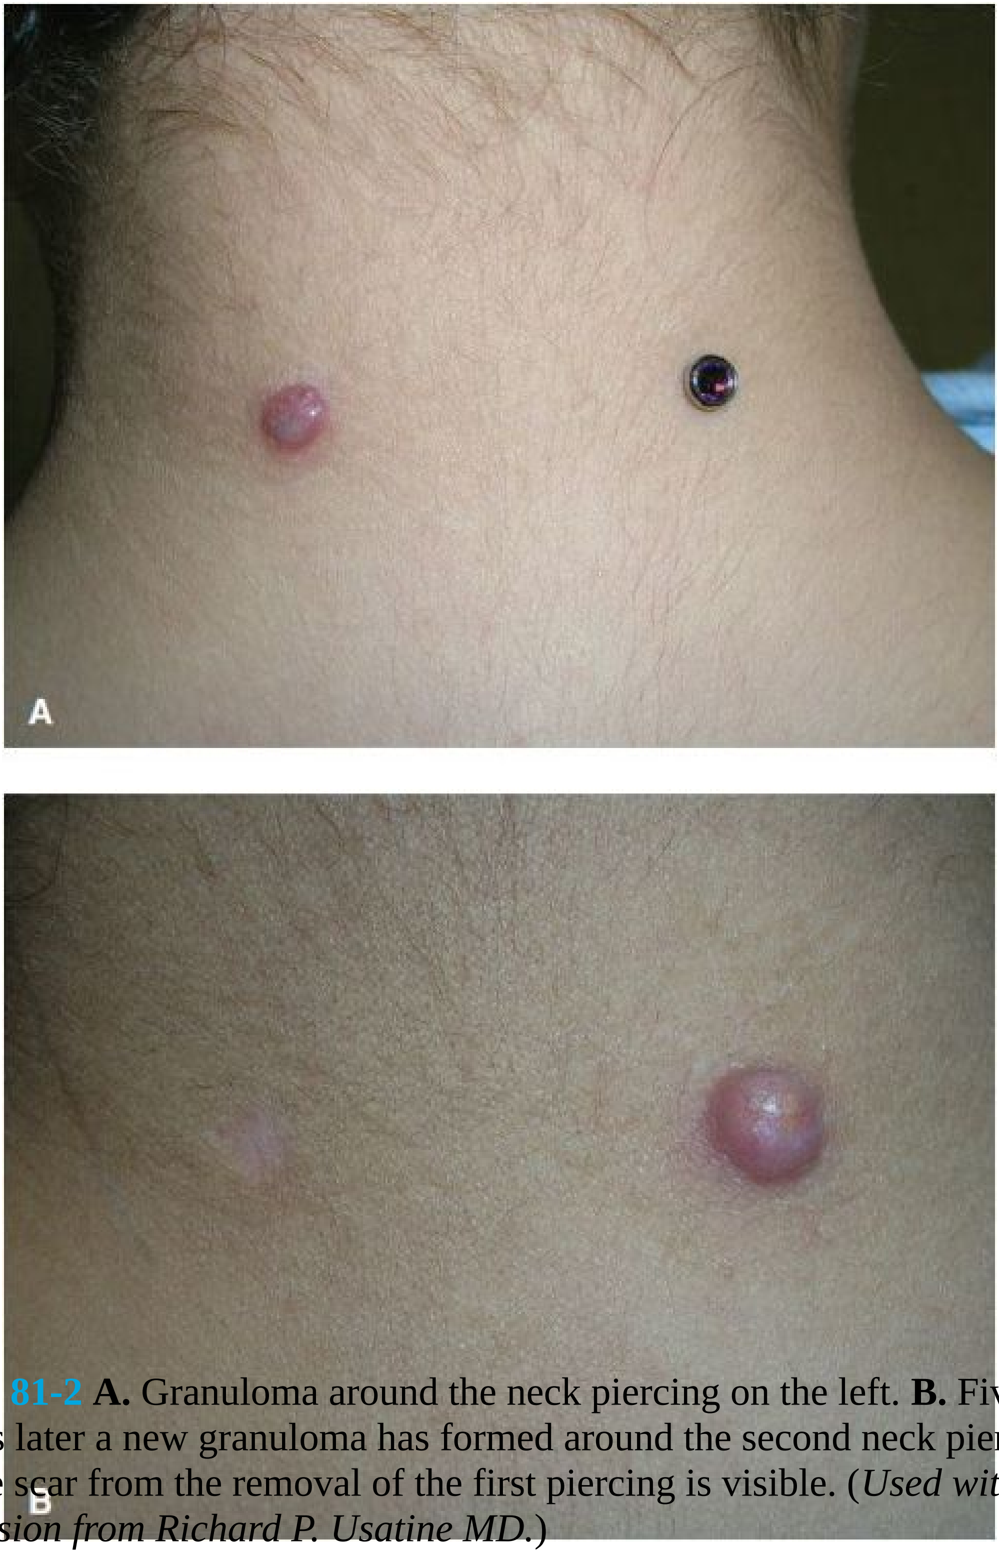

Figure 81-2 **A.** Granuloma around the neck piercing on the left. **B.** Five months later a new granuloma has formed around the second neck piercing and the scar from the removal of the first piercing is visible. (*Used with permission from Richard P. Usatine MD.*)

INTRODUCTION

Tattoos and piercings in both the adult and adolescent populations have become more commonplace. The complications of both have increased as the popularity of body art grows.

SYNONYMS

Tattoos and piercings are also called body art.

Dye, pigment, and ink are all interchangeable when referring to the color used in tattoos.

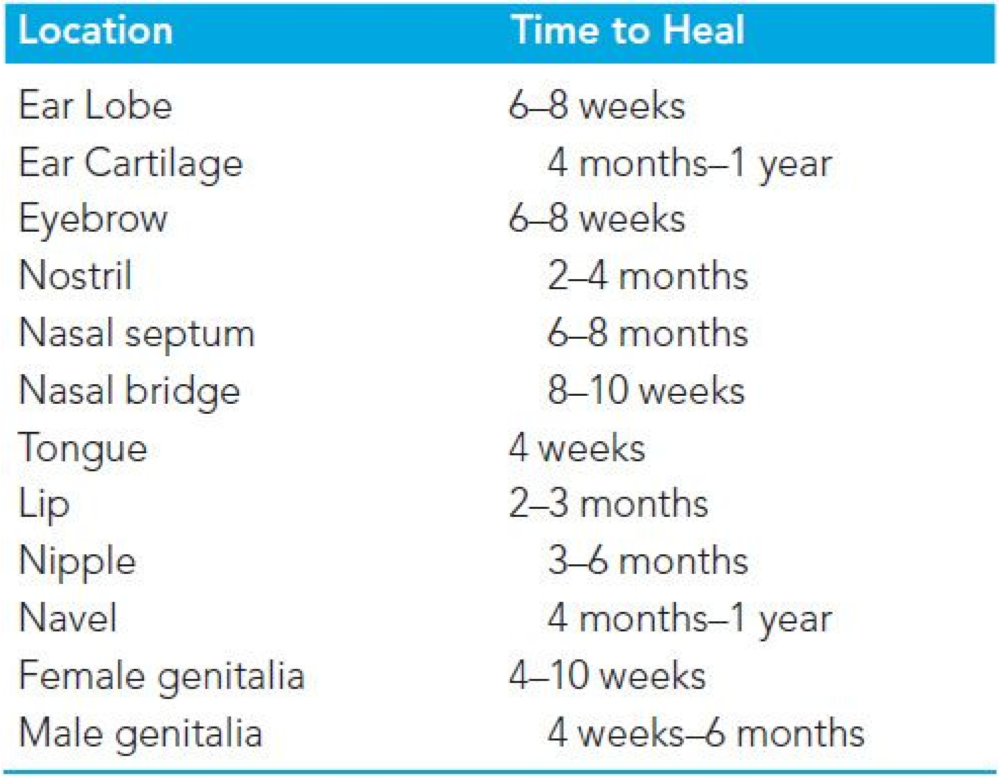
EPIDEMIOLOGY

- Body art including tattooing, piercings and scarification have been practiced worldwide since the beginning of history.
- Tattoos are increasingly popular in the US with an estimated percentage of adults with one or more tattoos at about 21 to 25 percent in 2012.[1]
- More adolescent and adults are choosing both tattoos and piercings as an expression of uniqueness.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

Complications result from permanent tattooing or piercing dependent on the location of the body, the healing time and the type of body art chosen. Because both tattoos and piercings break the protective skin barrier, there are increased risks for infections and bleeding. Further complications for piercings include an increased risk for local trauma, tearing of the skin and mucous membranes, keloid formation, and site-specific piercing complications. Delayed wound healing is also a problem with piercings and may complicate the body art.[4] Healing times for piercings vary by body location and are shown in **Table 81-1**.

TABLE 81-1 Common Healing Times for Piercings



Location	Time to Heal
Ear Lobe	6–8 weeks
Ear Cartilage	4 months–1 year
Eyebrow	6–8 weeks
Nostril	2–4 months
Nasal septum	6–8 months
Nasal bridge	8–10 weeks
Tongue	4 weeks
Lip	2–3 months
Nipple	3–6 months
Navel	4 months–1 year
Female genitalia	4–10 weeks
Male genitalia	4 weeks–6 months

RISK FACTORS

- Risk of complications is more common with piercings than with tattoos and reportedly range from 17 to 69 percent.[5] Genital piercings are especially prone to infections (**Figures 81-3** and **81-4**).[7]

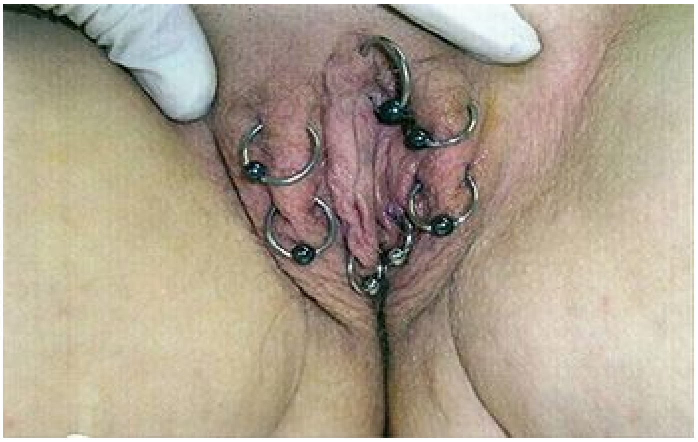


Figure 81-3 Clitoral and labial piercing. Piercings in the genital area are at higher risk of developing infections. (*Used with permission from Edward A. Jackson, MD.*)

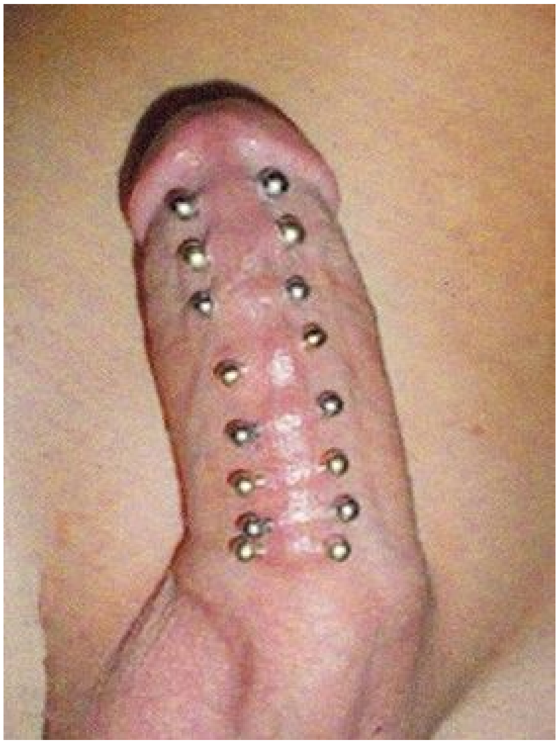

Figure 81-4 Penile piercing. While there are no signs of infection there is a higher risk of infections to piercings in the genital region. (*Used with permission from Edward A. Jackson, MD.*)

- Risks for infection from tattoos is related to contaminated dyes (pigments) and may include bacterial infections such as staph species, mycobacterial,[67–8] viral such as hepatitis B or C, and fungal.[4]

- The most common reported tattoo skin reaction is a hypersensitivity reaction to the pigment. The red pigment is most likely to provoke an allergic reaction (**Figures 81-1** and **81-5**).

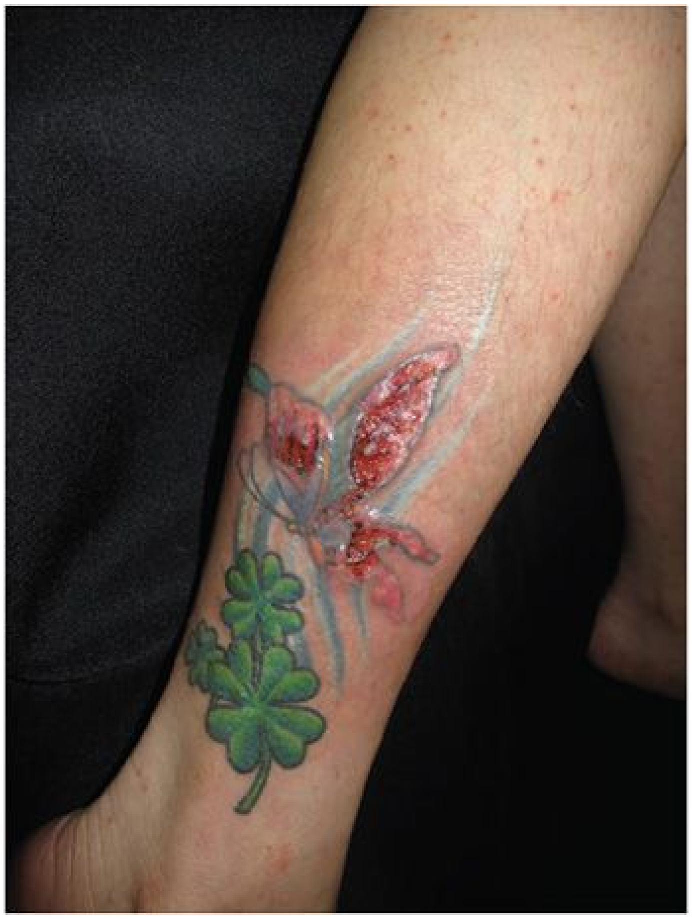

Figure 81-5 Allergic reaction to red pigment in a lower leg tattoo. Note that there is granuloma formation as well. (*Used with permission from Jonathan Karnes, MD.*)

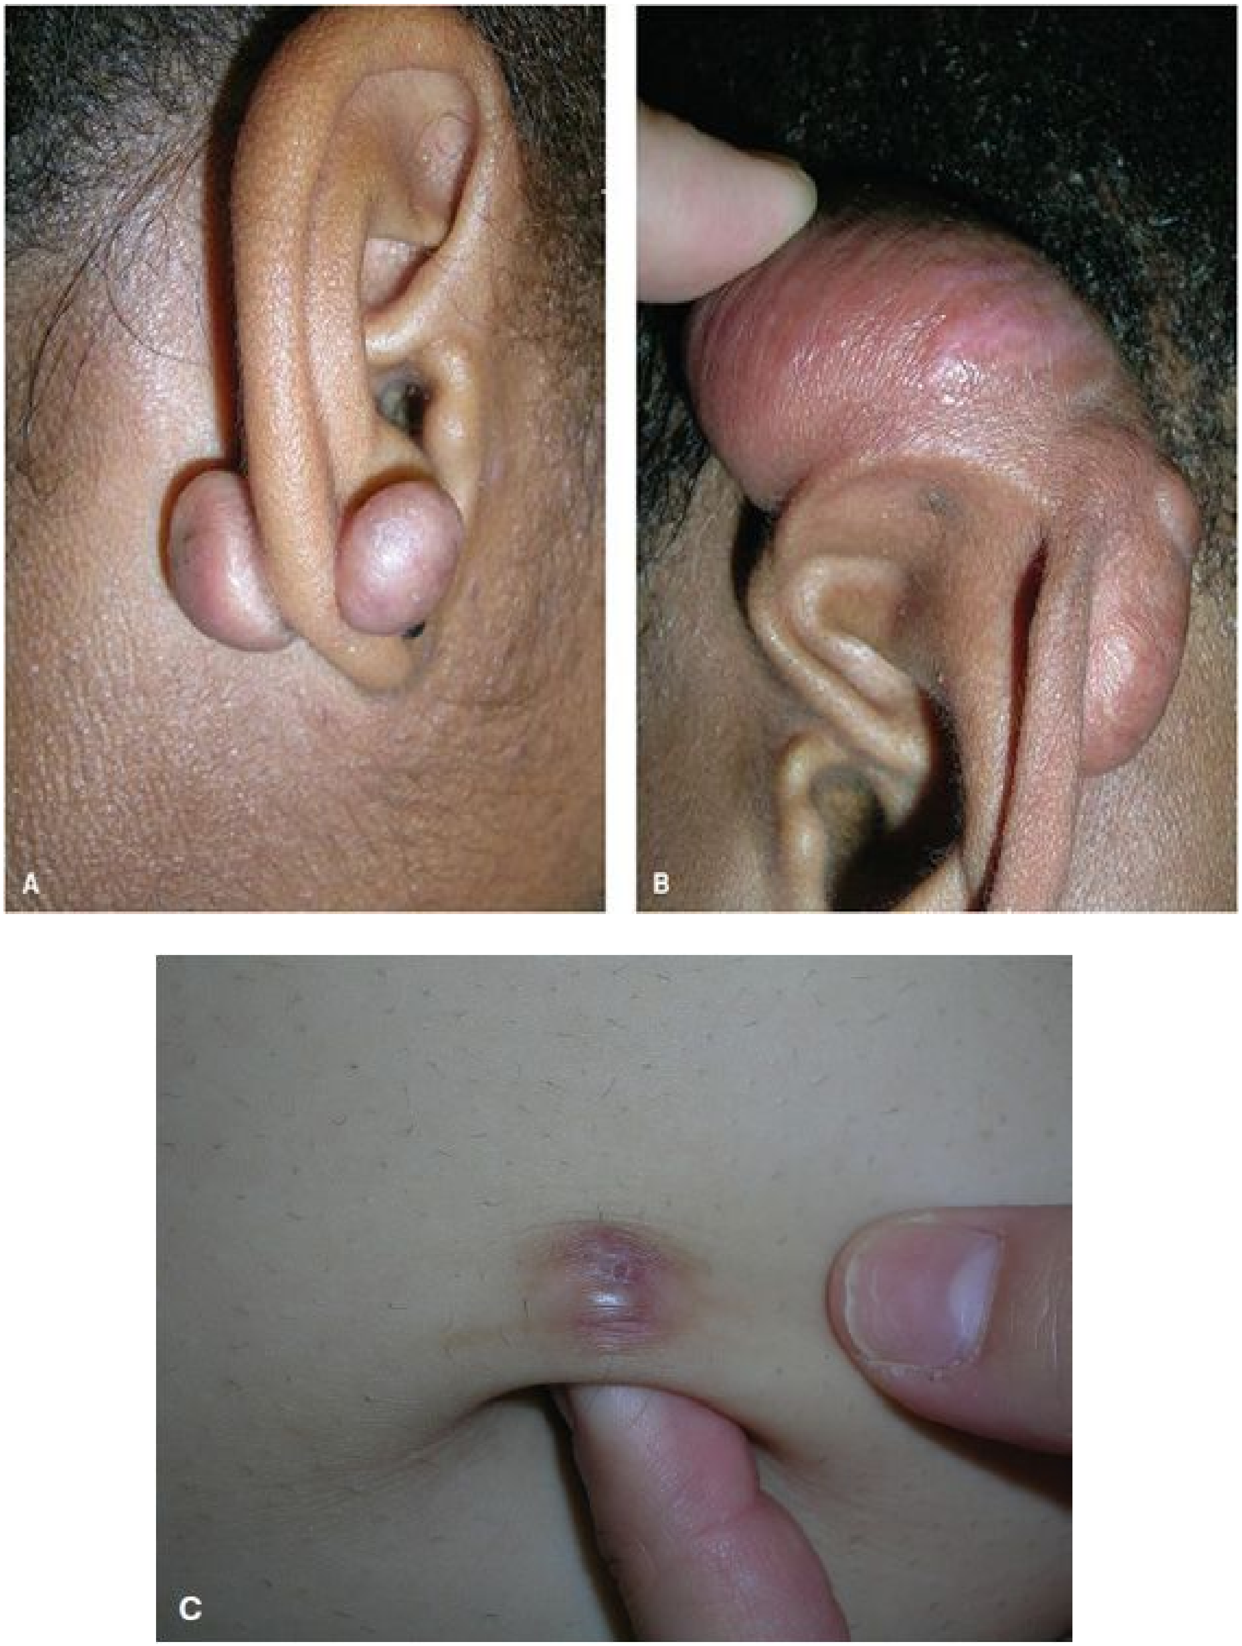
- Risks for piercings can be site specific and among these may be delayed healing, allergic reactions to metal of the piercing, (usually to the nickel component in the jewelry), and keloid formation at the piercing site (common in ears) (**Figure 81-6**).



A
B
C

Figure 81-6 **A.** Keloids on both sides of the earlobe of this African American teenage female that developed after the piercing of her ears. **B.** Large keloid on the pinna of a young African American female after piercing of the ear cartilage. **C.** Keloid from a belly-button piercing. (*Used with permission from Richard P. Usatine, MD.*)

DIAGNOSIS

The following complications are described and illustrated with photographs to help improve early diagnosis and treatment:

- Allergic reaction to dye (pigment)—Presents with skin swelling and pruritus. Reactions to red pigment are most common (**Figures 81-1** and **81-5**), but reactions to other colors do occur.
- Contact allergy on skin surface—nickel- or dye- related—presents with erythema, scaling and pruritus (**Figure 81-7**; see Chapter 131, Contact Dermatitis).

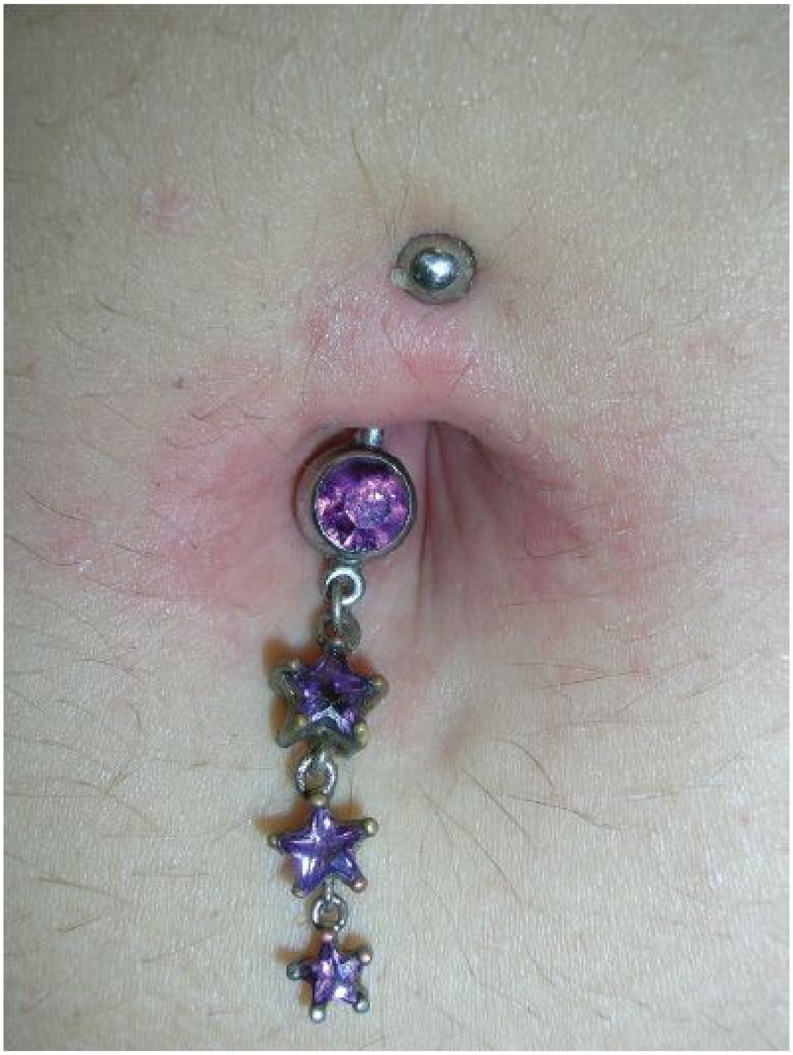


Figure 81-7 Nickel contact dermatitis surrounding the jewelry used in a belly button piercing. (*Used with permission from Richard P. Usatine, MD.*)

- Infection—Has the usual cardinal signs of redness, increased pain at the site, possible purulent drainage, and swelling. Most infections around piercings or tattoos are local but systemic symptoms such as fever may occur (**Figure 81-8**).

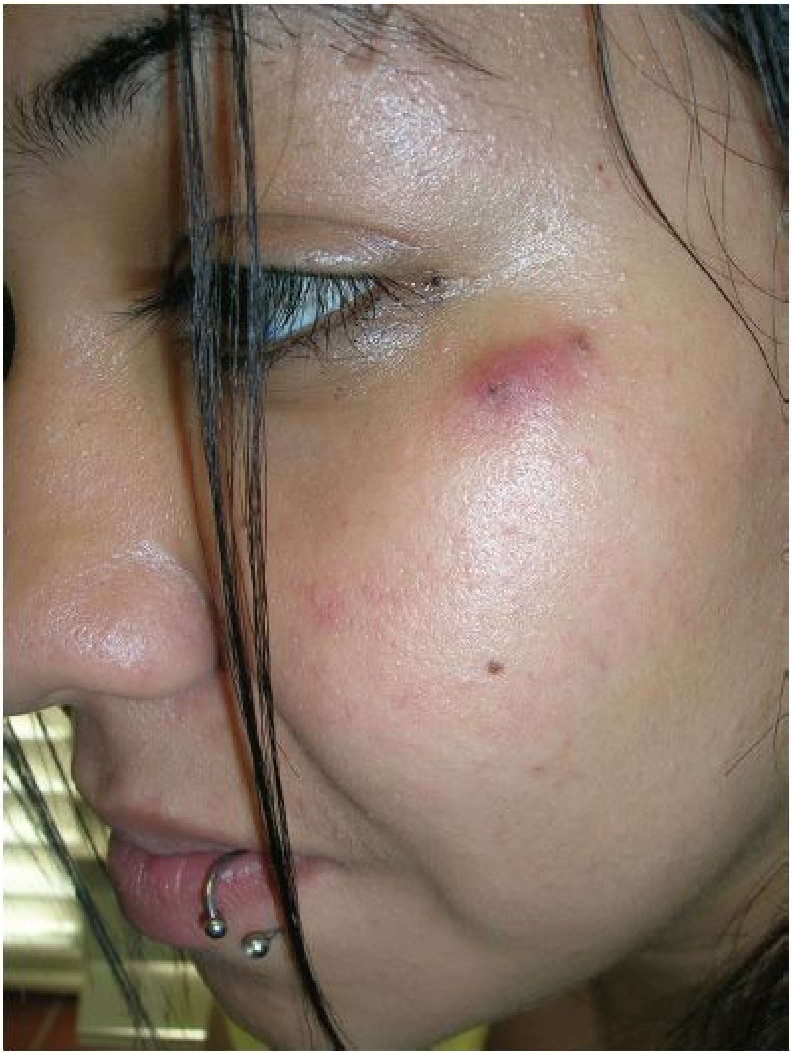

Figure 81-8 Infected piercing on the upper cheek of a teenage female secondary to a piercing. Note that her lip has also been pierced. (*Used with permission from Richard P. Usatine, MD.*)

- Inflammation (granuloma)—Erythema and swelling can occur around piercings and tattoos due to inflammation rather than infection (**Figures 81-2** and **81-5**). Sarcoidosis lesions may develop at sites of tattoos (**Figure 150-7**).
- Photo-aggravated reactions can occur when edema and erythema develop after exposure to sunlight. This occurs most commonly to yellow tattoo pigment.
- Keloids—Benign tumors that arise where skin has been traumatized, cut, or pierced. They are usually the color of the surrounding skin but can also

be erythematous or hyperpigmented. The ear is very prone to developing keloids including the earlobe and pinna (**Figure 81-6**; see Chapter 141, Keloids).

- Broken and chipped teeth are most likely to occur with tongue piercings and the piercings (**Figures 81-9** and **81-10**).

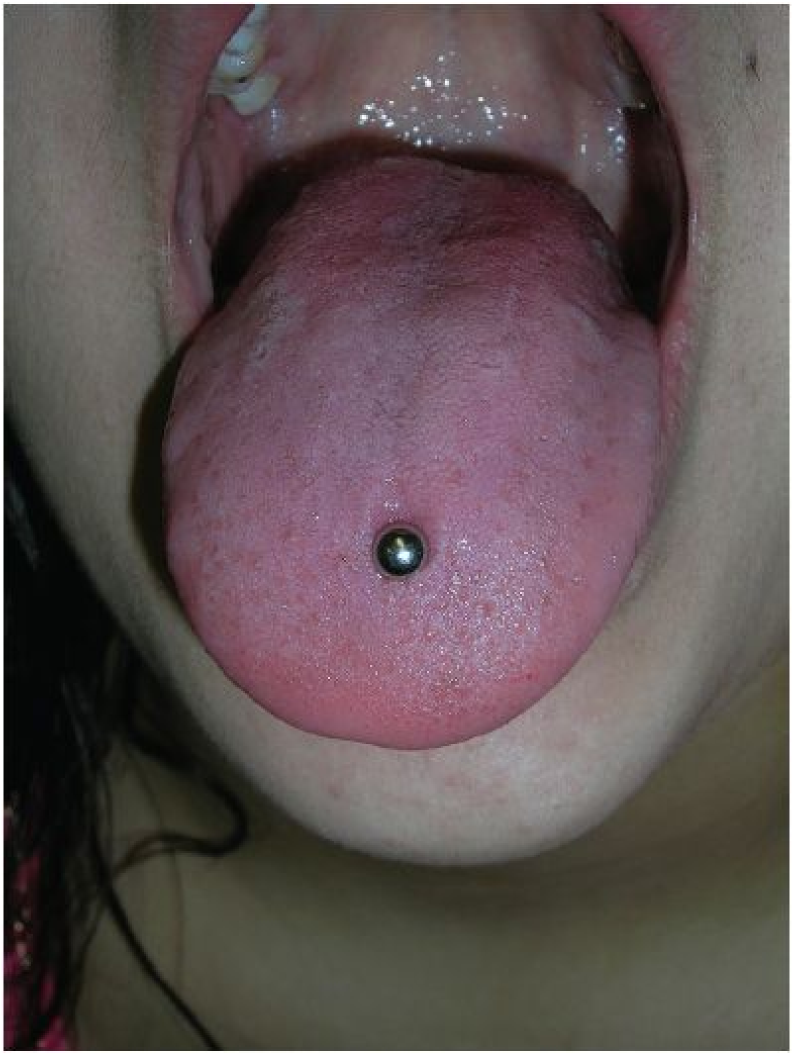

Figure 81-9 Tongue piercing putting this patient at risk for cracks and chips to her teeth. (*Used with permission from Richard P. Usatine, MD.*)

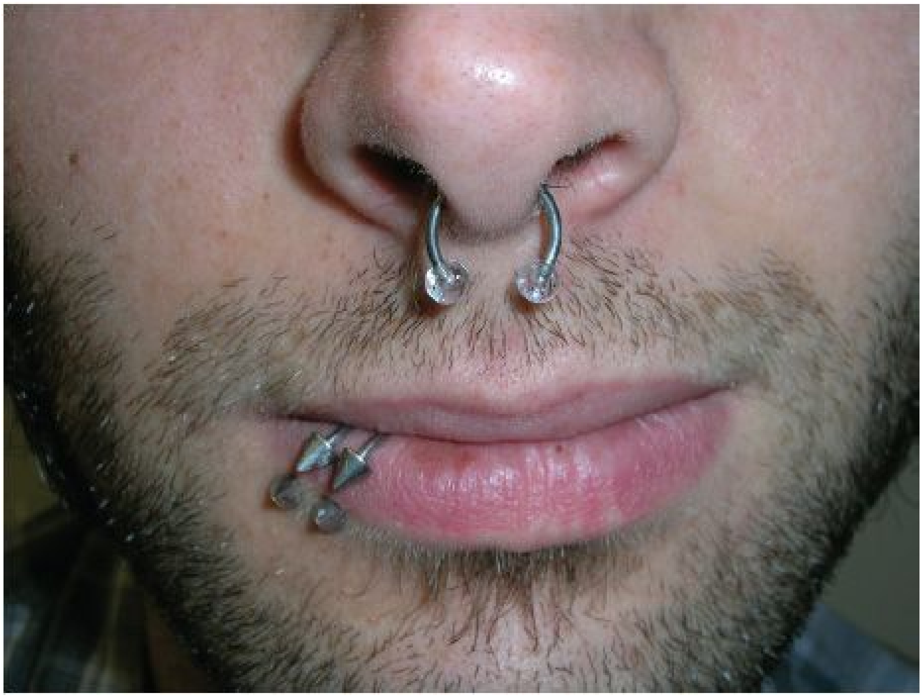

Figure 81-10 Facial piercings including a double lip piercing which could result in dental damage. (*Used with permission from Richard P. Usatine, MD.*)

- Anatomic distortion—Some piercings are meant to stretch the surrounding skin such as the earlobe (**Figure 81-11**). If the adolescent grows tired of such body art, they are left with anatomic distortions that can only be repaired with plastic surgery.

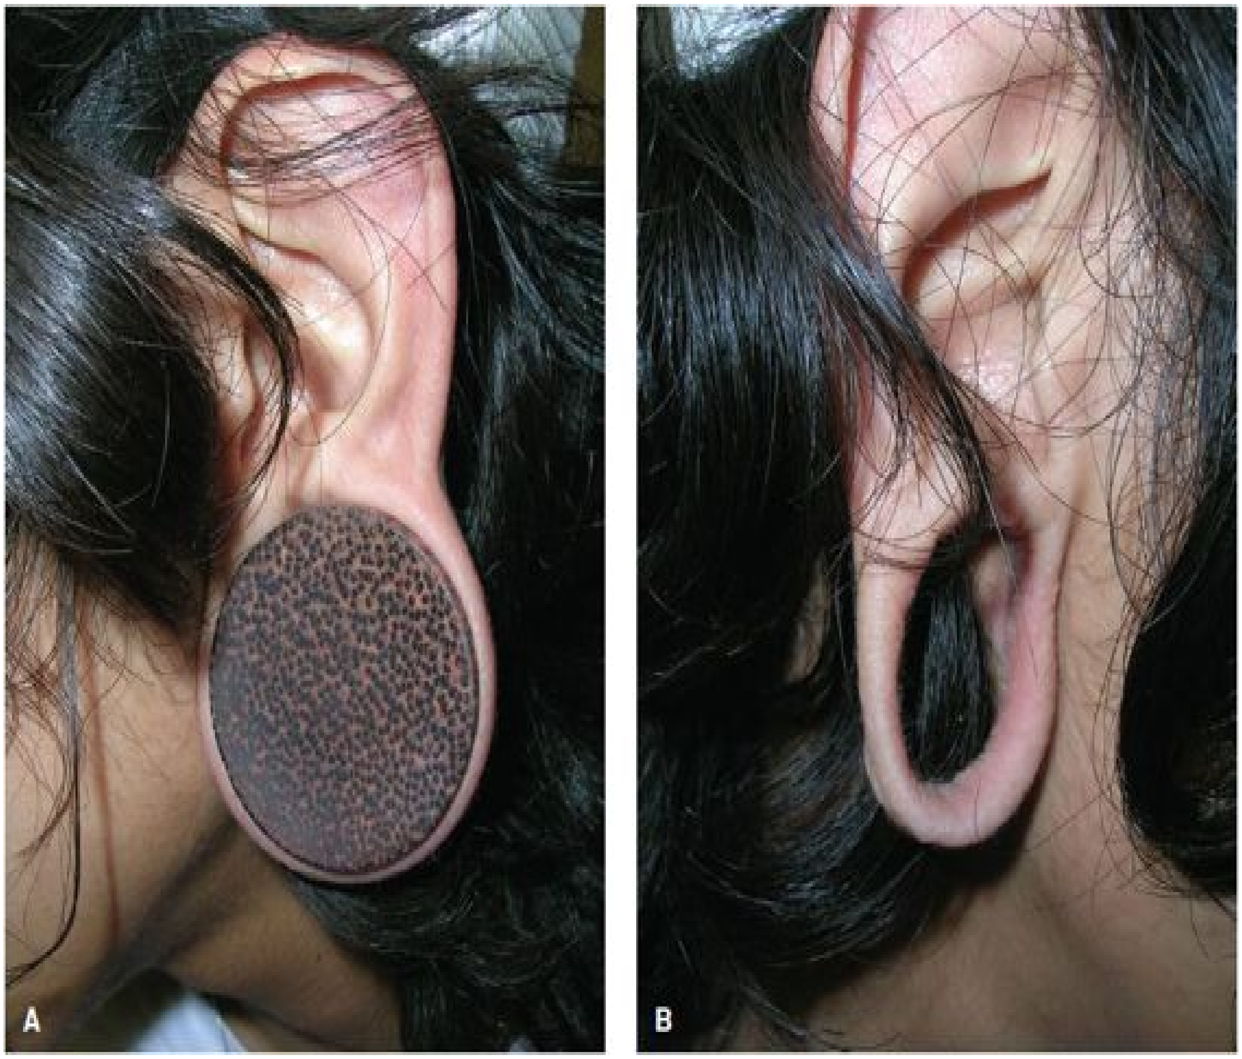

Figure 81-11 **A.** Large ear lobe insert used as body art. **B.** Note the anatomic distortion that has occurred to his earlobe when the insert has been removed. If this teenage male decides he no longer wants this body art his earlobe can only be repaired with plastic surgery. (*Used with permission from Richard P. Usatine, MD.*)

- Anatomic disruption.
  - Nipple piercings can result in disrupted milk ducts (**Figure 81-12**). While milk production is not a concern of adolescent males, and nipple piercing can be torn from the site resulting in pain and anatomic distortion (**Figure 81-13**).

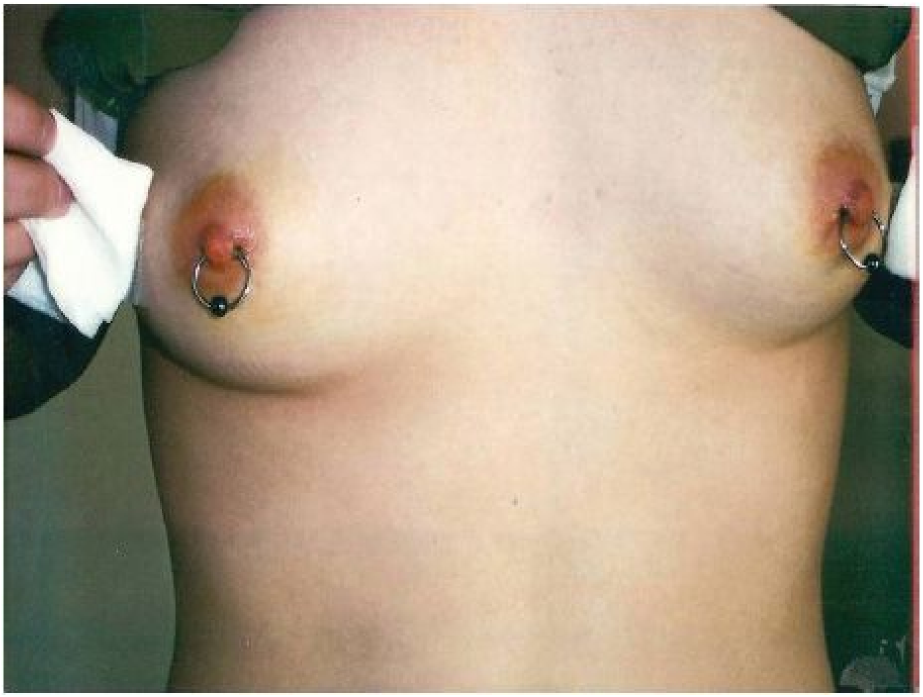

Figure 81-12 Bilateral nipple piercings in this teenage female. This type of piercing can result in disruption of the milk ducts that could affect breast-feeding in the future. (*Used with permission from Edward A. Jackson, MD.*)

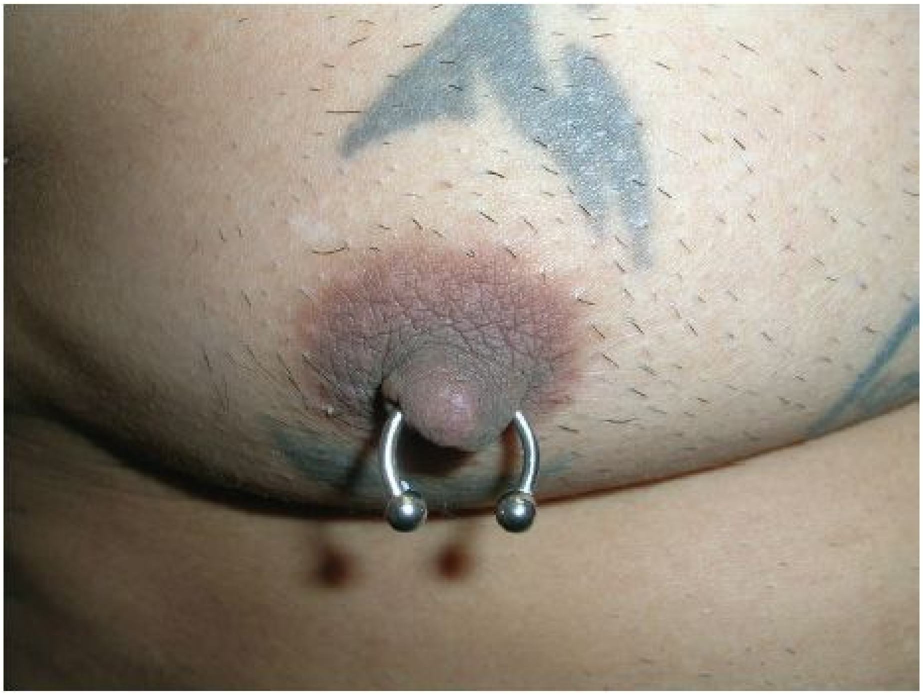

Figure 81-13 Nipple piercing in a young man. While breast-feeding is not an issue trauma to this area could pull the ring out and damage the nipple. (*Used with permission from Richard P. Usatine, MD.*)

  - Prince Albert piercings go through the urethra of the penis and can lead to a urethral rupture (**Figure 81-14**).

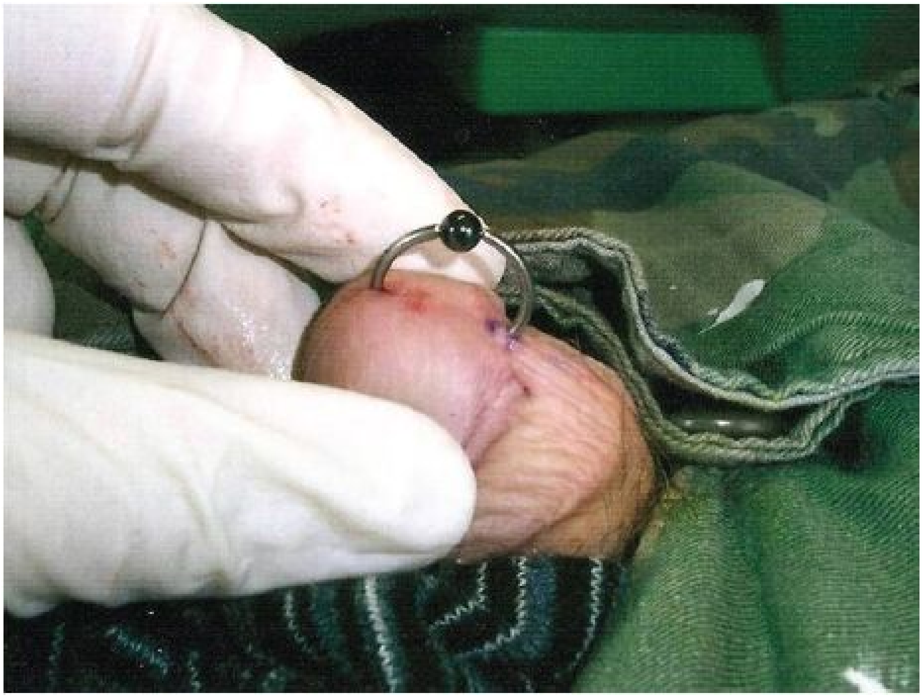

Figure 81-14 Prince Albert piercing of the penis, which goes through the urethra and the body of the penis. This can result in damage to the urethra including urethral disruption. (*Used with permission from Edward A. Jackson, MD.*)

- Piercings can become stuck in the skin so that surgery is needed to remove the piercing (**Figure 81-15**).

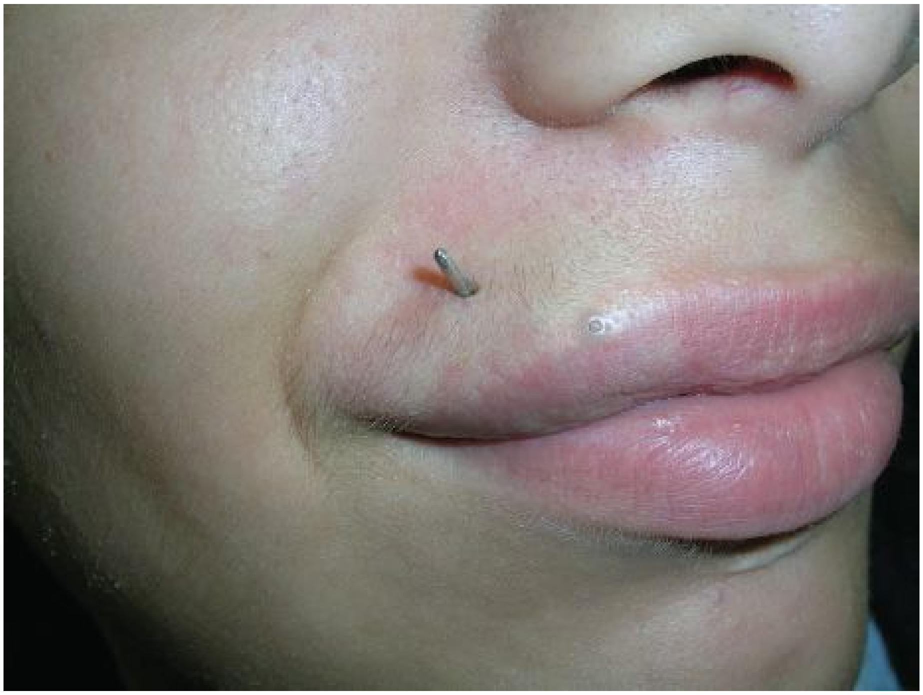

Figure 81-15 Lip piercing embedded and stuck in this teenage girl. The lip is somewhat swollen as the area has been anesthetized prior to surgical removal. (*Used with permission from Richard P. Usatine, MD.*)

LABORATORY TESTING

- Consider bacterial culture of an infected piercing or tattoo if methicillin resistant staphylococcal aureus (MRSA) is suspected.
- Fungal and mycobacterium species have been noted in recent reports to the CDC involving contaminated tattoo inks.[6] Testing for fungus can be performed with a KOH preparation if the suspected fungus is superficial or a punch biopsy sent to the pathologist for a periodic acid Schiff (PAS) stain looking for fungal elements. Mycobacterium species can be detected with an AFB stain from a biopsy of the infected tissue.

DIFFERENTIAL DIAGNOSIS

- Some piercings will continue to ooze fluid after the piercing which may be confused with an infection.[7] A culture may help to differentiate between these two entities.
- Keloid formation may be confused with a hypertrophic scar. A hypertrophic scar will not extend beyond the area of the piercing or trauma.[7] However, hypertrophic scars can be treated the same way that keloids are managed.

MANAGEMENT

- Hypersensitivity reactions to tattoo dyes may be managed with a topical steroid or intralesional injections of 5 mg/mL of triamcinolone. Intralesional injections are more potent and may need to be repeated for adequate results.
- Topical steroids may be used to treat contact dermatitis secondary to nickel or other contact allergens related to piercings or tattoos. Usually a mid-potency topical steroid will be needed for treatment success.
- Hypertrophic scaring and keloids may also be treated with intradermal steroid injections using 10 to 40 mg/mL of triamcinolone.
- Incision and drainage should be performed to treat an abscess secondary to the piercing (**Figure 81-8**).
- In sites of cellulitis or secondary impetiginization, appropriate selection of antibiotics should cover *Staphylococcus aureus* and *Streptococcus pyogenes*. Consideration for coverage of potential MRSA should be done in those areas that demonstrate high rates of resistance or when the infection is more of an abscess with surrounding cellulitis rather than a superficial impetiginization.
- In the cases with infections that involve piercings, it is recommended to leave the piercing in place during the treatment in order to prevent closure of the site. This may also help in drainage and stop an abscess from forming.[7] A local infection may be managed with good skin cleansers or a

topical antibiotic such as mupirocin cream. Avoid ointments as that may delay healing due to their occlusive nature.[8]

- Viral hepatitis is a known complication if clean needles or open vials of pigment were used for tattoos. A viral hepatitis is suspected standard evaluation including liver function tests and hepatitis serologies should be performed.

SURGERY

- When the piercing is stuck in the skin and the patient wants it removed the area may be anesthetized and the piercing may be surgically excised (**Figure 81-15**).
- Piercings which have developed granulomas around them may also need to be excised (**Figure 81-2**).
- In patients with keloids, if intralesional steroids are not successful surgery may be considered.
- For patients that have genital piercings, complications such as urethral rupture may require consultation with urology to repair the damage.
- Removal of tattoos may involve the use of lasers to mechanically disrupt the pigment particles and enable the macrophages to remove the smaller particles. However, this is expensive and may not totally remove the pigment or increase the risk of subsequent scarring. Since 2007, newer inks have been marketed with microencapsulated biocompatible pigments which can be absorbed by the body when the capsule is ruptured by laser treatment.

REFERRALS

- Refer to a dermatologist or surgeon for treatment of keloids or other surgical removals.
- Refer to urology for a urethral rupture.
- For patients wanting laser tattoo removal, refer to a cosmetic dermatologist or another physician trained in the use of cosmetic laser

tattoo removal.

- Referral to a hepatologist should be made for any patients newly diagnosed with viral hepatitis.

PREVENTION

- The best method to prevent the complications of tattoos and piercings would to consider not having permanent ones placed in the first place. Many have “buyer remorse” and regret getting a tattoo. Alternatives to permanent tattoos include temporary tattoos, “fake” tattoos or Henna tattoos. There are also “fake” body piercings that may be held in place by a magnet to secure the jewelry.
- Consumers should choose their tattoo or piercing artist with care. Guidelines from the Association of Professional Piercers (AAP) suggest that a good studio should have a certification of recognition by the association. This means that the piercer has had a least 1 year experience, documented training in CPR and blood-borne pathogens, and uses an autoclave with spore testing for sterilization.[8]
- Sterile unused needles and new unopened pigments are essential for safe tattoo technique. Equally important to the use of clean needles is the use of new vials of pigment for each client. The use of an opened bottle of pigment can result in spread of hepatitis from one client to another. Clients should insist on seeing brand-new bottles of pigments opened for their tattoos.
- After a tattoo or piercing, good aftercare may help to prevent the complications of infection.

FOLLOW-UP

Aftercare recommendations for tattoos and piercings include:[8]

- Keep area clean—Wash with antibacterial soap at least twice daily.
- Avoid use of rubbing alcohol, Betadine, or peroxide as these may discolor the jewelry inserted and are not better than soap and water.
- Avoid tight clothing to prevent irritation to the site.
- Avoid hot tubs or pools until healing complete.
- In genital piercings—Condoms or dental dams are recommended during sex to protect the healing wound from the secretions of a sexual partner.
- Oral piercings—Rinse 4 to 5 times daily with an antimicrobial alcohol free rinse.

82 NURSEMAID’S ELBOW

Paula Sabella, MD

PATIENT STORY

A healthy 2-year-old female is brought to the emergency department because she is not using her left arm. The patient was holding her father’s hand while walking when she tripped. To prevent her from falling, her father held onto the patient’s left hand and pulled her up as she tripped. The patient cried immediately and then she calmed. She did not seem to be in pain, but she would not move or use her left arm. She held her left arm close to her side with her elbow slightly bent and her palm turned toward her body (**Figure 82-1**). Father denies bruising, swelling, fevers, other injury, or recent illnesses. She was diagnosed with nursemaid’s elbow, which was successfully reduced in the emergency department and she regained full use of her arm immediately.

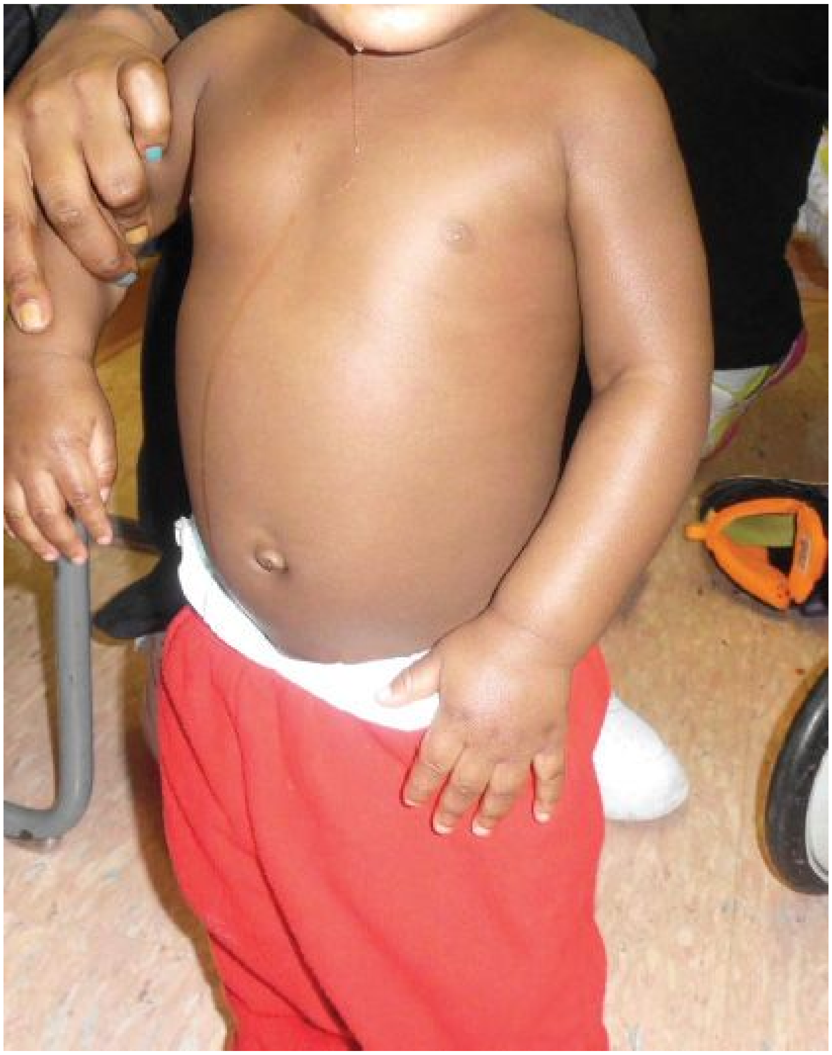

FIGURE 82-1 Typical posture of a child with nursemaid's elbow. Note how the affected left arm is held next to the body with the elbow slightly bent and the forearm pronated. (*Used with permission from Paula Sabella*, *MD*.)

INTRODUCTION

Nursemaid's elbow is a very common injury in preschool aged children. It usually results from a pull to the arm or wrist of a child causing displacement of the annular ligament of the elbow and subluxation of the radial head. This results in pain and refusal to use the arm. The child classically holds the affected elbow close to the body and mildly flexed with pronation of the forearm. The diagnosis is made clinically. The radial head subluxation is usually able to be quickly and easily reduced in the office or emergency department.

SYNONYMS

Radial head subluxation; temper tantrum elbow; annular ligament displacement; pulled elbow.

EPIDEMIOLOGY

- Occurs in children aged 6 months to 5 years, with the peak incidence between 2 and 3 years of age.[1–4]
- Left elbow is most commonly affected.[2,4]
- Affects girls more than boys.[1,2,4]

ETIOLOGY AND PATHOPHYSIOLOGY

- The classic mechanism of injury in nursemaid's elbow involves axial traction to a child's pronated forearm or upper extremity.[2] This usually involves a pulling or tugging motion to the upper extremity.
- When the radius is pulled distally, part of the annular ligament shifts proximally over the radial head and becomes caught in the radiohumeral joint (**Figure 82-2**).[2,3] This causes pain and refusal to use the affected arm.

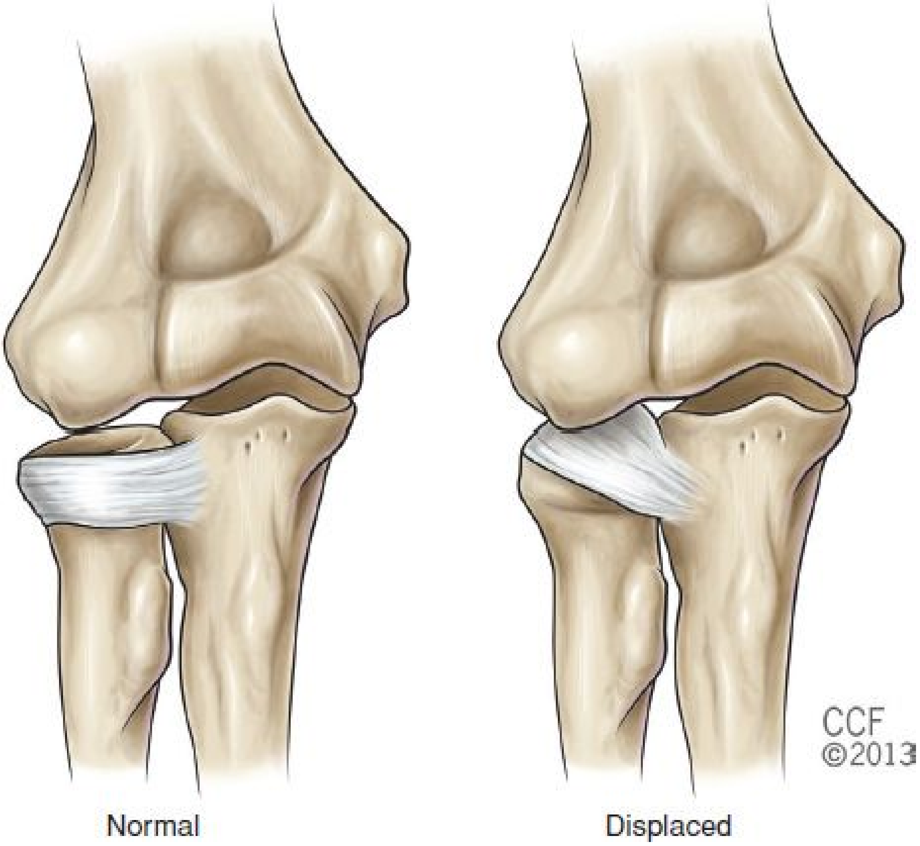

FIGURE 82-2 Drawing of a normal and a displaced annular ligament. Axial traction or tugging to the forearm allows the annular ligament to shift proximally over the radial head and remain caught in the radiohumeral joint. (*Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2013. All Rights Reserved*.)

- In many cases of nursemaid's elbow, the typical history of a pulling type of injury is not reported.[5]
- Examples of mechanisms reported in patients with nursemaid's elbow include:[1,2,5]
  - Swinging a child while holding the wrists or hands.
  - Lifting a child up by holding the hands or wrists.
  - Catching a child by the hand to prevent a fall.
  - A child holding onto something to prevent a fall.
  - An infant rolling over in bed.
  - Minor trauma to the elbow.

RISK FACTORS

- More common in girls.[1,2,4]
- The left elbow is more commonly affected.[2,4]
- Toddler age group is most affected.[123–4]
- Children with a history of nursemaid’s elbow are at an increased risk for recurrence.[2,4]

DIAGNOSIS

- A history of a pull or a traction type of injury to the arm is helpful in making the diagnosis, but is not necessary.[5] A history of brief crying or pain at the time of the injury may also be reported.

CLINICAL FEATURES

- Nursemaid’s elbow is a clinical diagnosis, which should be suspected when evaluating a child who refuses to use an upper extremity, and is observed holding the arm in the classic nursemaid’s position (**Figure 82-1**).
- The child will typically hold the affected arm next to the body with elbow slightly flexed and the forearm pronated (**Figure 82-1**).
- The child usually does not have severe pain at the time of presentation.[3,5]
- The entire affected upper extremity, including clavicle, should be thoroughly visualized, palpated and evaluated. Children with nursemaid’s elbow do not have bruising, swelling, deformity, or other clinical evidence of injury or neurovascular compromise.
- The child may have tenderness with palpation of the radial head.[2,5] There is typically pain with attempts at supination.

DISTRIBUTION

- The elbow is the area involved. Frequently, parents report a concern of wrist or shoulder injury due to the appearance of the child not using the affected arm.

IMAGING

- Radiographs are not indicated to diagnose nursemaid's elbow. Nursemaid's elbow is a clinical diagnosis.[3,6]
- When the history and physical findings are not consistent with nursemaid's elbow, radiographs should be obtained.
- Radiographs are indicated if the child is still not using the arm after failed reduction attempts.[3,6]

DIFFERENTIAL DIAGNOSIS

Fractures (supracondylar, radial, ulnar, clavicular) and dislocations of the arm are usually differentiated from nursemaids elbow by the history of trauma and the presence of pain, distress, point tenderness, swelling, bruising, or deformity on physical examination.

MANAGEMENT

NONPHARMACOLOGIC

- Reduction of the suspected nursemaid's elbow may be carefully attempted when the clinical presentation and physical exam are consistent with nursemaid's elbow.[5] SOR C

- The two techniques used for reduction are hyperpronation and supination-flexion.
- Both of the reduction techniques should be performed with the patient seated on the parent's lap facing the examiner. The examiner should be positioned at a similar height to the patient and facing the patient.
- No sedation is required.
- **Reduction Methods**
  - Hyperpronation technique—The examiner holds the affected elbow and applies pressure with a finger over the radial head. The examiner simultaneously holds the patient's distal forearm/wrist with the other hand and hyperpronates the forearm (**Figure 82-3**).[1]

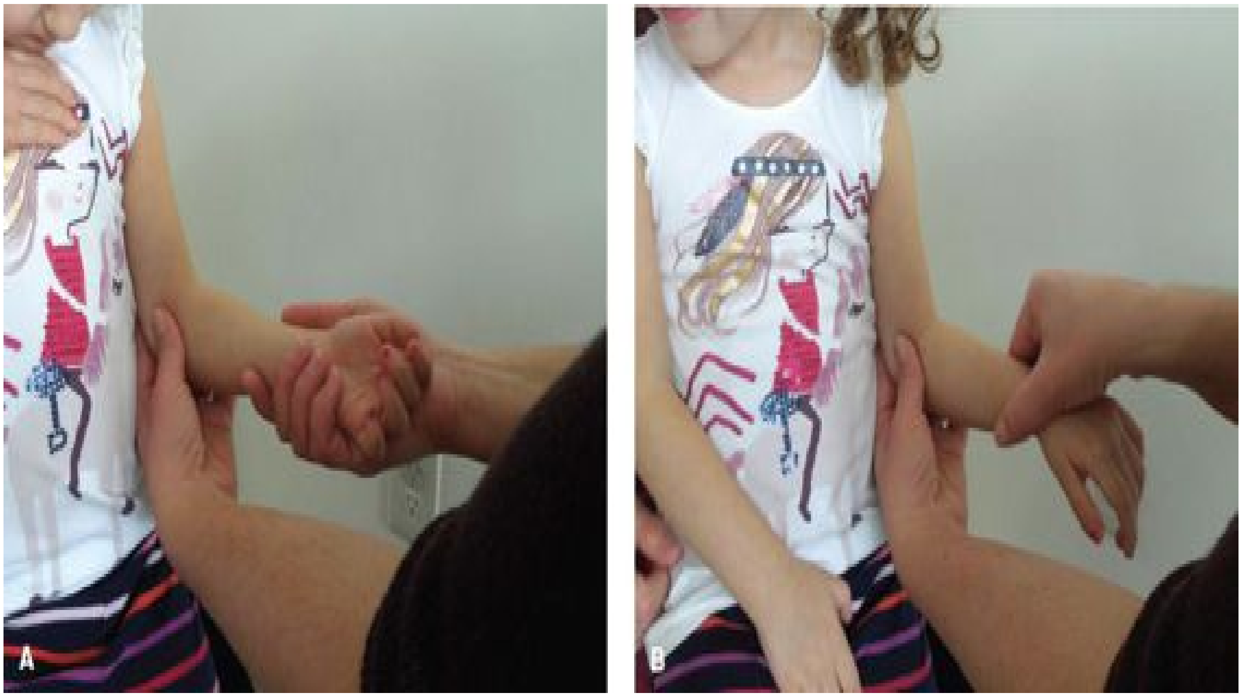

FIGURE 82-3 Hyperpronation Reduction method. (**A**) The examiner firmly holds the affected elbow with one hand and (**B**) hyperpronates the forearm with the other hand. (*Used with permission from Paula Sabella, MD.*)

  - Supination-Flexion technique—The examiner holds the affected elbow and applies pressure with a finger over the radial head. The examiner simultaneously holds the patient's distal forearm/wrist with the other hand. In one continuous flowing motion, the examiner applies mild traction, full supination of the forearm, and full flexion at the elbow (**Figure 82-4**).[12–3]

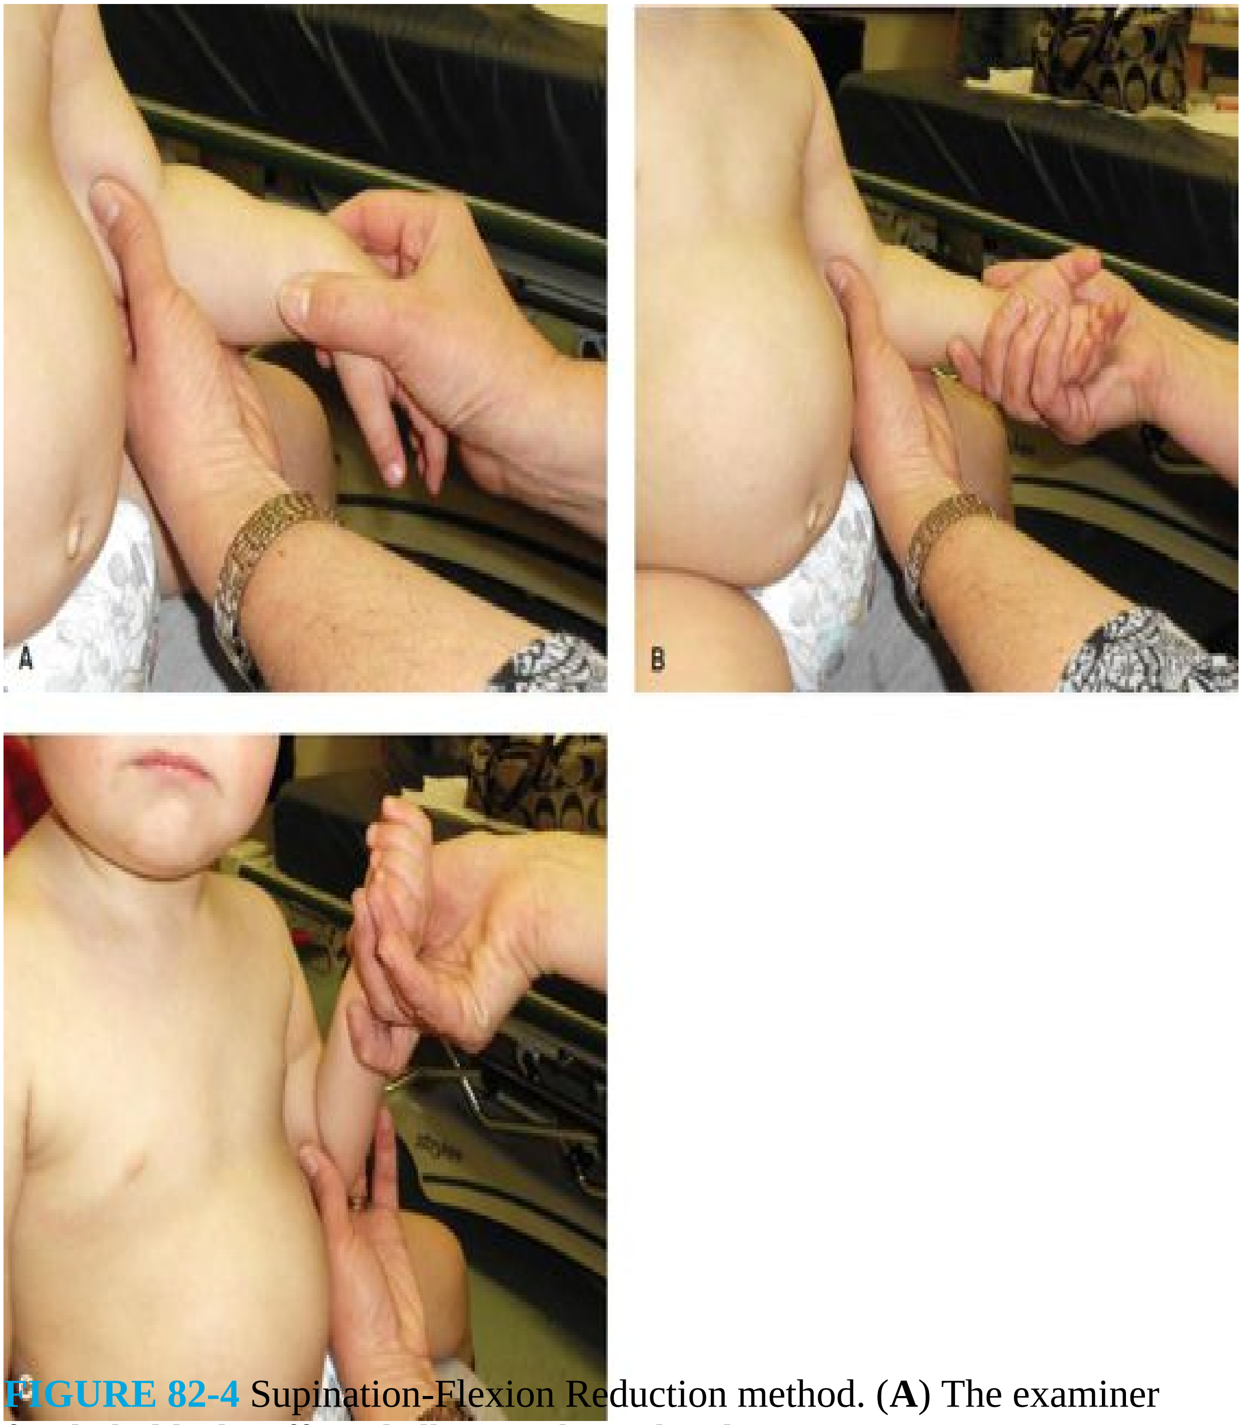

FIGURE 82-4 Supination-Flexion Reduction method. (**A**) The examiner firmly holds the affected elbow with one hand. In one continuous motion, the examiner applies gentle distal traction with the other hand, (**B**) supinates

the forearm, and (**C**) then fully flexes the elbow. (*Used with permission from Paula Sabella, MD.*)

- During both methods of reduction, the examiner should feel a click when the annular ligament relocates back into its normal position.[23–4] Most children will cry with the reduction and then calm with family.
- Spontaneous use of the arm usually occurs within 10 to 15 minutes of successful reduction.[1,2,5]
- Toys, books, and family members may be used to entice the child to reach for objects to use the arm (**Figure 82-5**).

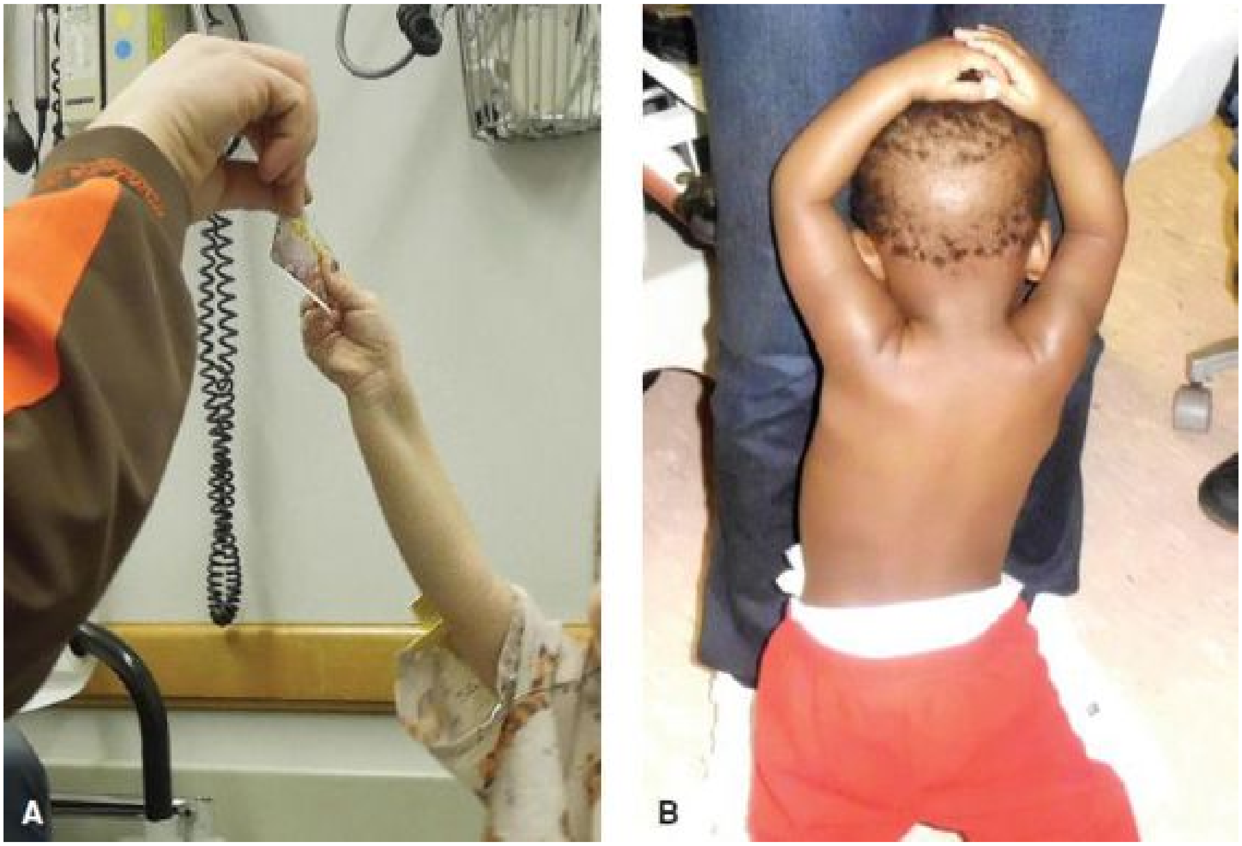

FIGURE 82-5 Successful reduction of nursemaid's elbow results in normal use of the arm (A, B). (*Used with permission from Paula Sabella, MD.*)

- Normal use of the arm after reduction confirms the diagnosis of nursemaid's elbow and of a successful reduction. The patient may immediately resume normal activity.

- If the reduction is unsuccessful, radiographs should be obtained if the child is still not using the arm after several failed reduction attempts.[3,6]
- Reduction may occur spontaneously while waiting for the examiner or en route to the hospital.
- Reduction may also occur after the arm is positioned for radiographs.

REFERRAL

- Referral to an orthopedic specialist is recommended for the child with normal radiographs who is still not using the arm after failed reduction attempts. A sling or splint should be applied to the affected arm.[2,3,6]

PREVENTION AND SCREENING

- Families should be encouraged to lift the child by holding under the axillae.
- Instruct family to avoid tugging, or pulling to the hands, wrists and arms of the child.

PROGNOSIS

- The reduction methods are associated with a very a high rate of success.

FOLLOW-UP

- Follow-up is required for recurrences or if the child is again not using the arm.

PATIENT EDUCATION

- Family should be encouraged to lift the child by holding under the axillae.
- Instruct family to avoid tugging, or pulling to the hands, wrists, and arms of the child.
- Family should be educated regarding the diagnosis and the method of reduction at the time the diagnosis is made.

83 CLAVICULAR FRACTURE

Heidi Chumley, MD
Emily Gale Scott, MD

PATIENT STORY

A 15-year-old girl slipped on the ice and landed directly on her lateral shoulder. She had immediate pain and swelling in the middle of her clavicle. Her parents took her to the emergency room and a radiograph confirmed a displaced mid-clavicular fracture with considerable overlap (**Figure 83-1**). She was placed in a sling and saw her primary care physician the next day. In consultation with a sports medicine expert, she, her family, and her primary care physician decided on conservative treatment. A follow-up radiograph 4 months later demonstrated good healing. The bump on her clavicle is still palpable; but this does not bother her (**Figure 83-2**).

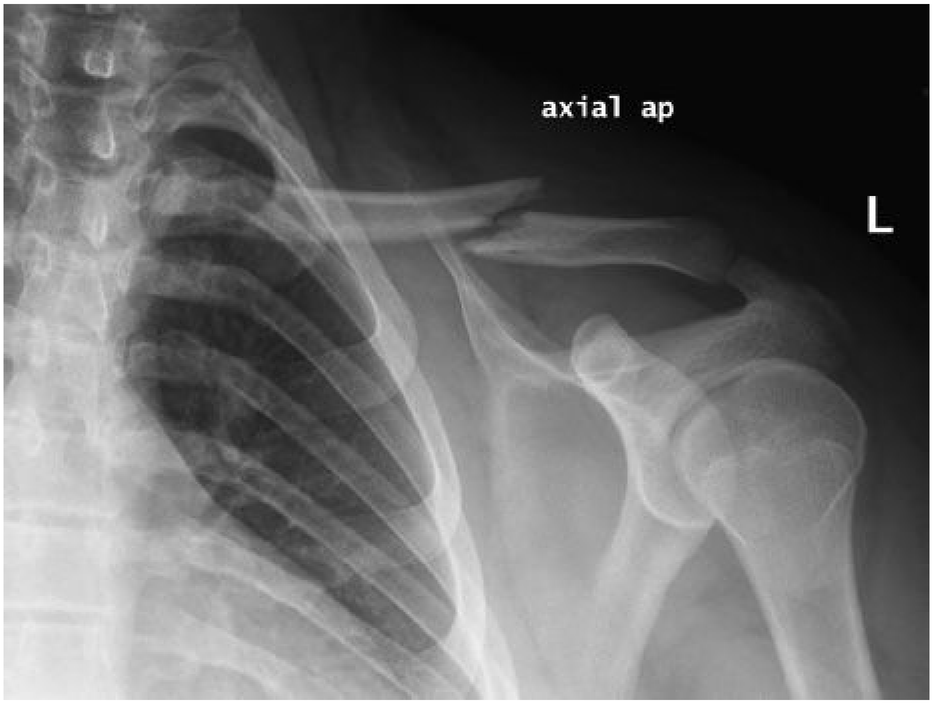

FIGURE 83-1 Midshaft clavicular fracture in a 15-year-old girl who slipped on the ice. (*Used with permission from Emily Scott, MD.*)

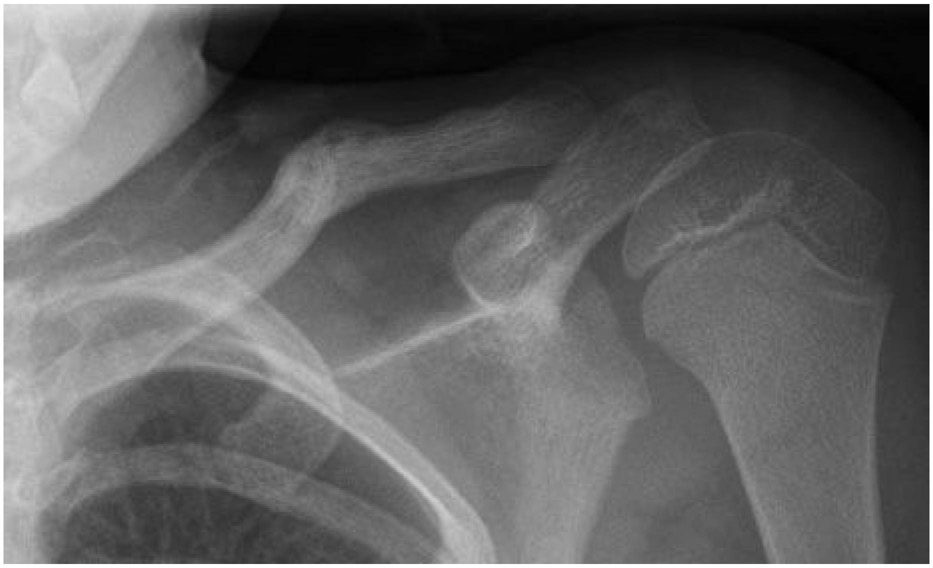

FIGURE 83-2 Healing callous after a midshaft clavicular fracture in the 15-year-old girl in Figure 83-1. (*Used with permission from Emily Scott, MD.*)

INTRODUCTION

Clavicular fractures are common and are most often caused by accidental trauma. The clavicle most commonly fractures in the midshaft (**Figures 83-3**), but can also fracture distally (**Figure 83-4**). Most fractures can be treated conservatively. Refer patients with significant displacement or distal fractures for surgical evaluation.

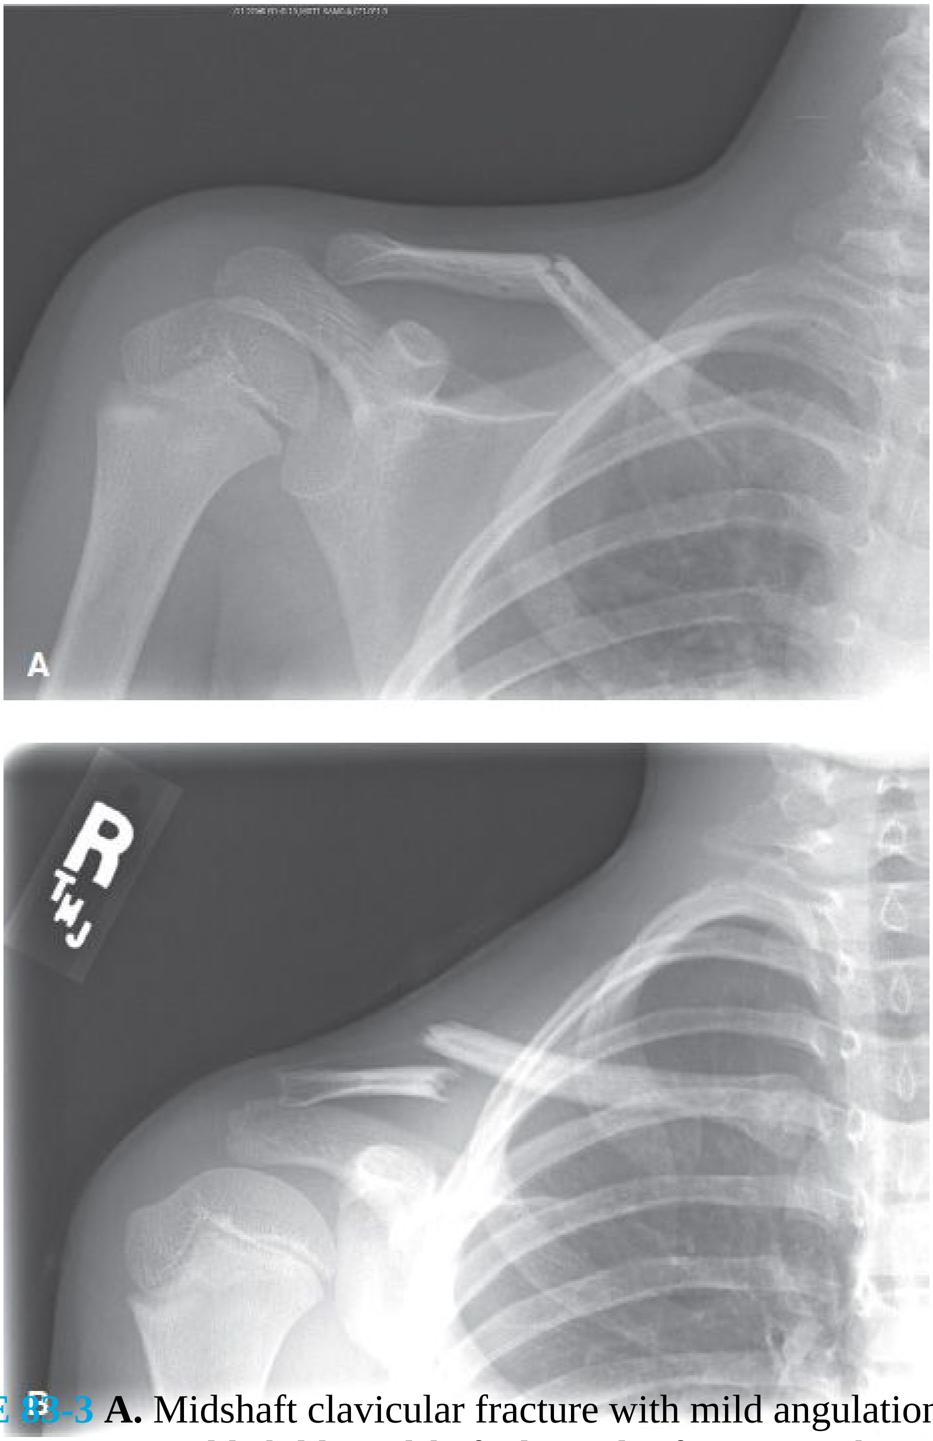

FIGURE 83-3 **A.** Midshaft clavicular fracture with mild angulation but not overriding in 8-year-old child. Midshaft clavicular fracture with overlap in an 11-year-old child. **B.** Usually the proximal fragment is displaced superiorly from the pull of the sternocleidomastoid muscle. (*Used with permission from Emily Scott, MD.*)

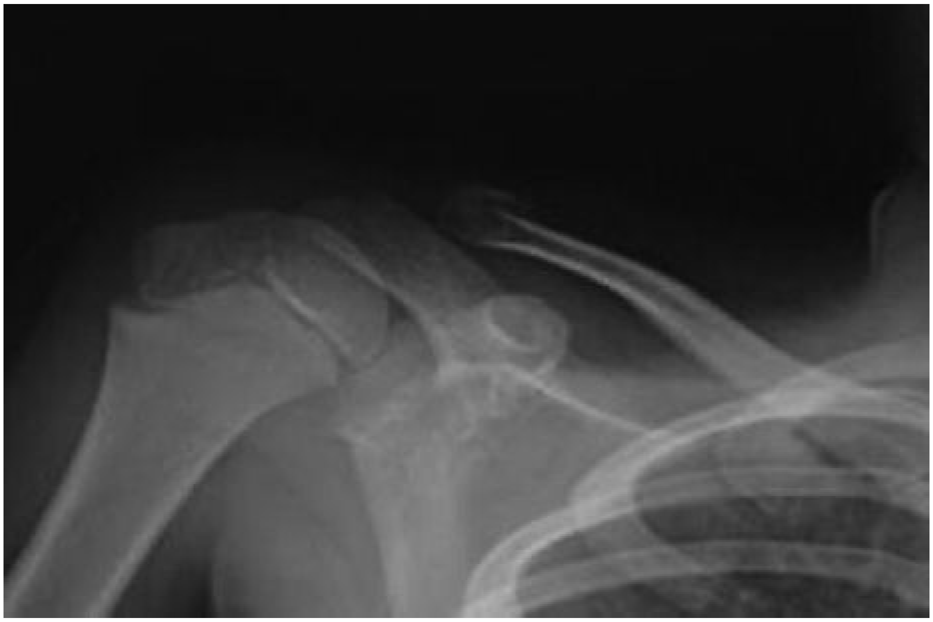

FIGURE 83-4 Right distal clavicular fracture in an 8-year-old boy after he fell off the top bunk. (*Used with permission from Emily Scott, MD.*)

EPIDEMIOLOGY

Accounts for 10 to 15 percent of fractures in children; 90 percent are midshaft fractures.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Ninety percent of clavicle injuries are caused by accidental trauma from fall against the shoulder as result of a direct blow to the clavicle or can be fall on an outstretched hand.[2] However, stress fractures in gymnasts and divers have been reported.
- Neonatal clavicular injuries are usually from birth trauma, commonly breech presentations.

- In children under 2 years of age, a fall from the bed/crib is most common mechanism.[3]
- Sports injuries are common in the adolescent population.
- Physical assaults and child abuse can cause clavicular fractures and need to be considered (**Figure 83-5**).

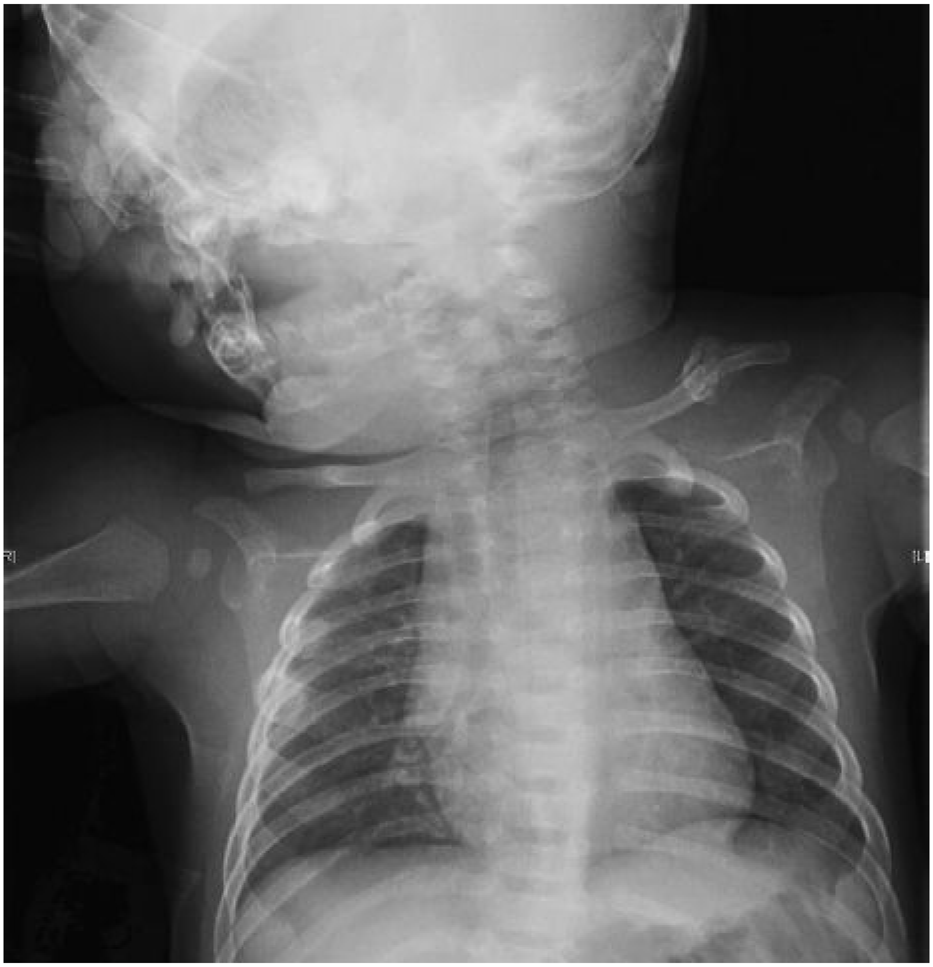

FIGURE 83-5 Healing left clavicular fracture in a 6-month-old infant showing callous formation. This fracture was discovered on radiographic screening for physical abuse. (*Used with permission from Emily Scott, MD.*)

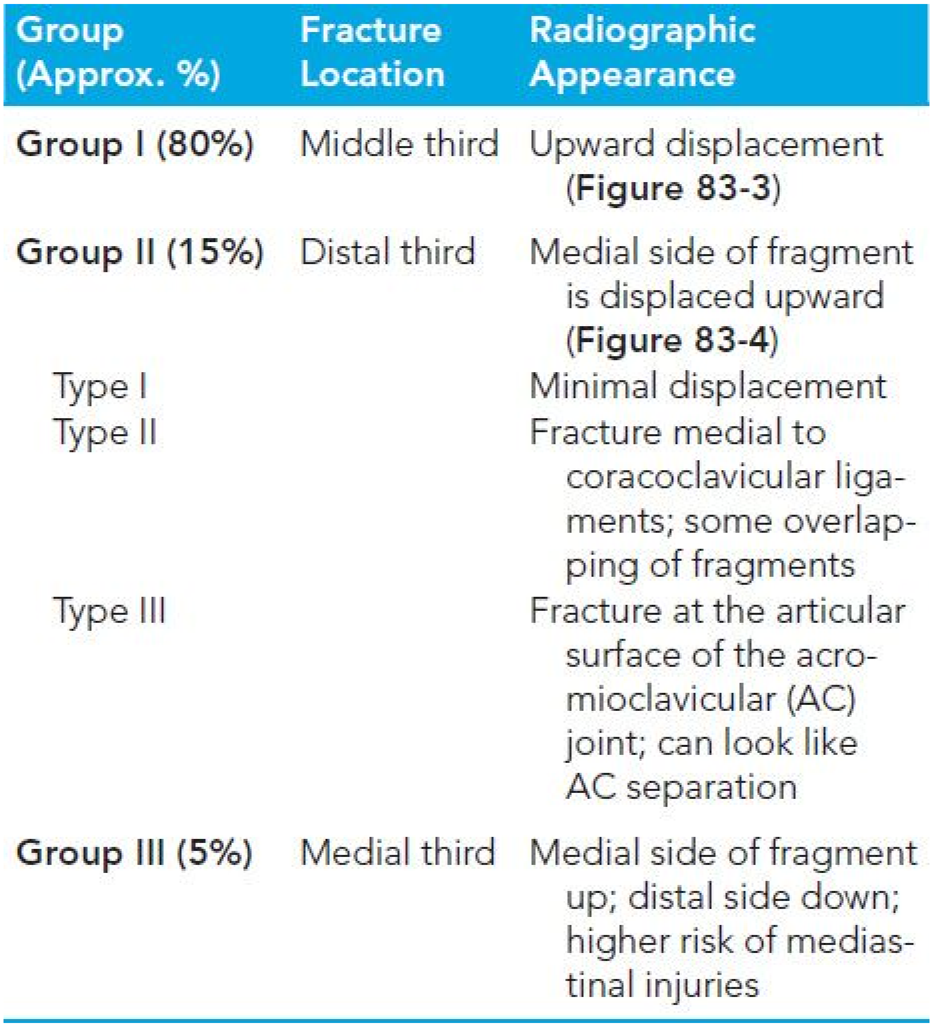
- Pathologic fractures (uncommon) can result from lytic lesions, bony cancers or metastases, or radiation.

TYPICAL DISTRIBUTION

- For the typical distribution and classification of clavicular fractures, see **Table 83-1**.

TABLE 83-1 Typical Distribution/Classification



Group (Approx. %)	Fracture Location	Radiographic Appearance
Group I (80%)	Middle third	Upward displacement (**Figure 83-3**)
Group II (15%)	Distal third	Medial side of fragment is displaced upward (**Figure 83-4**)
Type I		Minimal displacement
Type II		Fracture medial to coracoclavicular ligaments; some overlapping of fragments
Type III		Fracture at the articular surface of the acromioclavicular (AC) joint; can look like AC separation
Group III (5%)	Medial third	Medial side of fragment up; distal side down; higher risk of mediastinal injuries

DIAGNOSIS

CLINICAL FEATURES

- History of trauma with a mechanism known to result in clavicle fractures (i.e., fall on an outstretched hand or lateral shoulder, or direct blow).
- Pain, bruising, and swelling at the fracture site.
- Gross deformity at the site of fracture.
- Young children present with inability to raise their arms above their head and often will present as having trouble getting shirts on and getting into buckled car seats.

IMAGING

- Obtain plain films of the clavicle for radiographic evidence of fracture.

DIFFERENTIAL DIAGNOSIS

- Acromioclavicular (AC) separation—Fall directly on the “point” of the shoulder or a direct blow, pain with overhead movement, tenderness at the AC joint, and AC joint separation on radiographs.
- Sternoclavicular dislocation—Fall on the shoulder, chest and shoulder pain exacerbated by arm movement or when lying down, and a prominence from the superomedial displacement of the clavicle (uncommon; **Figure 83-6**).

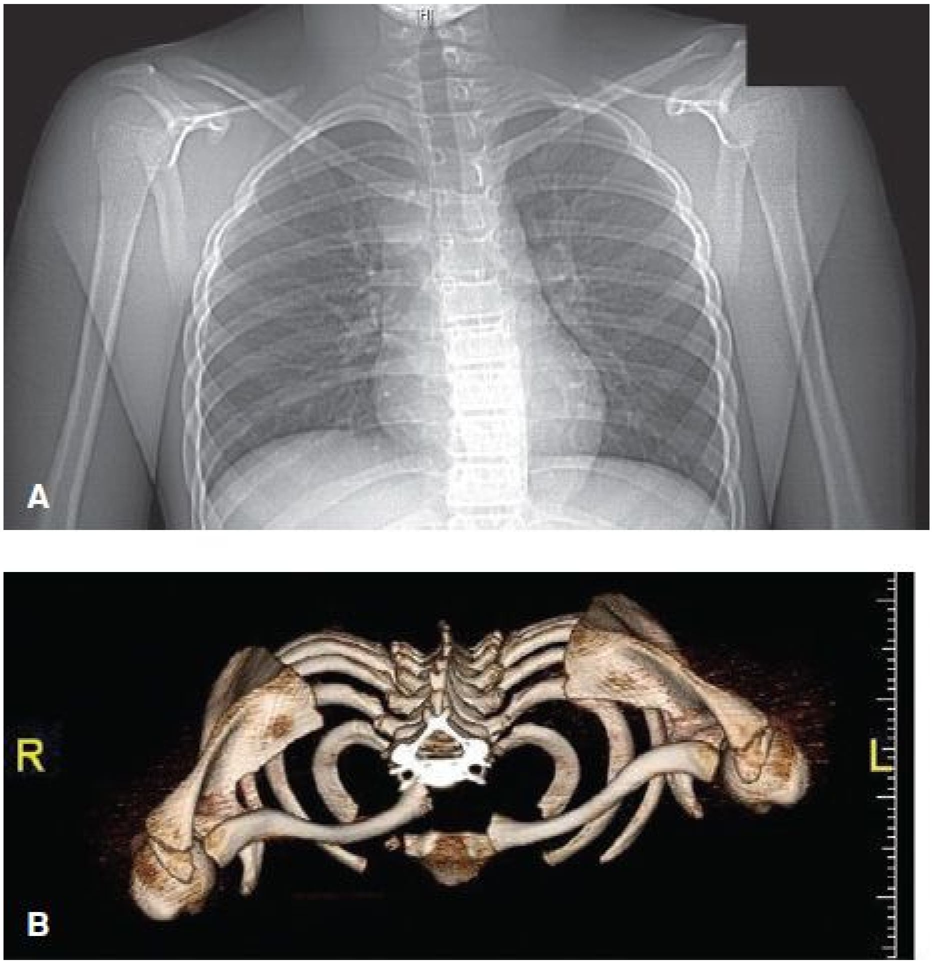


FIGURE 83-6 Sternoclavicular dislocation of right clavicle in a 15-year-old boy who was wrestling and took a knee to the chest. Plain x-ray (**A**) and 3D reconstruction view (**B**). This required surgical repair. (*Used with permission from Emily Scott, MD.*)

- Pseudoarthrosis of the clavicle—Painless mass in the middle of the clavicle from failure of the central part of the clavicle to ossify (extremely rare).

MANAGEMENT

- Assess neurovascular status of injured extremity.

- Treat pain as needed with acetaminophen or NSAIDs. Narcotics may be indicated at the time of evaluation and potentially the first few days.
- Assess for damage to lungs (pneumothorax or hemothorax).
- Determine the classification and amount of displacement by radiograph (**Table 83-1**).

TREATMENT

Most clavicular fractures can be treated nonoperatively. Fixation with plates is sometimes required.

- Treat most children with clavicle fracture conservatively, with immobilization figure of eight splints for young children and slings for older patients.[1]
- Children can be treated nonoperatively even with 90-degree displacement and several inches of overlap.[1]
- Operative indications currently are open fractures, comminuted fractures, multitrauma patients and shortened fractures in adolescent population.[4]
- Recent studies have explored earlier operative management in midshaft fractures in the adolescent populations (**Figure 83-7**).[5]

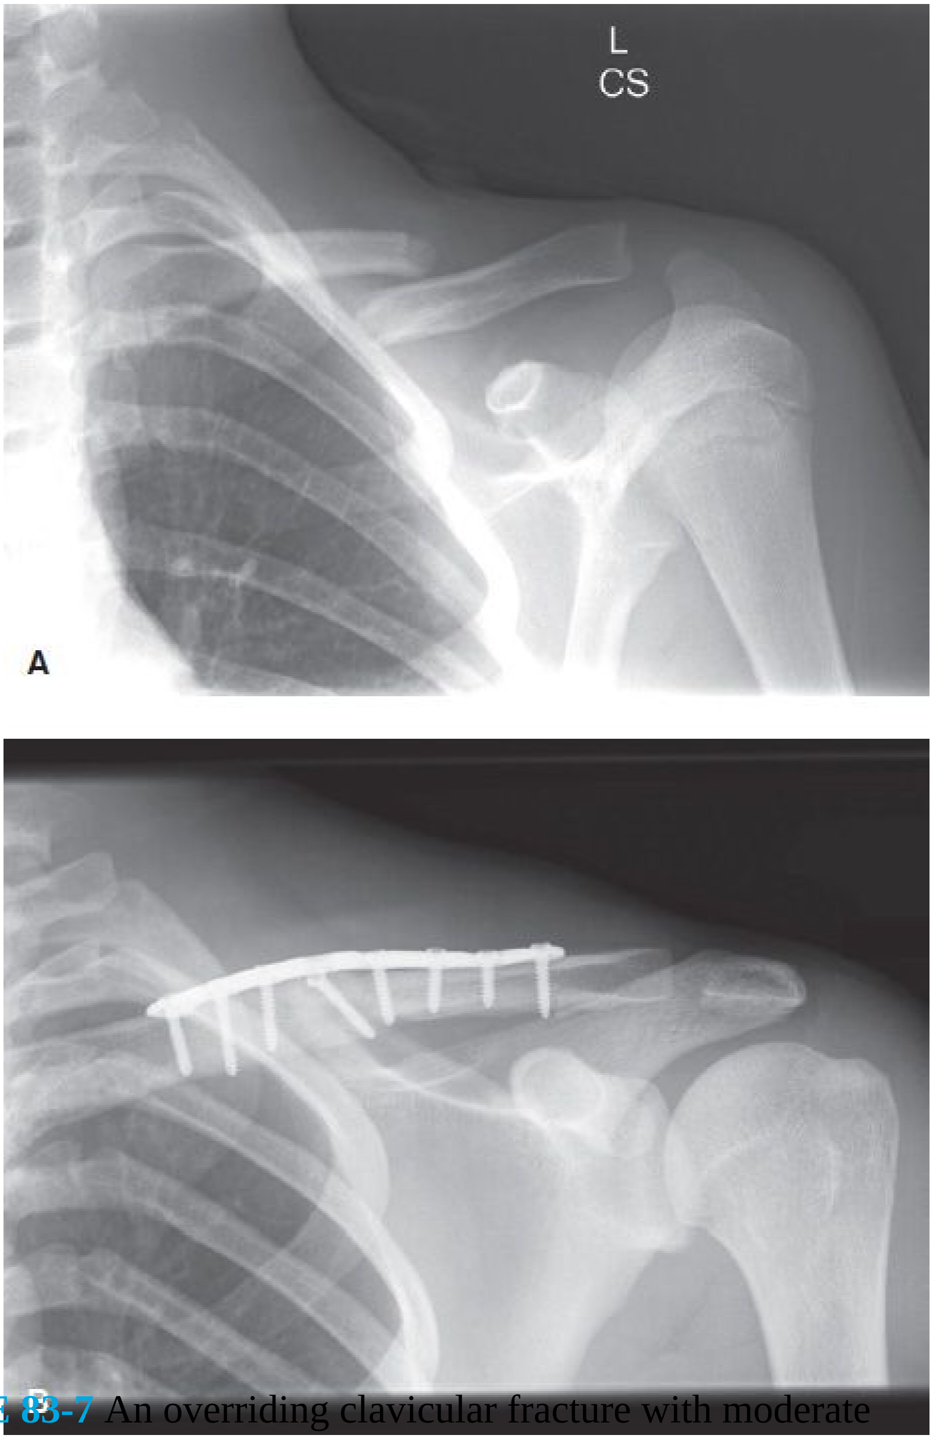

FIGURE 83-7 An overriding clavicular fracture with moderate displacement (**A**), in a 15-year-old hockey player, requiring surgical plating (**B**). (*Used with permission from Emily Scott, MD.*)

REFERRAL

- Refer for surgical evaluation, children with impingement of soft tissue/muscle, instability of shoulder girdle, displacement with skin perforation/necrosis, or risk to mediastinal structures.[1]
- Consider consulting with a physician skilled in managing clavicular fractures in patients with a distal clavicle fracture. These fractures have a high rate of nonunion; however, only a portion of nonunions are painful or inhibit function. If the patient continues to have a symptomatic nonunion after many months, surgery may be considered.

PROGNOSIS

- Mid-clavicular fractures in newborns and children heal completely without surgery in most cases.
- Mid-clavicular fractures in adolescents heal without surgery in most cases. Return to activities may be shortened from 16 to 12 weeks with operative intervention.[5]

FOLLOW-UP

- Monitor with examination and radiographs until pain has resolved, any lost function has returned, and there is radiographic evidence of healing.
- If the fracture is stable, repeat x-ray every 4 to 6 weeks until the clavicle has healed. If there is no evidence of healing after 2 to 3 months, referral should be considered.

PATIENT EDUCATION

Most clavicle fractures heal without surgery, especially if the fracture is not displaced. Fractures in children take approximately 3 to 4 weeks to heal. Often, there will be a “bump” at the site of the healed fracture, which is underlying bone callous. The callous usually does not does not interfere with any activities but can start forming in the first few days and last for months, which is important to communicate with the families.

84 FOREARM FRACTURES

Emily Gale Scott, MD
Heidi Chumley, MD

PATIENT STORY

A 5-year-old boy fell off his bicycle and had immediate pain and swelling of his right wrist. He continued to complain of pain and could not use his right arm because of severe pain. In the emergency department a radiograph was obtained which showed a Buckle (Torus) right radius fracture (**Figure 84-1**). He was treated by immobilization with a short arm cast for 3 weeks and had an excellent recovery.

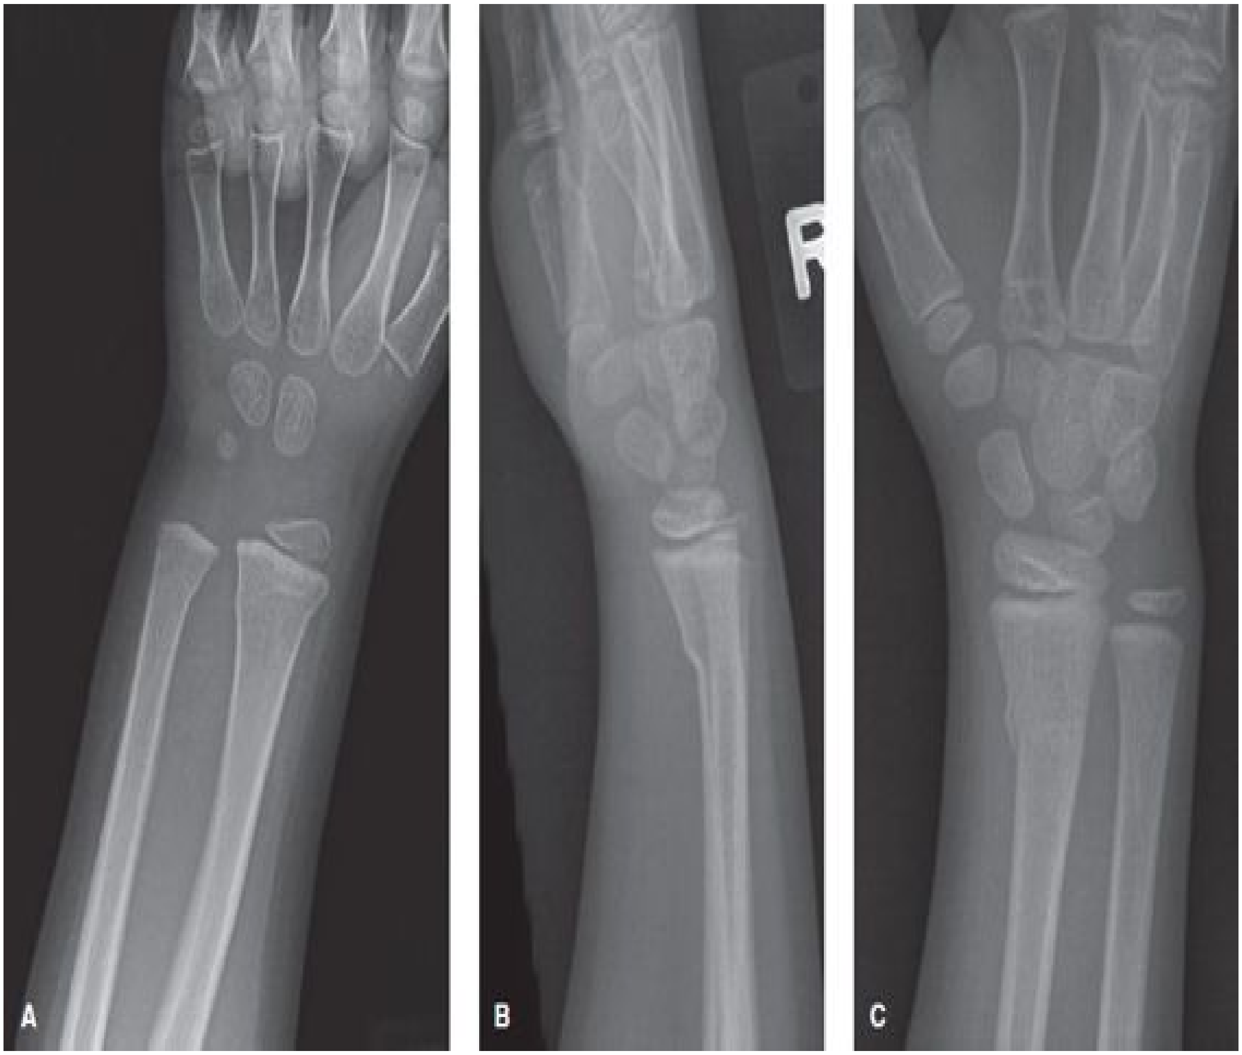

FIGURE 84-1 Buckle fracture (Torus) of the distal radius on AP (**A**), lateral (**B**), and oblique (**C**) forearm x-ray views. This 5-year-old boy fell off his bicycle. (*Used with permission from Emily Scott, MD.*)

INTRODUCTION

Distal radius and forearm fractures are common in children and adolescents. Patients typically present after falling on an outstretched arm. The diagnosis is confirmed by radiographs. Treatment in the pediatric population is usually non-operative with prolonged immobilization but can require operative care depending on the type of fracture, degree of displacement and the age of the patient.

SYNONYMS (TYPES OF FRACTURES)

Physeal fractures (growth plate injuries), Buckle (Torus), Greenstick fractures can occur in the forearm. Galeazzi and Monteggia fractures are more rare forearm fractures, but important to recognize.

EPIDEMIOLOGY

- Radius/ulna fractures are the most common upper extremity fracture (37%) in children under the age of 6 years.[1]
- Distal radial fractures (**Figure 84-2**) accounted for 25 to 30 percent of fractures in children ages 2 to 14.[2,3]

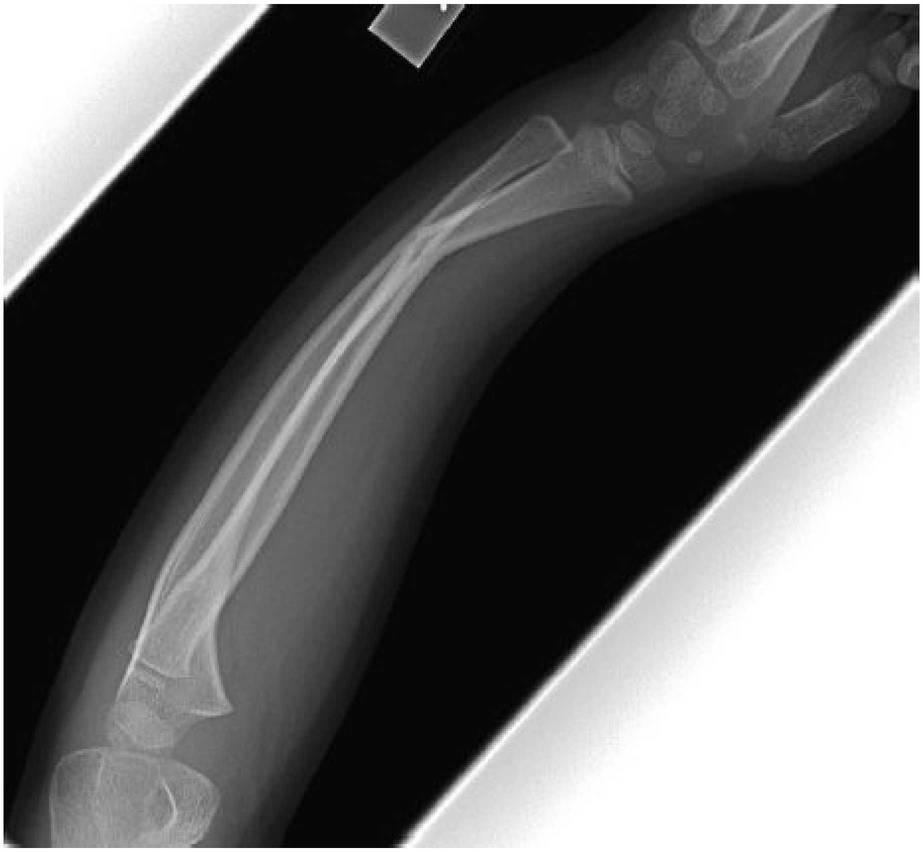

FIGURE 84-2 Distal radius fracture on lateral view in a 7-year-old child. (*Used with permission from Emily Scott, MD.*)

- Incidence is 373/100,000 children.[4]
- Peak incidence is age 11 to 14 in boys and ages 8 to 11 in girls.[4]
- More common in boys across all ages.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Classic history is a fall from a height (bed or playground equipment), down stairs, or while running, biking, or skating on an outstretched arm.
- Increase in incidence of fractures during pubertal years is thought to be from increase physical activity concurrent with transient deficit in cortical

bone mass and secondary to an increase in height that is not accompanied by an adequately increased accrual of bone mineralization.[4]

- Abuse: in infants (less than one year), should be considered especially if the history of injury is not plausible and inconsistent with injury pattern.[5]

RISK FACTORS

- Male gender.
- Pubertal age.
- Previous history of fracture.

DIAGNOSIS

Diagnosis is suspected by a compatible history such as falling, physical findings of trauma and confirmed by radiographs (two or three views). In regard to radiographs, more than one view is essential to determine the degree of angulation and deformity. Typical radiographs include anterior posterior (AP), lateral and oblique films (**Figure 84-3**). For some specific injuries it is necessary to image the elbow because it can often have dislocation or other injuries associated with forearm fracture.

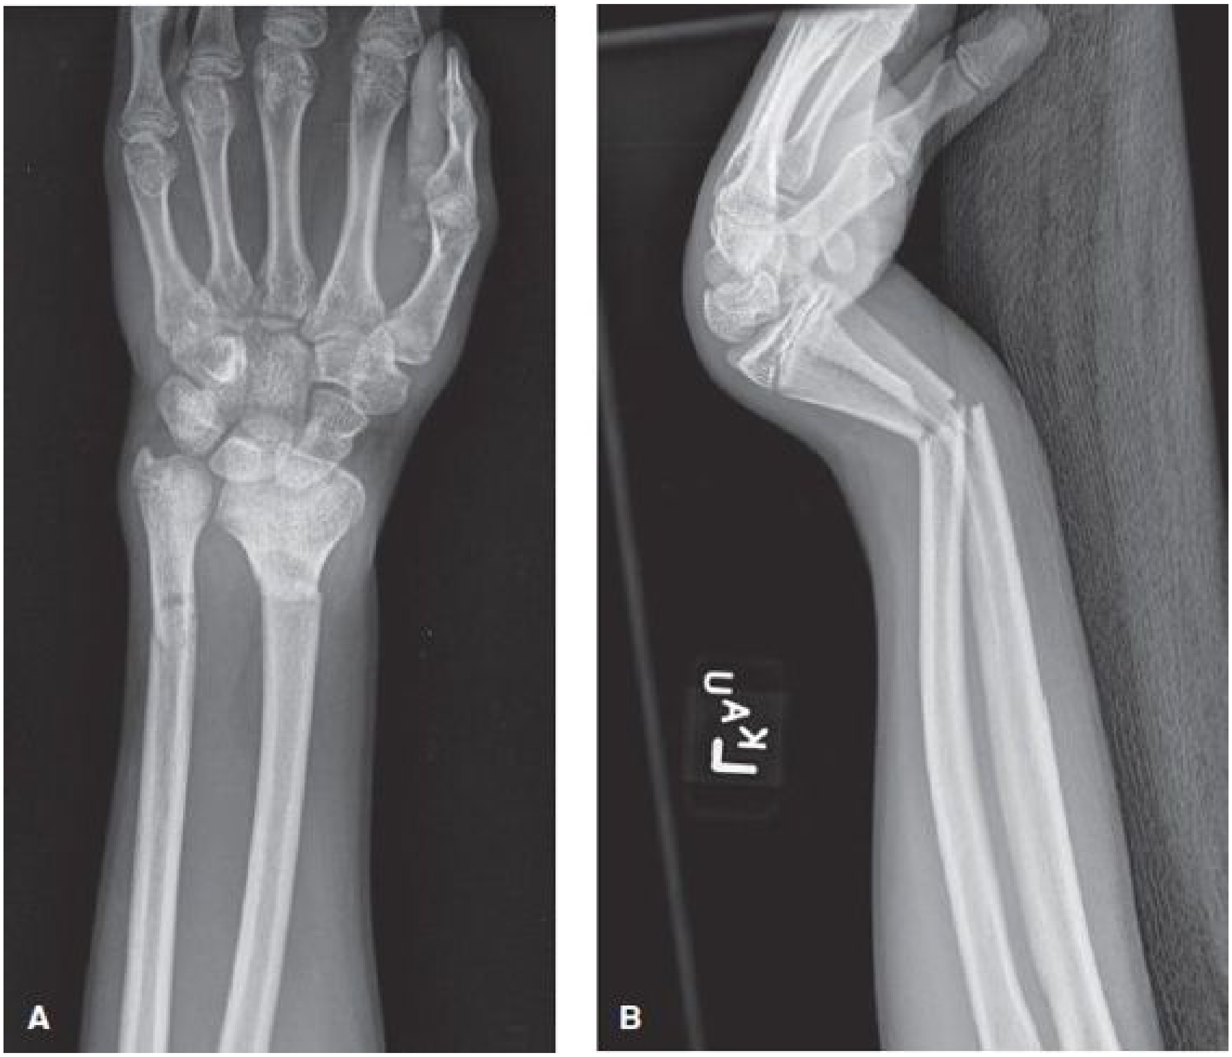

FIGURE 84-3 Midshaft radial fractures in a 10-year-old child. Two x-ray views are essential to determine the degree of injury in forearm fractures. The fracture is seen on the AP (**A**) view, but the lateral (**B**) view clearly demonstrates severe angulation not seen on the AP view. (*Used with permission from Emily Scott, MD.*)

CLINICAL FEATURES

Pain, obvious swelling, and/or deformity are usually present after accidental injury. External sign of injury and abnormal use of the arm is present in most cases. However, some children under the age of 6 years do not always manifest these signs. Fifteen percent of children will not have an external sign of injury and 16 percent may use a fractured arm normally.[1]

TYPES OF FRACTURES

Type of forearm fractures in children include:

- Physeal fractures (growth plate injuries)—Most common in children ages 6 to 10 years after falling on an outstretched hand. Most are Salter-Harris type I or II (**Figures 84-4** and **84-5**).

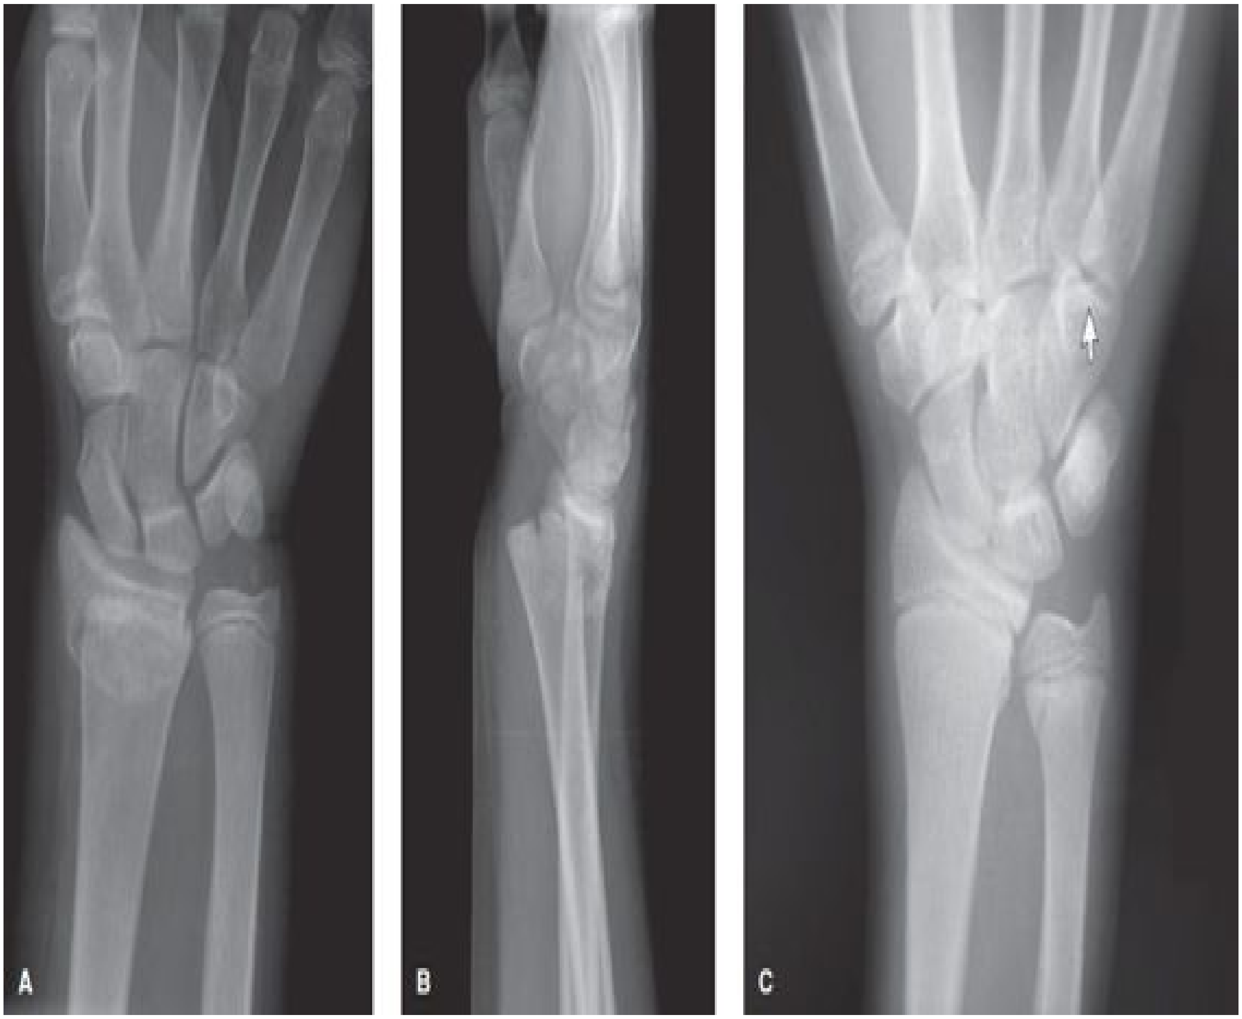

FIGURE 84-4 Salter Harris II physeal radius fracture of the growth plate on AP (**A**), Lateral (**B**) views in a 10-year-old child. (**C**) Classic Salter-Harris II fracture of ulna and buckle fracture of the radius in a 13-year-old boy who fell on an outstretched arm. (*Used with permission from Emily Scott, MD.*)

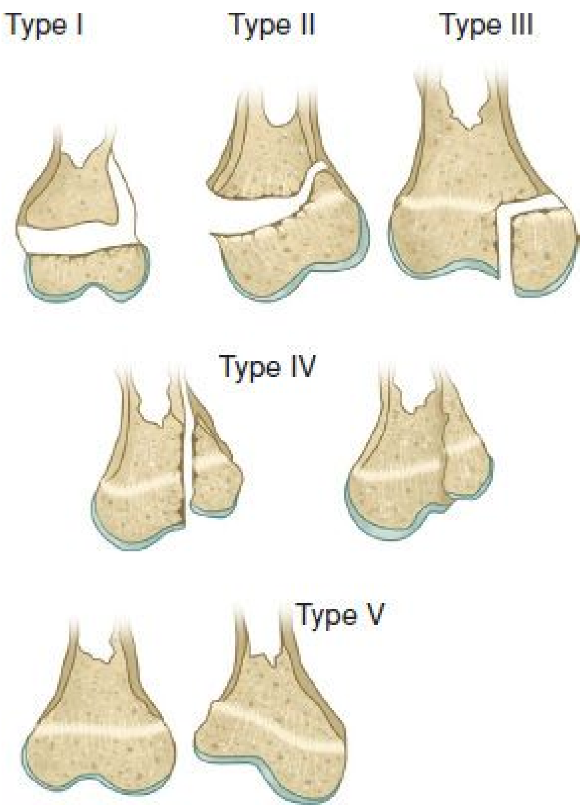

FIGURE 84-5 Salter-Harris classification system of growth plate fractures. Type I, separation of the physis; type II, fracture through the physis and adjacent metaphysis; type III, fracture through the physis and adjacent epiphysis; type IV, fracture through the physis, adjacent metaphysic and epiphysis; type V, crush injury of the physis. (*Used with permission from Patel DR, Greydanus DE, Baker RJ: Pediatric Practice: Sports Medicine: www.accesspediatrics.com*).

- Torus (Buckle) fractures—Common in young children; fracture through dorsal cortex 2 to 3 cm proximal to the physis with dorsal angulation of distal fragment after falling on an outstretched hand (**Figures 84-6** and **84-7**).

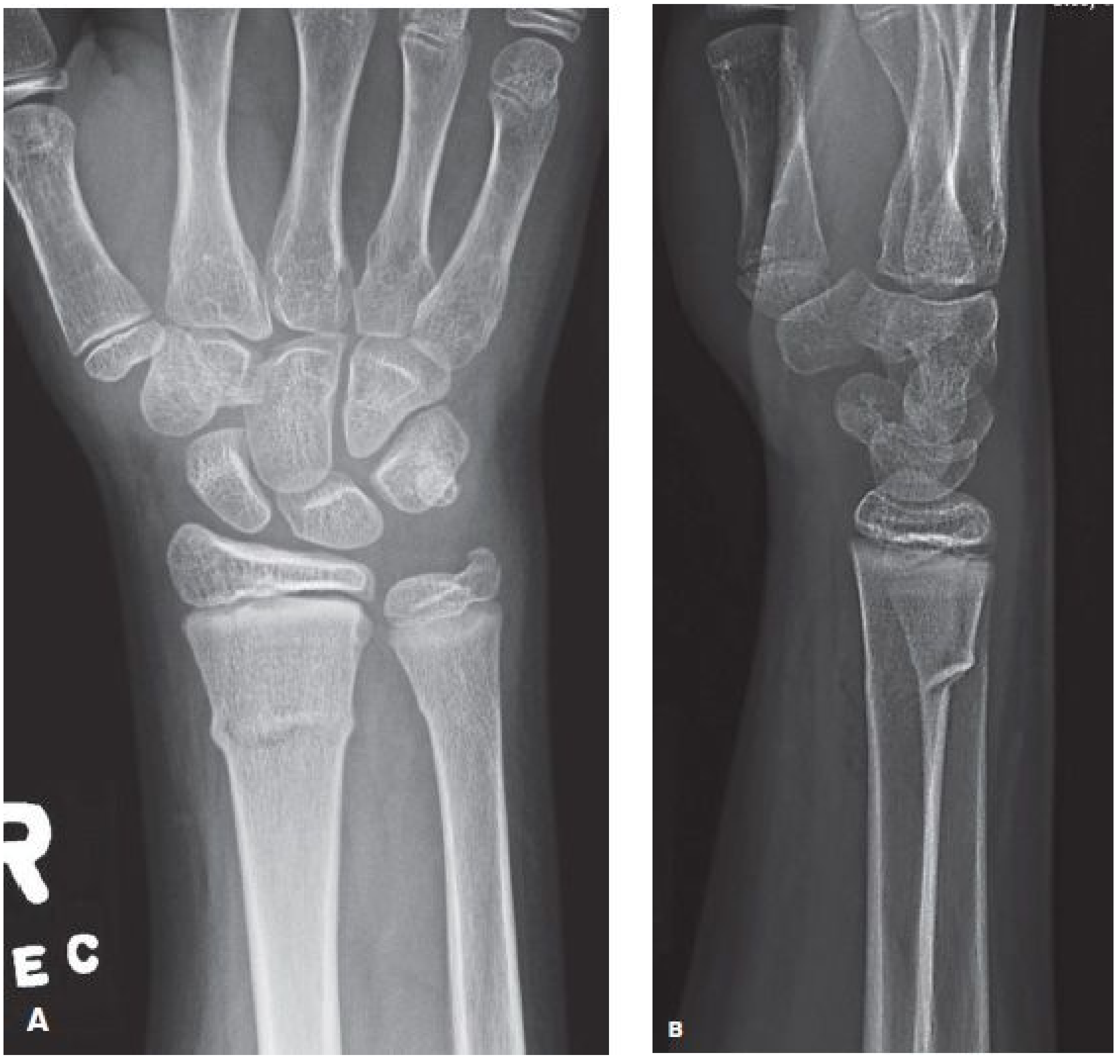

FIGURE 84-6 Distal radius Buckle (Torus) fracture on AP (**A**) and lateral (**B**) views in a 10-year-old child. (*Used with permission from Emily Scott, MD.*)

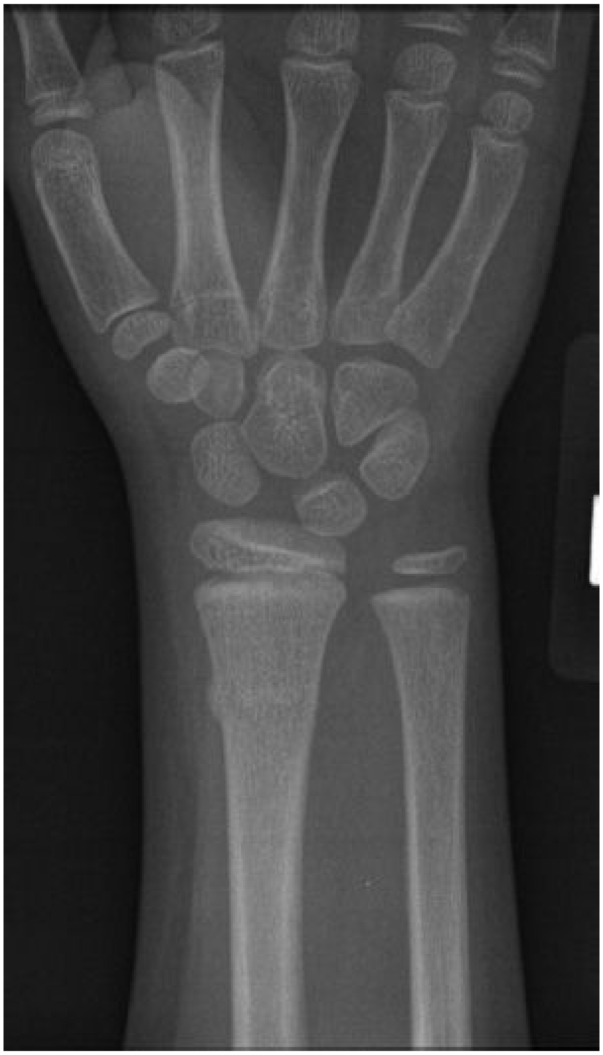

FIGURE 84-7 Buckle (Torus) Fracture in a 13-year-old child. (*Used with permission from Emily Scott, MD.*)

- Greenstick fracture—Incomplete fracture, which may occur on the dorsal or volar side of the radius or ulna or both. Greenstick fracture of one forearm bone can accompany a complete fracture of the other forearm bone (**Figure 84-8**).

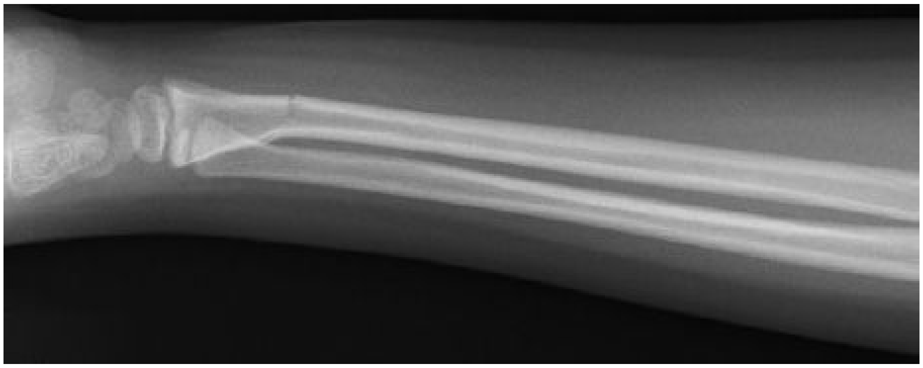

FIGURE 84-8 Greenstick fracture of the radius in an 8-year-old child. (*Used with permission from Emily Scott, MD.*)

- Complex Radius and Ulna fractures—Fractures present in both bones, either complete or incomplete (Greenstick); caused by a fall on an outstretched hand, severe trauma, or intentional injury, especially in infants. These usually occur in the mid-shaft. They often require operative management (**Figure 84-9**).

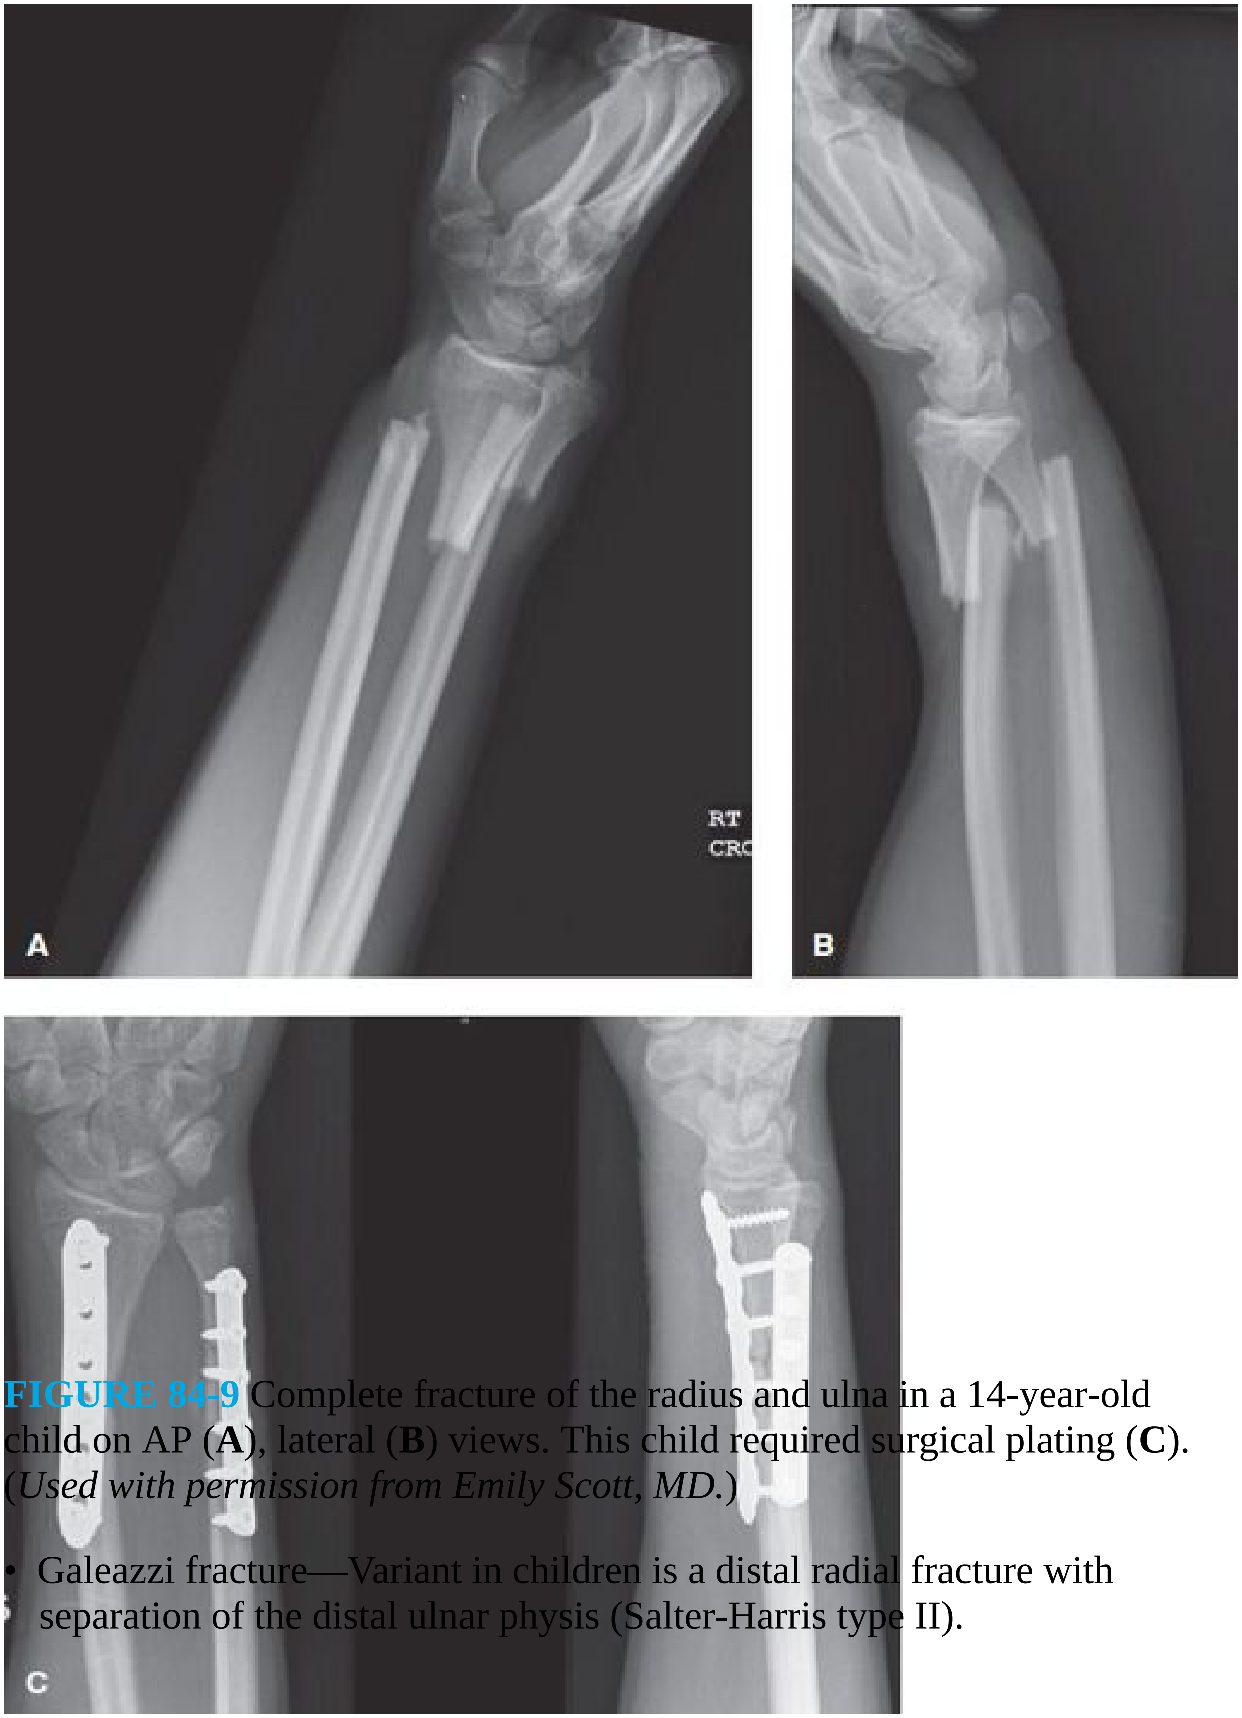

FIGURE 84-9 Complete fracture of the radius and ulna in a 14-year-old child on AP (**A**), lateral (**B**) views. This child required surgical plating (**C**). (*Used with permission from Emily Scott, MD.*)

- Galeazzi fracture—Variant in children is a distal radial fracture with separation of the distal ulnar physis (Salter-Harris type II).

- Monteggia Fracture—A rare specific type of forearm fracture that involves proximal ulna fracture with associated radial head dislocation. If isolated ulna fracture is present, one needs to evaluate the elbow for additional injury (**Figures 84-10** and **84-11**).

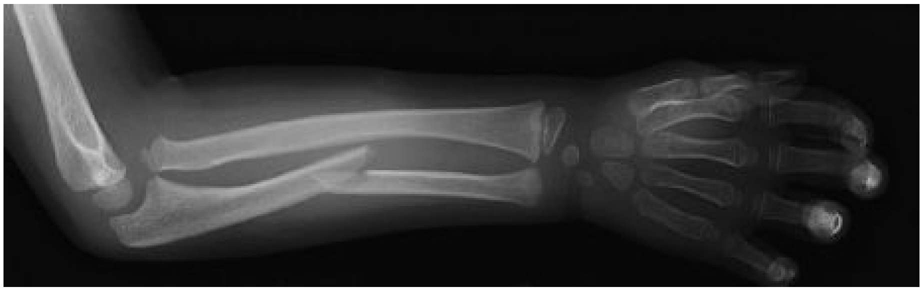

FIGURE 84-10 Monteggia fracture in a 9-year-old child. Lateral view of the elbow and forearm showing the midshaft ulnar fracture with radial head dislocation. (*Used with permission from Emily Scott, MD.*)

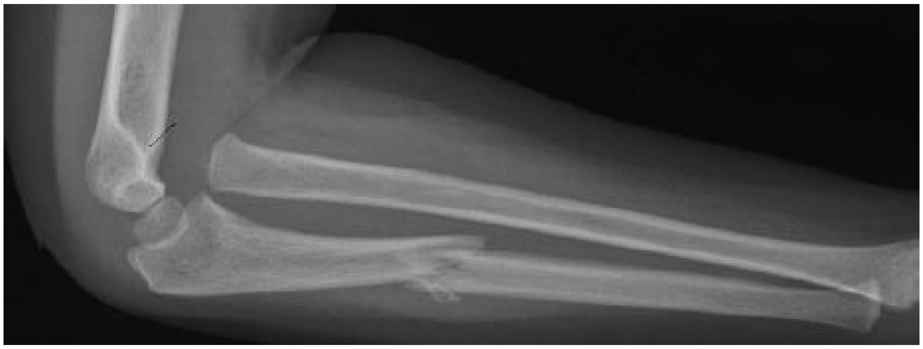

FIGURE 84-11 Monteggia fracture in a 3-year-old child showing a midshaft ulnar fracture with radial head dislocation. (*Used with permission from Emily Scott, MD.*)

DIFFERENTIAL DIAGNOSIS

Other causes of pain at the wrist include:

- Wrist sprains or strains present with tenderness, pain, and swelling but with normal radiographs.

- Stress or overuse injuries (e.g., in gymnasts) present with less acute onset and include soft-tissue and bony lesions that can be identified on MRI.

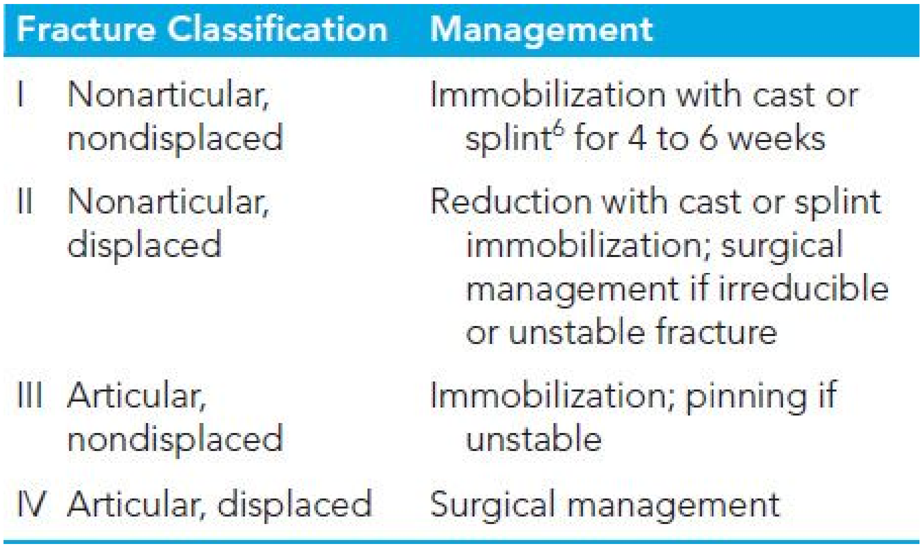
MANAGEMENT

Initial management requires complete exam including neurovascular and motor components, pain management, and radiographs. Type of fracture, amount of displacement, and age of child guide management help guide the management plans for forearm fractures.

PHYSEAL FRACTURES (GROWTH PLATE INJURIES)

- Look for a concomitant distal ulnar fracture and avulsion fracture of ulnar styloid.
- Evaluate for compartment syndrome and acute carpal tunnel and if present, refer immediately.
- Apply long arm splint with 25 degrees wrist flexion and 15 degrees ulnar deviation.[5]
- Refer to a physician experienced in managing physeal fractures, such as an orthopaedic surgeon
- Described by Salter Harris Classification (**Table 84-1**).

TABLE 84-1 Universal Classification of Radial Fractures



Fracture Classification		Management
I	Nonarticular, nondisplaced	Immobilization with cast or splint[6] for 4 to 6 weeks
II	Nonarticular, displaced	Reduction with cast or splint immobilization; surgical management if irreducible or unstable fracture
III	Articular, nondisplaced	Immobilization; pinning if unstable
IV	Articular, displaced	Surgical management

BUCKLE (TORUS) FRACTURES

- Ensure that the fracture is on the compression side and that the tension side is intact.
- Place in a short-arm cast for three weeks.[5]

GREENSTICK FRACTURES

- Minimally angulated (<15 degrees) can be treated with a short arm cast or splint for 4 weeks.[6]
- Consult with a physician experienced in managing Greenstick fractures as they sometimes require completing the fracture to adequately reduce the fracture and minimize the risk of recurrent deformity while in the cast.

COMPLEX RADIUS AND ULNAR FRACTURES

- Evaluate neurovascular status.
- Refer to a physician experienced in managing forearm fractures to determine whether closed or open reduction is most appropriate.

PREVENTION

The Center for Disease Control and Prevention recommends these safety practices to prevent injuries from falls in children.

- Ensure child wears protective gear during sports and recreation including helmets and wrist guards.
- Use window guards, stair gates, and guard rails.
- Ensure the surface under playground equipment is safe and soft (e.g., wood chips instead of dirt).
- Supervise young children at all times when around fall hazards such as staircases and playground equipment.

PROGNOSIS

Most children with distal radial fractures will recover function with appropriate treatment.

FOLLOW-UP

- Management and follow-up often involve a physician with expertise in managing distal radial fractures.[7]

PATIENT EDUCATION

- Most children will recover completely with appropriate management.
- Safe practices can help prevent further injuries.

- Discuss safety tips with parents to prevent future injuries.

85 METATARSAL FRACTURE

Heidi Chumley, MD

PATIENT STORY

A 13-year-old boy inverted his ankle while playing basketball in his driveway. He felt a pop and had immediate pain. He had tenderness over the base of his fifth metatarsal. Having met the Ottawa ankle rules for radiographs (see Management Section), a radiograph was obtained, which revealed a displaced styloid fracture at the base of the fifth metatarsal (**Figure 85-1**).

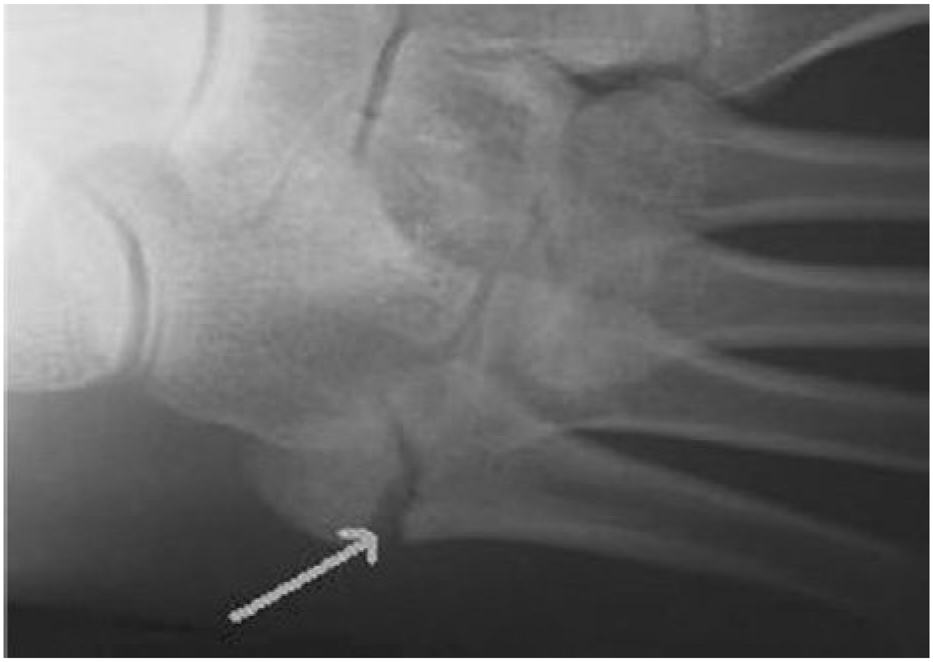

FIGURE 85-1 Displaced styloid fracture at the base of the fifth metatarsal. (*Used with permission from Patel DR, Greydanus DE, Baker RJ: Pediatric Practice: Sports Medicine: www.accesspediatrics.com. Figure 28-26, with permission.*)

INTRODUCTION

Most metatarsal fractures in children over the age of 5 years involve the fifth metatarsal and include avulsion fractures at the base, acute diaphyseal fractures (Jones fracture), and diaphyseal stress fractures (**Figure 85-2**). Fractures of the first through fourth metatarsals are less common but can be associated with a Lisfranc injury. Children under the age of 5 years more commonly fracture the first metatarsal. Diagnosis is based on the mechanism of injury or type of overuse activity and radiographic appearance. Treatment depends on the type of fracture. Most metatarsal fractures have a good prognosis; however, Jones fractures have a high rate of nonunion and Lisfranc injuries can result in chronic symptoms.

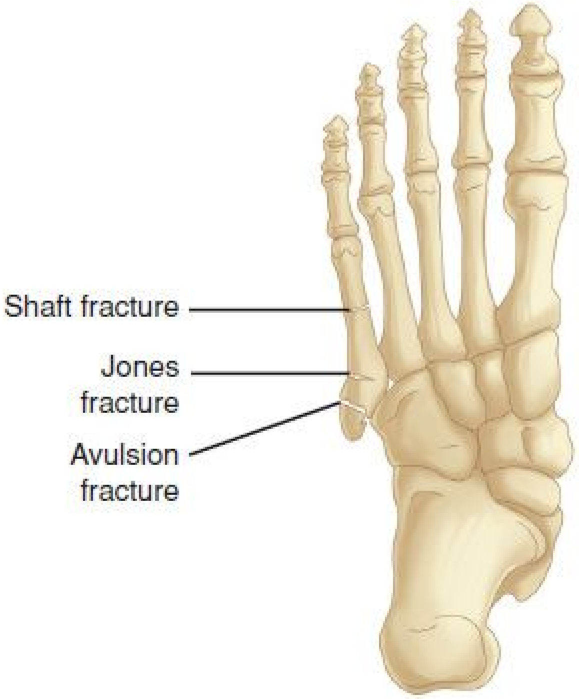

FIGURE 85-2 Fractures of the fifth metatarsal. Avulsions or shaft fractures are most common in pediatrics. The Jones fracture (metaphyseal–diaphyseal junction) is rare in children. (*Used with permission from Strange GR, Ahrens WR, Schafermeyer RW, Wiebe RA: Pediatric emergency Medicine, 3*rd *edition: http://www.accessemergencymedicine.com. Figure 38-11, with permission.*)

SYNONYMS

Avulsion fracture at base of fifth metatarsal: fifth metatarsal tuberosity fracture, dancer fracture, pseudo-Jones fracture.

Jones fracture—Acute diaphyseal fracture of the fifth metatarsal.

EPIDEMIOLOGY

- Foot fractures are common injuries among recreational and serious athletes; however, incidence and prevalence in most populations is unknown.
- Children under the age of 5 years most frequently fracture the first metatarsal, generally from a fall from a height.[1]
- Children over the age of 5 years most frequently fracture the fifth metatarsal generally from a fall on a level surface.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Avulsion fractures result when the peroneus brevis tendon and the lateral plantar fascia pull off the base of the fifth metatarsal, typically during an inversion injury while the foot is in plantar flexion.
- Jones (acute diaphyseal) fracture results from landing on the outside of the foot with the foot plantar flexed.
- Stress fractures at base of second and third metatarsal bones are seen in repetitive trauma in ballet dancing.
- Diaphyseal stress fractures are caused by chronic stress from activities such as jumping and marching.

- Fractures of the first through fourth metatarsals are caused by direct blows or falling forward over a plantar-flexed foot. These fractures may be associated with a Lisfranc injury.

DIAGNOSIS

The diagnosis of avulsion or Jones fractures is made on plain radiographs in a patient with a history of injury and acute lateral foot pain. Comparative views of the uninjured foot may be helpful. Diaphyseal stress fractures may require CT imaging.

CLINICAL FEATURES

- Avulsion injury—Sudden onset of pain (and tenderness on examination) at the base of the fifth metatarsal after forced inversion with the foot and ankle in plantar flexion.
- Acute Jones fracture—Sudden pain at the base of the fifth metatarsal, with difficulty bearing weight on the foot, after a laterally directed force on the forefoot during plantar flexion of the ankle.
- Stress fracture—History of chronic foot pain with repetitive motion.

IMAGING

- Avulsion fracture—Fracture line at base of fifth metatarsal oriented perpendicularly to the metatarsal shaft (**Figure 85-1**). May extend into joint with cuboid bone, but does not extend into the intermetatarsal joint.
- Acute Jones fractures (**Figure 85-3**) and stress fractures both have a fracture line through the proximal 1.5 cm of the fifth metatarsal shaft. These should be classified into type I, II, or III:[2]

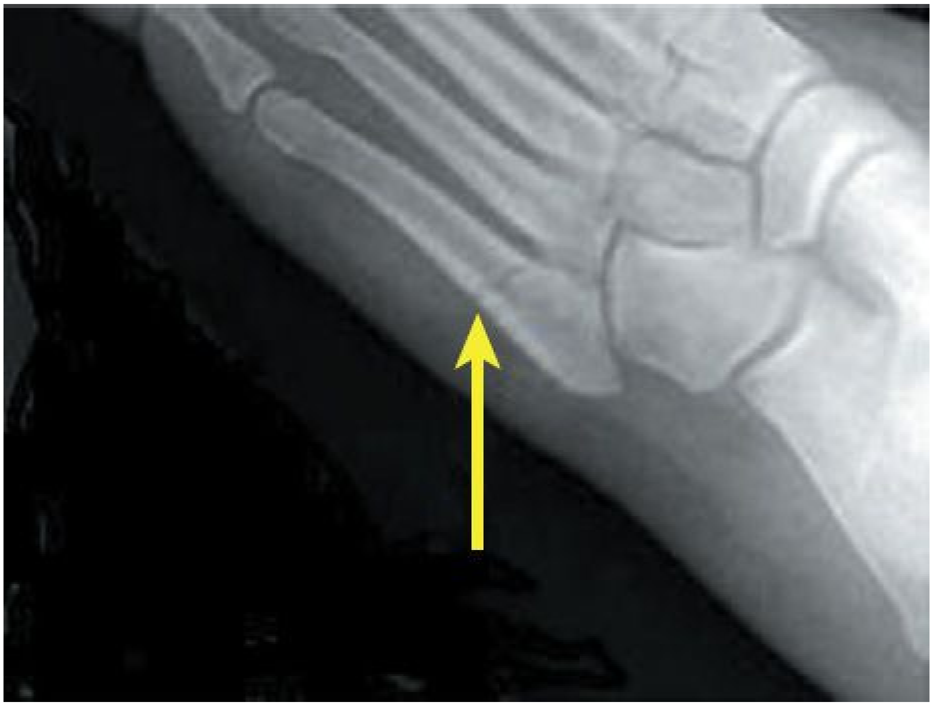

FIGURE 85-3 Jones fracture, a transverse fracture at the junction of the diaphysis and metaphysis. (*Used with permission from Patel DR, Greydanus DE, Baker RJ: Pediatric Practice: Sports Medicine: www.accesspediatrics.com. Figure 28-25, with permission.*)

  - Type I fractures have a sharp, narrow fracture line, no intramedullary sclerosis, and minimal cortical hypertrophy.
  - Type II fractures (delayed unions) have a widened fracture line with radiolucency, involve both cortices, and have intramedullary sclerosis.
  - Type III fractures (nonunions) have a wide fracture line, periosteal new bone and radiolucency, and obliteration of the medullary canal by sclerotic bone.

- Early stress fractures may have normal radiographs and can be seen on CT, MRI, or bone scan. Ultrasound may be a less expensive option—sensitivity 83 percent, specificity 76 percent, positive predictive value 59 percent and negative predictive value 92 percent in one small study.[3]

DIFFERENTIAL DIAGNOSIS

Pain at the fifth metatarsal can also be caused by:

- Diaphyseal stress fracture—May be radiographically similar to Jones fracture but is often seen more distally in the shaft; occurs in patients with no injury and history of overuse (e.g., ballet dancing, marching).
- Lisfranc injury—Disruption of the tarsal metatarsal joints (**Figure 85-4**). This pain is typically in the midfoot and more commonly medial. May be associated with fractures in the first through fourth metatarsals.

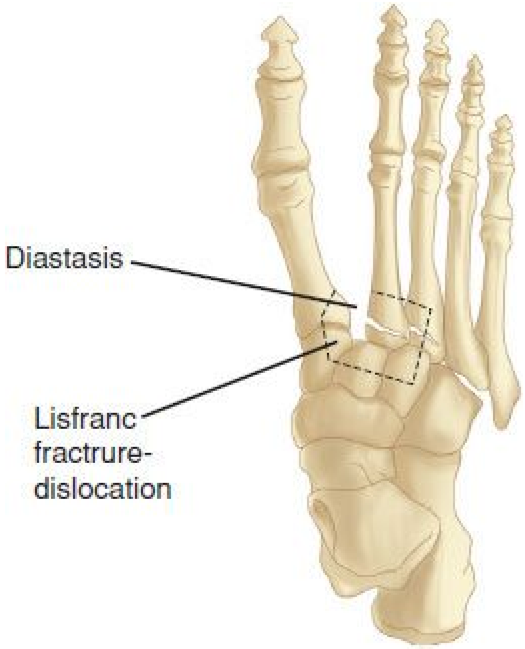

FIGURE 85-4 Illustration of the Lisfranc injury, which is a tarsal–metatarsal dislocation. This is rare in pediatric patients. (*Used with permission from Strange GR, Ahrens WR, Schafermeyer RW, Wiebe RA: Pediatric emergency Medicine, 3rd edition: http://www.accessemergencymedicine.com. Figure 38-12, with permission*.)

x-ray findings that can be confused with foot fractures include:

- Apophysis, a secondary center of ossification at the proximal end of the fifth metatarsal seen in girls, ages 9 to 11 years, and boys, ages 11 to 14 years. The apophysis is oblique to the metatarsal shaft, whereas avulsion fractures are perpendicular.

- Accessory ossicles (i.e., os peroneum, located at the lateral border of the cuboid) have smooth edges, whereas avulsion fractures have rough edges.

MANAGEMENT

Fractures of fifth metatarsals in children have been found to be similar to those in adults. Management is based on adult literature.[4]

Apply the Ottawa ankle rules in children over the age of 5 years to determine which patients with an injury and ankle/foot pain should have an x-ray.[5,6] SOR Ⓐ Ottawa rules: x-ray patients who cannot walk four steps immediately after the injury or who have localized tenderness at the posterior edge or tip of either malleolus, the navicular, or the base of the fifth metatarsal.[5]

- Treat nondisplaced avulsion fractures with an ankle splint or walking boot with ambulation for 3 to 6 weeks.[7] SOR Ⓑ Refer displaced avulsion fractures.
- Consider referring Jones fractures because of the high rate of nonunion caused by the poor blood supply. Type I or II may be treated with immobilization for at least 6 to 8 weeks. Type II can also be treated with surgery. Type III requires surgical repair. Elite athletes or patients needing a faster recovery are often surgically treated.[8] SOR Ⓑ
- Treat stress fractures with elimination of the causative activity for 4 to 8 weeks. Immobilization is often not required. If walking is painful, partial or non–weight-bearing for 1 to 3 weeks may be necessary.[9]

Refer patients with:[9]

- Neurovascular compromise, compartment syndrome, or open fractures.
- First metatarsal fracture, multiple metatarsal fractures, displaced fracture, intraarticular fracture, or Lisfranc injury.
- Inadequate response to treatment.

PROGNOSIS

Prognosis in children is thought to be excellent. Metatarsal fractures in older adolescents and adults have an excellent outcome, with most patients symptom free at 33 months. Patients with higher body mass index (BMI), diabetes mellitus, women, and a dislocation with the fracture have less-positive outcomes.[10]

FOLLOW-UP

Patients should be followed every 1 to 3 weeks to evaluate for appropriate clinical and radiographic response to treatment.

PATIENT EDUCATION

Patients with nondisplaced avulsion fractures require a splint or boot, but can remain ambulatory. Jones fractures have a poor blood supply and often do not reconnect, even with immobilization. Surgery may result in a faster return to activities in some cases.

PATIENT RESOURCES

86 CLUB FEET

David S. Ebenezer, MD
Paul M. Saluan, MD

PATIENT STORY

A 4-day-old baby boy is brought to the pediatrician’s office for their first visit after birth. The pregnancy was full-term and uneventful, except for that the baby was a breech birth. The baby’s mother has noticed that although both legs and feet appear a little “curved,” both feet are almost “sideways” and look abnormal (**Figure 86-1**). On examination of both feet the hindfoot is clearly inverted, the toes point medially, and the foot is plantar flexed. The deformity is somewhat correctible by forcing the foot into a more normal position, but not completely. The baby does not appear to be in pain. He has no other abnormalities, has a normal neurologic exam for his age, and appears to be otherwise healthy. The child is referred to a pediatric orthopaedic surgeon, who begins serial Ponseti casting within one to two weeks. After several weeks of weekly serial casting, the feet have a more normal appearance. The child is then splinted full-time using a special orthosis for approximately three months, after which he is only splinted at night until walking age, at which time splinting is discontinued. He has no residual deformity.

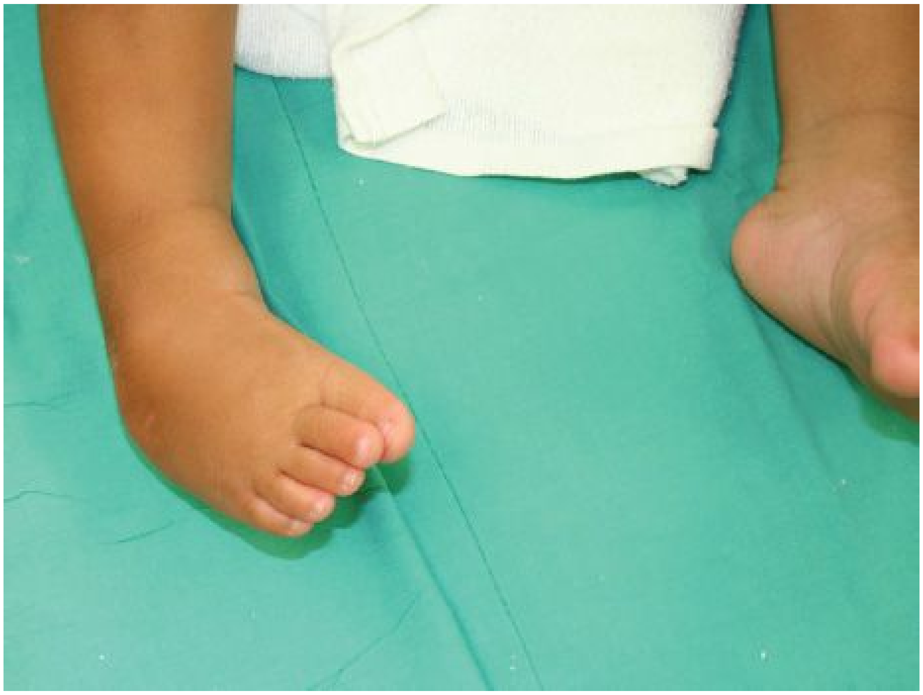

FIGURE 86-1 Bilateral clubfeet in an infant. Note the deepened medial crease (*Used with permission from David Gurd, MD.*)

INTRODUCTION

Clubfeet is one of the most common congenital abnormalities of the lower extremities.[1] As with any congenital deformity, it can be very concerning to new parents. However, the current gold standard of early non-operative treatment, with surgery only if needed later in life, has led to generally excellent functional results long-term.[2]

SYNONYMS

Congenital Talipes Equinovarus.

EPIDEMIOLOGY

- Approximately 1.2 per 1000 live births in Caucasians.[3]
- Varies across cultures, with only 0.39 to 0.5 per 1000 live births in Asian nations to 7 per 1000 live births in the South Pacific.[1,3]
- Two-to-one male predominance across all populations, with 50 percent of cases bilateral.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- Due to the numerous bones and joints in the foot, a great deal of very descriptive but complicated orthopaedic terminology is associated with understanding the normal and abnormal relationships within the foot. However, this knowledge becomes useful in deciphering and communicating how to correct the deformity.
- The pathophysiology in clubfoot is characterized by four fundamental deformities of the foot, remembered by the mnemonic CAVE:[5]
    - Cavus (a deformity describing a higher or cavitary arch of the foot).
    - Adductus of the forefoot (the rays of the toes abnormally point medially).
    - Varus of the hindfoot (the plantar aspect of the calcaneus points medially if looked at from behind the patient).
    - Equinus (the foot is relatively plantar flexed, usually with a tight Achilles tendon).
- Another useful descriptive term for the forefoot is supination (a combination of inversion and adduction).
- The deformity can vary from mild and very flexible to severe and rigid.[1]
- The etiology is thought to be multifactorial but may include:[1]
    - Genetic factors.

  - Environmental exposure, for example, cigarette smoke.
  - Vascular deficiencies.
  - Abnormal function of the neuromuscular unit.
  - Late-term in utero positioning was historically thought to be a factor, but the evidence appears less likely that it plays a major role in the development of clubfoot.
- May be associated with syndromes such as arthrogryposis, constriction bands (Streeter dysplasia), prune belly, tibial hemimelia, Möbius syndrome, Freeman-Sheldon syndrome, diastrophic dwarfism, Larsen syndrome, Opitz syndrone, and Pierre Robin syndrome.[6]

DIAGNOSIS

CLINICAL FEATURES

- Clubfoot has a very typical appearance.
- After birth clubfoot is primarily a clinical diagnosis based on physical examination showing foot equinus with some degree of cavus, varus, and adductus.[6]
- Frequently the involved calf is smaller in circumference.
- Examination of the skin creases around the foot and ankle can aid in diagnosis.
  - The involved side tends to have a single heel crease, versus multiple on the uninvolved side.[6]
  - The depth of the medial skin crease indicates the severity of the deformity.
- Numerous classification schemes exist, with none entirely prognostic. The system described by Deméglio is most popular to describe severity and track progress of treatment.[5]

IMAGING

- Radiographs can be performed but their role is unclear as the bones of the foot of a newborn are mostly cartilage with ossification centers that are not centered, making the images difficult to interpret.
  - As the bones ossify, classic changes seen include parallelism of the angle made between the long axis of the talus and calcaneus on AP and lateral radiographs when compared to the normal foot (**Figure 86-2**).

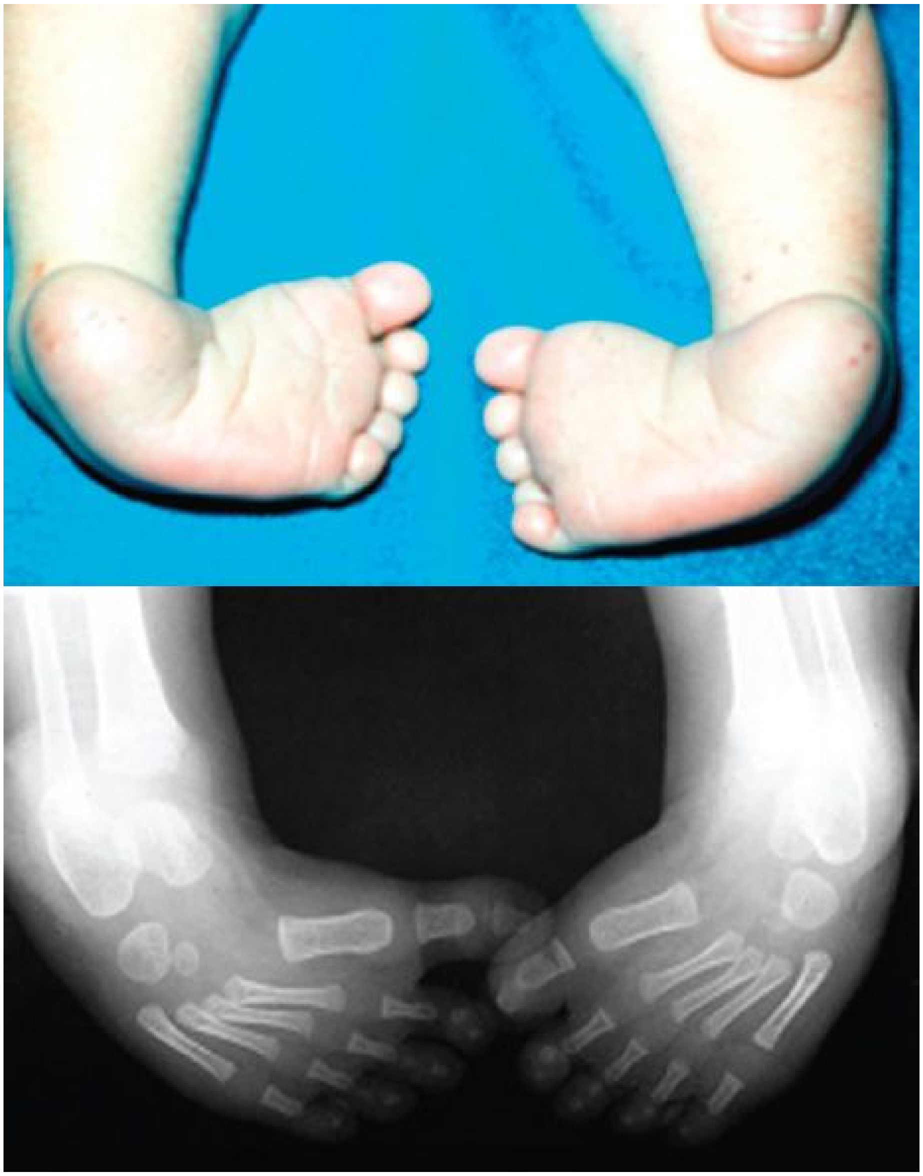

FIGURE 86-2 Bilateral clubfeet with associated radiographic appearance. Note the parallelism of the talus and calcaneus on the radiographs, typical of

clubfeet (*Used with permission from Ryan Goodwin, MD.*)

  - Clubfoot can be visualized on prenatal ultrasound.
  - Other modalities after birth such as MRI, and CT have been used but are not essential.

- Radiographs can be useful in cases of tibial hemimelia, or for surgical planning if and when intervention is considered.
- There is a high incidence of associated disorders and syndromes; therefore a full neurologic examination as well as assessment of all joints and the spine is important.[3,6]

DIFFERENTIAL DIAGNOSIS

- Physiologic intrauterine molding/packaging, which results in external rotation of the hips, internal rotation of the tibia, and variable foot position, the combination of which can present with complaints such as “bowed legs” and possibly a foot deformity. These findings are usually mild and usually spontaneously resolve on their own as the child grows.
- Metatarsus Adductus may appear similar to clubfoot, and is one of the component deformities of clubfoot, but can be an isolated entity of its own.[6] In this condition there is no involvement of the hindfoot.
- Congenital vertical talus, characterized by a rocker-bottom foot.[6]

MANAGEMENT

NONSURGICAL

Serial casting has become the preferred choice for initial management of clubfeet among Pediatric Orthopaedic Surgeons over the last decade with dramatic results.[5,7] SOR Ⓐ

- Ideally started within the first month of life.
- Primarily two popular nonsurgical methods utilized today:
  - The Ponseti method of serial casting,
    - Currently the most popular method in the US.[7]
    - Gentle manipulation and casting in a long leg cast (**Figure 86-3**).

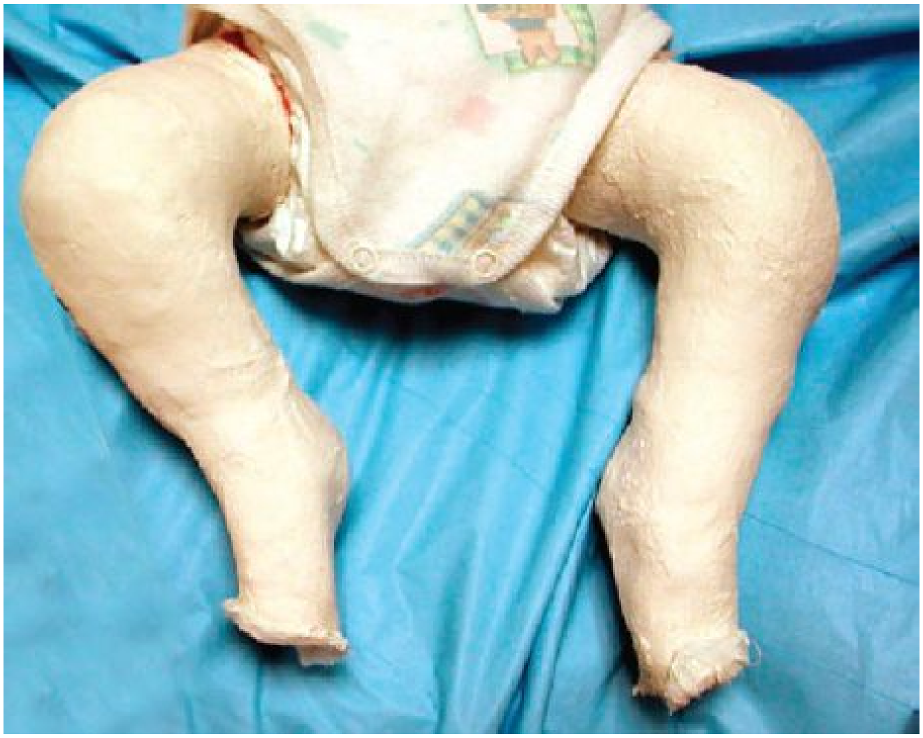

FIGURE 86-3 Bilateral Ponseti casting using plaster casts. The casts must go above the knee as casts below the knee can easily fall off in infants. (*Used with permission from Ryan Goodwin, MD.*)

    - Casts are changed on a weekly basis.
    - The mode of deformity correction follows the mnemonic CAVE: first cavus, followed by adductus and then varus; only after all of those are corrected is equinus addressed (**Figure 86-4**).

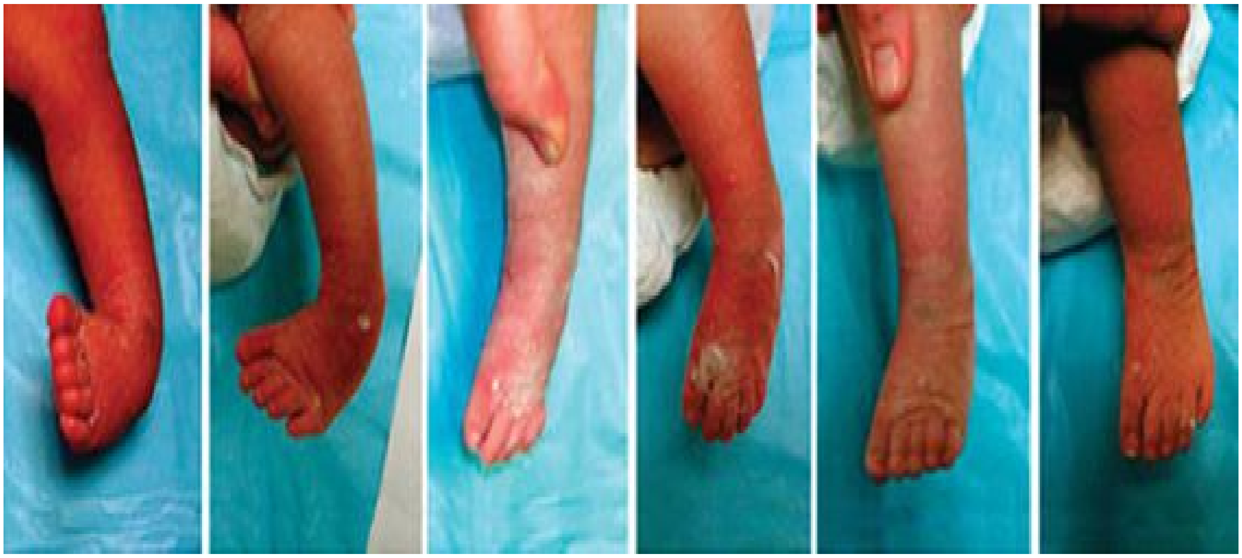

FIGURE 86-4 Time-lapse images of serial Ponseti casting in clubfoot. Note the slow and gradual correction to a normal-appearing foot. (*Used with permission from Ryan Goodwin, MD.*)

    - This usually takes between 6 to 8 weeks total.
    - After the fourth or fifth cast, sometimes a percutaneous Achilles tendon tenotomy is performed if there is still an equinus deformity,[1] This usually heals with little to no abnormality of the tendon and no residual weakness,[5] and the foot is casted for 3 to 4 more weeks.
    - Once full correction has been achieved and the final cast is removed, the patient is placed in a foot-abduction brace such as a Denis-Browne bar with the affected foot in approximately 70 degrees of external rotation.[1]
    - This is done 23 hours per day for 3 months, followed by night and nap time wear at least until walking age, although this may be done up to age 4 to prevent recurrence.[1,6]
- The French method.
    - More dynamic system involving daily manipulations, stretching, and exercises by a trained physical therapist combined with adhesive taping to hold the correction achieved with the therapy.[1,6]
    - Has also incorporated continuous passive motion (CPM) devices into its regimen.[5]

- Compliant patients have been shown to have success with both methods, with minimal difference in success rates between the two, although Ponseti appears to be much more widely used in the US.[8,9]
- Main problem causing recurrence is noncompliance with bracing, which can be treated with recasting and/or subsequent surgery.[9]
- “Successful” nonoperative management often requires an Achilles tendon tenotomy and possibly an anterior tibial tendon transfer to the lateral cuneiform to achieve lasting correction.[1,9]

SURGICAL

- Early operative intervention, with the increased cellularity and collagen response of connective tissues early in life, has been shown to lead to scarring, muscle weakness, pain, recurrence of deformity, damage to neurovascular structures, and overcorrection, and thus should be avoided.[1,3]
- Successful nonoperative treatments have greatly reduced the need for extensive surgical releases and even reduced the overall number of surgeries for clubfoot.[1,6]
- The current trend is toward starting all patients with non-operative management, and approach surgery in a more limited manner, with more selective releases and or tendon transfers as needed to supplement nonoperative management.[1]
- More extensive releases are still required for severe deformity, syndromic clubfoot, neurogenic clubfoot, and refractory recurrent cases.[1,6]
- These can involve release or lengthening of some or all of the soft tissue structures involved, including the Achilles tendon, flexor digitorum longus tendon, flexor hallucis longus tendon, posterior tibal tendon, abductor hallucis, plantar fascia, subtalar and calcaneocuboid capsules, talonavicular capsule, superficial deltoid ligament, talonavicular (“spring”) ligament, and the posterior tibiotalar joint capsule.[3]
- Most surgeons prefer to wait until the child is at least 9 months of age to address any of these deformities surgically.[3]

- Many of these extensive releases require reoperation for late loss of correction, or for complications such as wound problems, resultant bony deformity, or overcorrection.
- Some of these late deformities or complications may require osteotomy and bone realignment if the deformity is rigid and cannot be solved by soft tissue releases.
- Very late presentation of severe clubfoot when the child is much older (**Figures 86-5** and **86-6**) may require more heroic efforts, such as treatment with external fixator spatial frames. This presentation is very uncommon in developed countries, however.

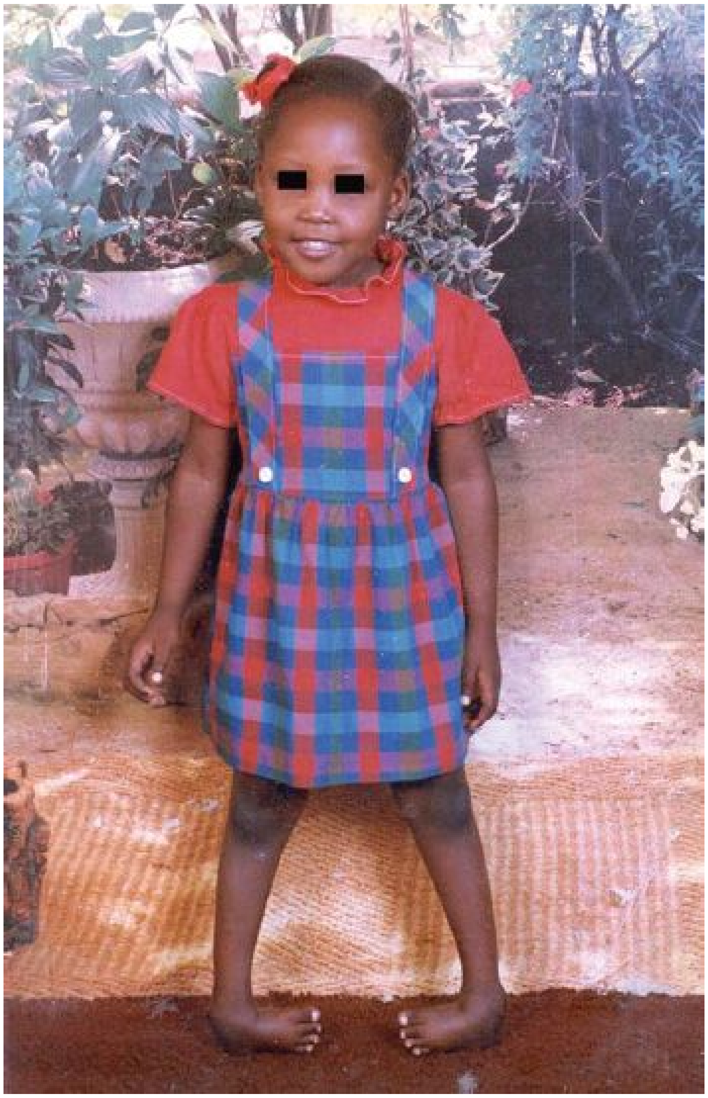

FIGURE 86-5 A young girl with untreated bilateral clubfeet. (*Used with permission from Kaye Wilkins, MD.*)

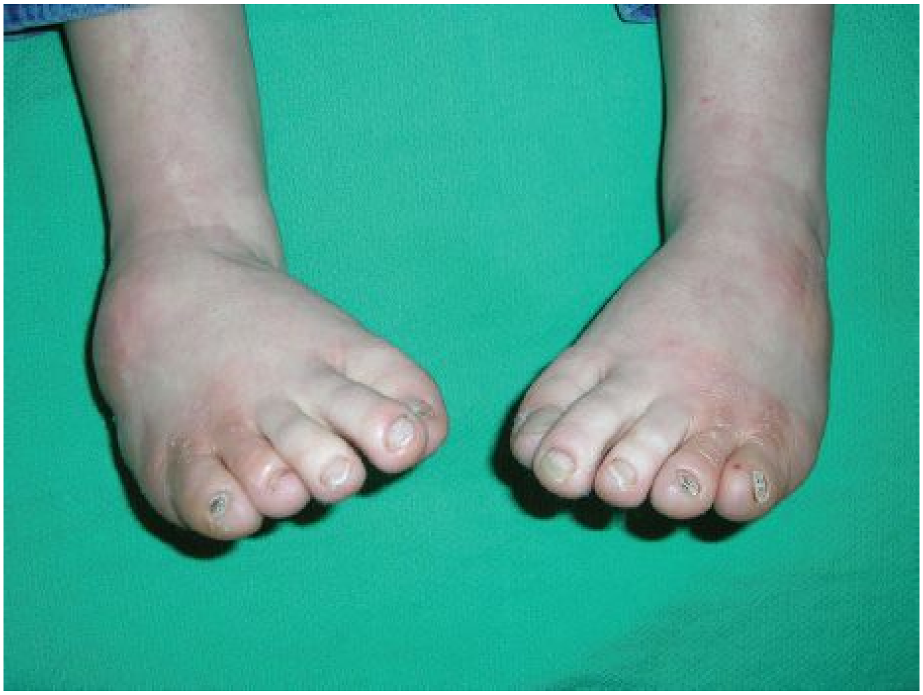

FIGURE 86-6 Late presentation of untreated clubfoot. Note the classic development of calluses along the lateral and dorsal aspect of the foot, reflecting the abnormal areas of the foot the child is forced to walk on due to the deformity. (*Used with permission from Richard Usatine, MD.*)

- If all other treatments are unsuccessful, eventual joint fusion such as a triple arthrodesis can be performed.

PREVENTION AND SCREENING

- Parents and pediatricians should screen for clubfoot immediately after childbirth and at the first well-child visit.
- Referral to a Pediatric Orthopaedic Surgeon should be made immediately for any suspected clubfoot to allow early treatment and ensure the best possible outcome.

PROGNOSIS

- With early serial Ponseti casting, compliance with bracing, combined with selective adjunctive surgical procedures (Achilles tenotomy or anterior tibial tendon transfer) in some patients, excellent results have been achieved, reported at 93 to 100 percent.[9]
- Long-term studies have also shown excellent long-term functional results.[2]

FOLLOW-UP

- Children with clubfeet need to be followed very closely while being treated for their serial cast changes, and then for maintenance of correction once they are in the bracing phase.
- These children should continue to be followed periodically into mid-late childhood to monitor for late recurrence.

PATIENT EDUCATION

- Clubfoot has excellent success with nonoperative management and limited surgical intervention as needed.
- It is important to see a pediatrician and have the child seen by an orthopaedic surgeon within the first few weeks of life to start treatment. Late treatment is not as successful.
- Even with successful treatment, brace compliance is critical to long-term success.

87 DEVELOPMENTAL DYSPLASIA OF THE HIP

Rachel M. Randall
R. Tracy Ballock, MD

PATIENT STORY

A three day old female was brought to her pediatrician for a routine newborn evaluation. Prenatally, the infant was noted by ultrasound to be in the frank breech position, and was born via Cesarean section at 40 weeks of gestation. She is the mother’s first child. At this visit, the pediatrician noted that the infant’s left thigh segment was shorter than the right, and a palpable “clunk” was felt when pressure was applied to lift the greater trochanter and the left hip was abducted (**Figure 87-1**). The pediatrician ordered an ultrasound of the left hip joint, which revealed a dislocated femoral head. The patient was subsequently placed in a Pavlik harness. After three months, the hip was completely reduced and stable on exam, and the harness was discontinued. Her standing x-ray of the hips at one year was normal.

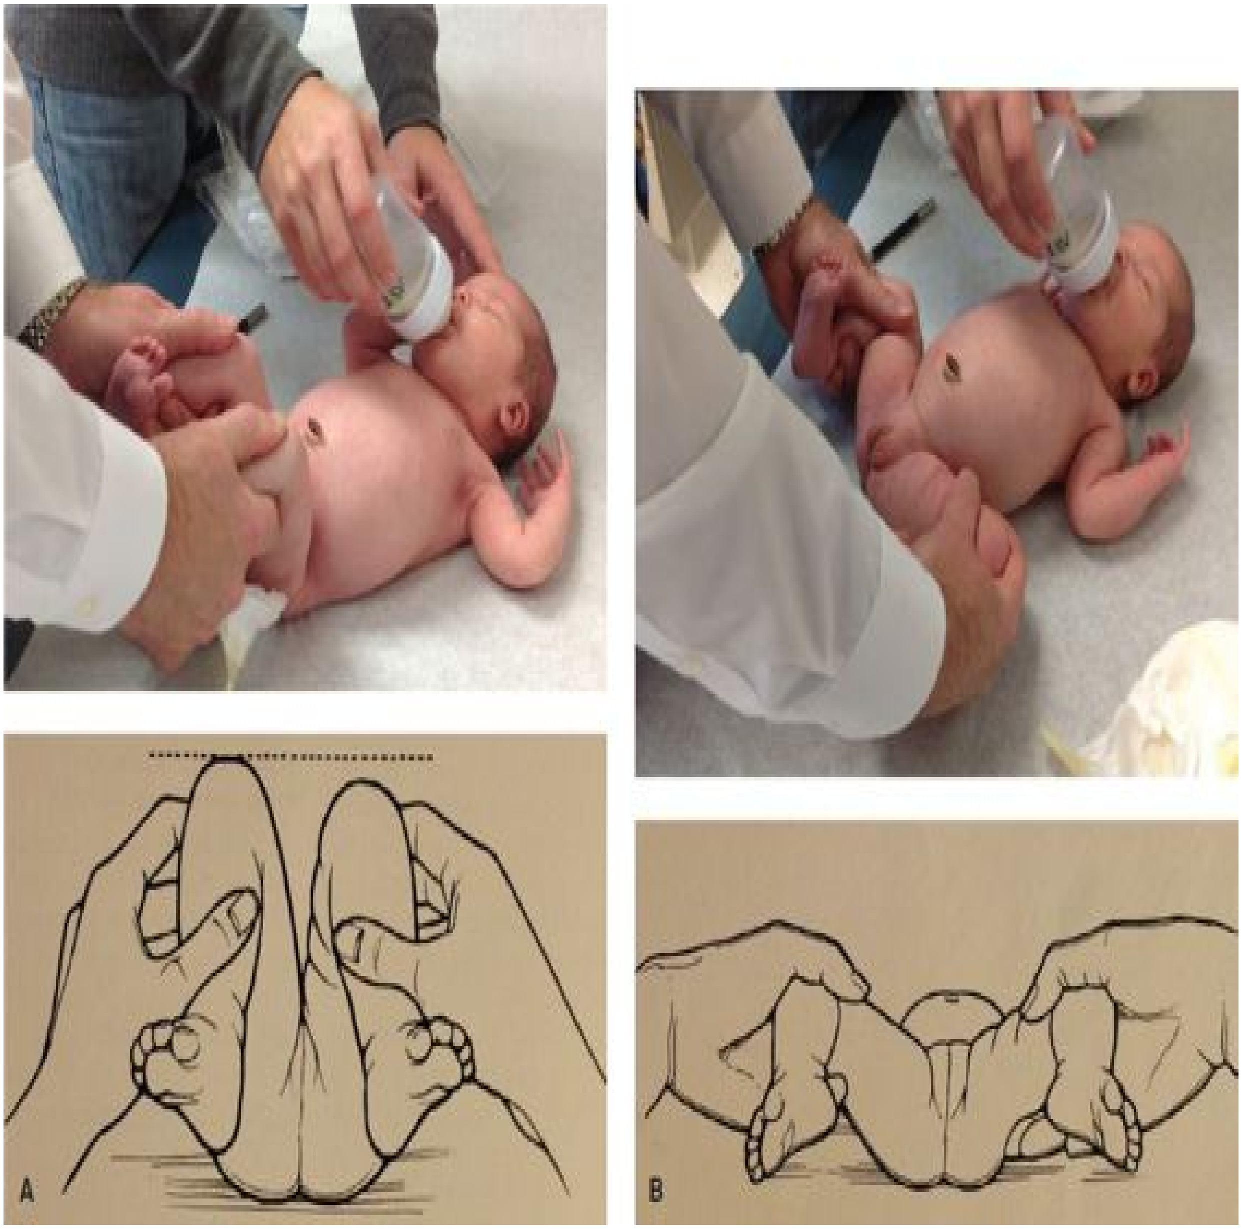

FIGURE 87-1 Physical exam maneuvers for assessment of Developmental Dysplasia of the Hip (DDH). Note that the infant must be calm and relaxed for accurate assessment of these subtle findings. (**A**) Barlow sign (Photo). Gentle posterior pressure over the knee, with hips and knees flexed to 90 degrees, causes subluxation of the femoral head. Galeazzi sign (Sketch). With the hips and knees flexed to 90 degrees, discrepancy of the length of the thigh segment can be evaluated. In DDH, the thigh segment on that side

may appear shorter than the unaffected side. (**B**) Ortolani maneuver. Lifting the greater trochanter upwards with the hip maximally abducted causes the dislocated femoral head to reduce back into the acetabulum. (*Sketches Adapted and Reprinted with permission from Ballock and Richards, Contemporary Pediatrics 1997;14:108. Contemporary Pediatrics is a copyrighted publication of Advanstar Communications Inc. All rights reserved*.)

INTRODUCTION

Developmental Dysplasia of the Hip (DDH) is a disorder of acetabular development leading to a shallow acetabulum (acetabular dysplasia), which may or may not be associated with an unstable or dislocated hip joint.[1]

SYNONYMS

Hip dysplasia, Congenitally dislocated hip.

EPIDEMIOLOGY

- Most common in females, especially those of Native American descent.
- Incidence of DDH is approximately 1 in 100 live births, but only 1 in 1000 requires treatment.
- Can be discovered in neonates, infancy, or later in childhood.

ETIOLOGY AND PATHOPHYSIOLOGY

- Intrauterine positioning is crucial for proper development of the acetabulum.
- Intrauterine crowding can result in excessive hip flexion and adduction, which leads to acetabular flattening, stretching of the labrum, and ultimately hip joint instability.
- Frank breech positioning and oligohydramnios are the most common causes of intrauterine crowding.

RISK FACTORS

- Breech positioning (especially frank breech, 20 percent risk).
- Positive family history of DDH.
- First born.
- Female (6:1).
- Disorders associated with ligamentous laxity (i.e., Ehlers-Danlos).
- Oligohydramnios.
- Postnatal positioning with hips held in extension.
- Infrequently associated with torticollis and metatarsus adductus.

DIAGNOSIS

CLINICAL FEATURES

- Galeazzi sign—Shortened thigh segment with the hip and knee flexed to 90 degrees compared to the unaffected side (**Figure 87-1A**). One may also see asymmetric skin folds, with excessive folds over the affected side due to superior/posterior dislocation of the femur.

- Barlow sign—Palpable “clunk” with hip adduction and posterior pressure applied on the femur, with the hip and knee flexed to 90 degrees (**Figure 87-1A**). Indicates subluxation of the femoral head out of the acetabulum.
- Ortolani sign—Palpable “clunk” with abduction and anterior pressure applied over the greater trochanter (**Figure 87-1B**). Indicates reduction of a dislocated femoral head.
- In children older than 3 months with DDH, the femur becomes fixed in a dislocated position, and the Barlow and Ortolani tests are no longer helpful. Instead, the prominent physical exam finding is limited abduction on the affected side due to tightening of the adductor muscles (**Figure 87-2**). However, if the DDH is bilateral, the limited abduction is difficult to appreciate. If the child is of walking age, he or she may have a waddling gait, with the unaffected side of the pelvis “dropping” as the child bears weight on the affected side, as well as lumbar hyperlordosis. This is due to weakened abductor muscles on the affected hip.

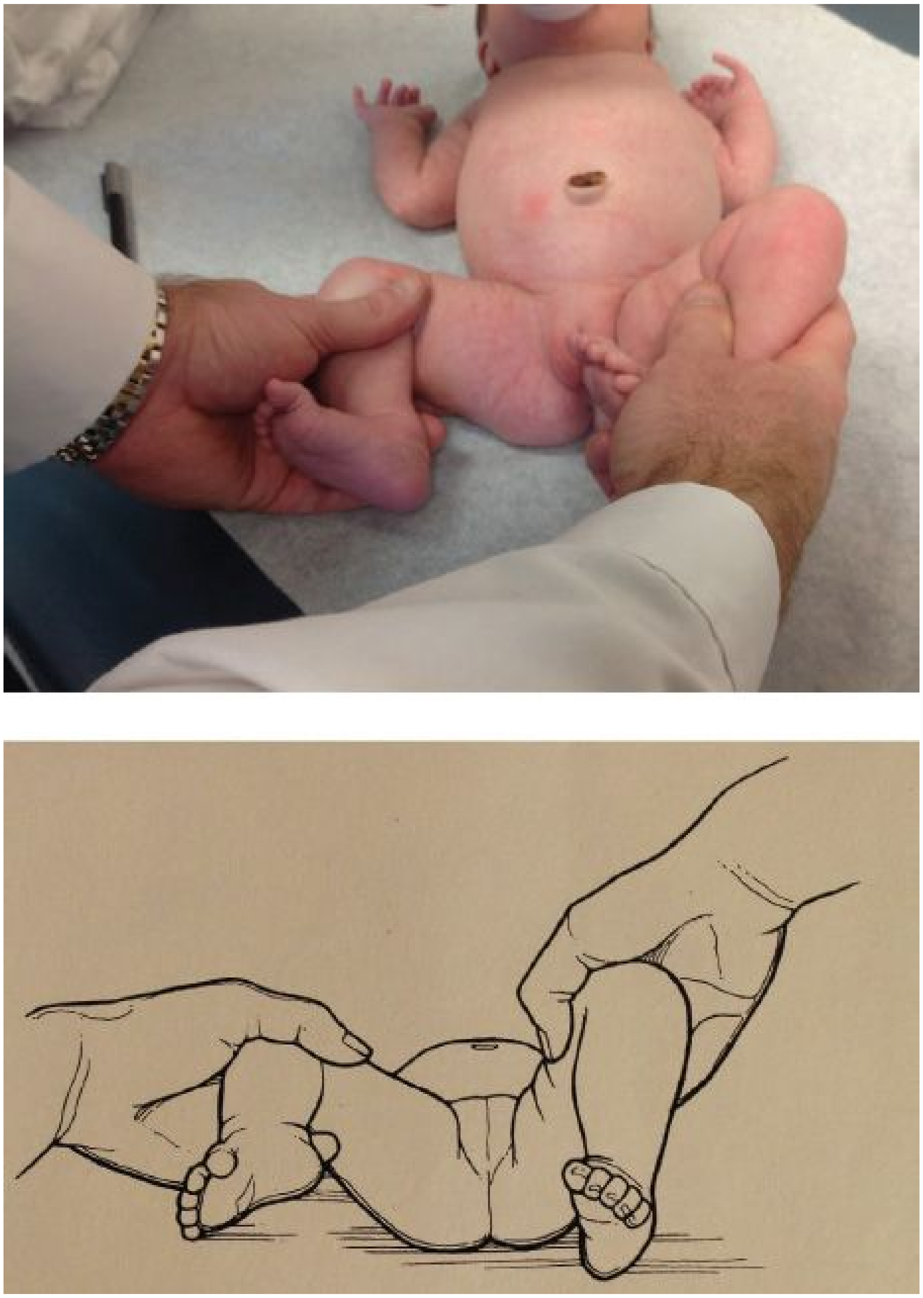

FIGURE 87-2 Limited abduction of the affected left hip. Tight adductor and iliopsoas muscles are often associated with DDH in children older than 3 months, where the femur is in a fixed position out of socket. (*Sketches Adapted and Reprinted with permission from Ballock and Richards, Contemporary Pediatrics 1997;14:108. Contemporary Pediatrics is a copyrighted publication of Advanstar Communications Inc. All rights reserved*.)

DISTRIBUTION

The left hip is disproportionately affected (67 percent of DDH cases) due to the positioning of the left femur against the spinal column in the most common fetal position (left occiput anterior).[1] However, DDH may affect either side or it may be bilateral.

LABORATORY TESTING

- Not usually indicated unless a septic dislocation is suspected.

IMAGING

All infants with breech positioning, a positive family history of DDH, or oligohydramnios should have a screening ultrasound at 6 weeks of age or an AP radiograph at 3 months of age.[2]

- Ultrasound—Best imaging modality before 3 months of age due to the cartilaginous nature of the immature hip joint. Used for evaluation of the degree of hip subluxation or dislocation.
- X-ray—Typically used for diagnosis in children 3 months of age or older at initial presentation. Does not show the anatomic detail or soft tissue structures that ultrasound offers, but can be interpreted using several helpful lines and angles (**Figure 87-3**). Hilgenreiner’s line (orange), Perkin’s line (red), and Shenton’s line (green) and Acetabular index (blue line and angle).

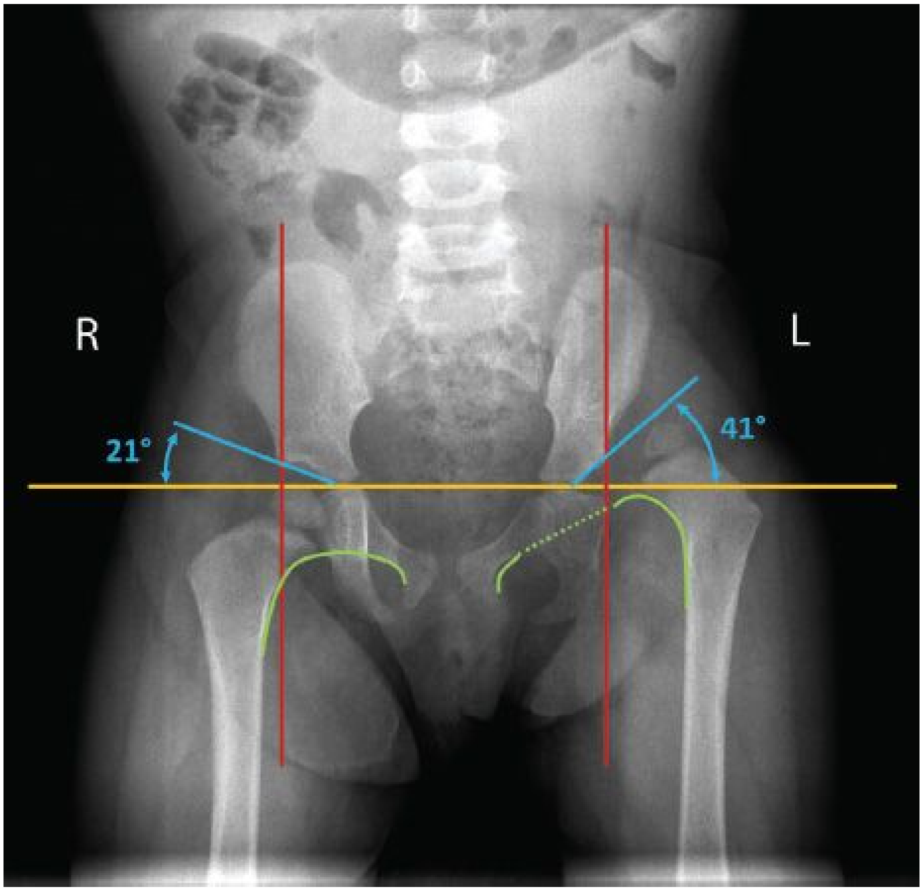

FIGURE 87-3 X-ray of a pelvis with a normal R hip and DDH of the left hip. Hilgenreiner’s line (orange), Perkin’s line (red), and Shenton’s line (green) are shown bilaterally. Note that Shenton’s line appears broken on the DDH side. The Acetabular index (blue line and angle) is normal if *less* than 25 to 27 degrees, and decreases with age as the acetabular depth increases. Note how the DDH side has an Acetabular index of 41 degrees. (*Used with permission from R. Tracy Ballock, MD.*)

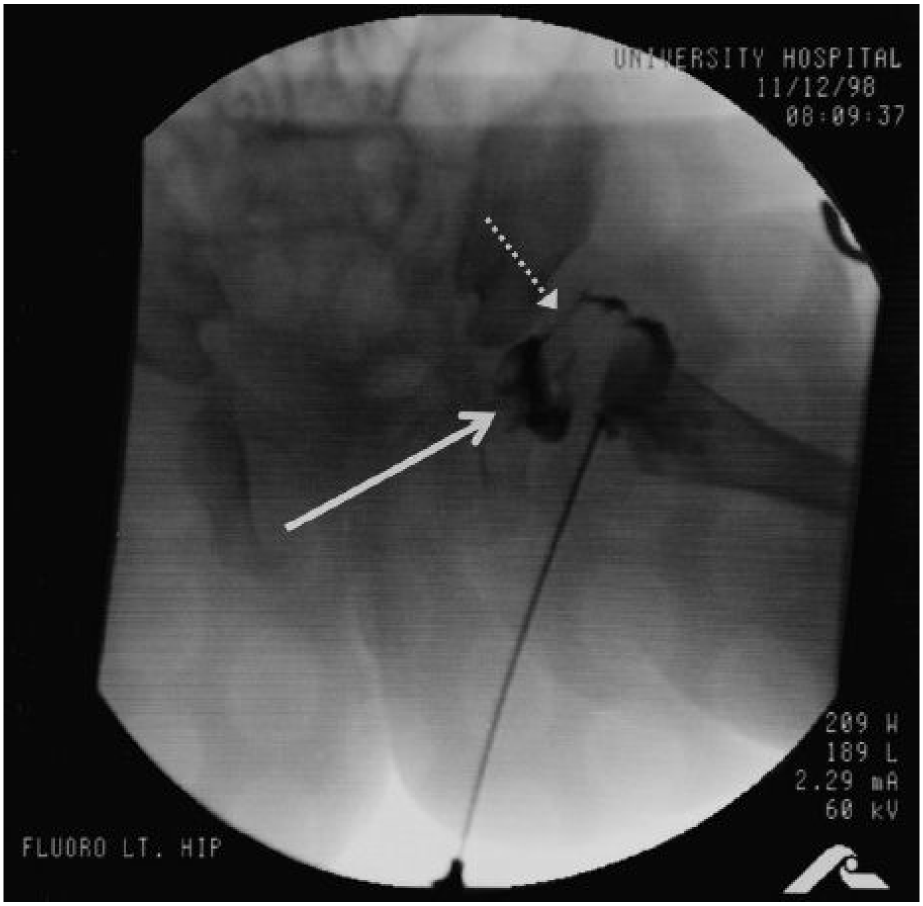
- Arthrogram—Radio-opaque dye injected directly into the hip joint. Useful for visualizing the cartilaginous femoral head and its relationship to the acetabulum.
    - Medial pooling of dye indicates an abnormal space where the femoral head is normally located (**Figure 87-4**).



UNIVERSITY HOSPITAL
11/12/98
08:09:37
209 W
189 L
2.29 mA
60 kV
FLUORO LT. HIP

FIGURE 87-4 Arthrogram of DDH hip. Medial dye pooling, commonly seen in DDH, indicates subluxation of the femoral head (solid arrow). Blunting of the labrum is also seen in this arthrogram (broken arrow). (*Used with permission from R. Tracy Ballock, MD.*)

  - Shape of the capsule can be distorted by abnormal iliopsoas compression of the capsule (hourglass sign), or an inverted labrum from femoral head subluxation (rose thorn sign).

DIFFERENTIAL DIAGNOSIS

- Septic hip—Usually associated with marked irritability and systemic signs of illness.
- Coxa vara—Varus angulation of the proximal femur.

- Teratologic dislocation of the hip—Associated with neuromuscular conditions, such as arthrogryposis and spina bifida.

MANAGEMENT

NONPHARMACOLOGIC

- Abduction orthosis (such as the Pavlik harness) is most commonly used modality for young infants (**Figure 87-5**).

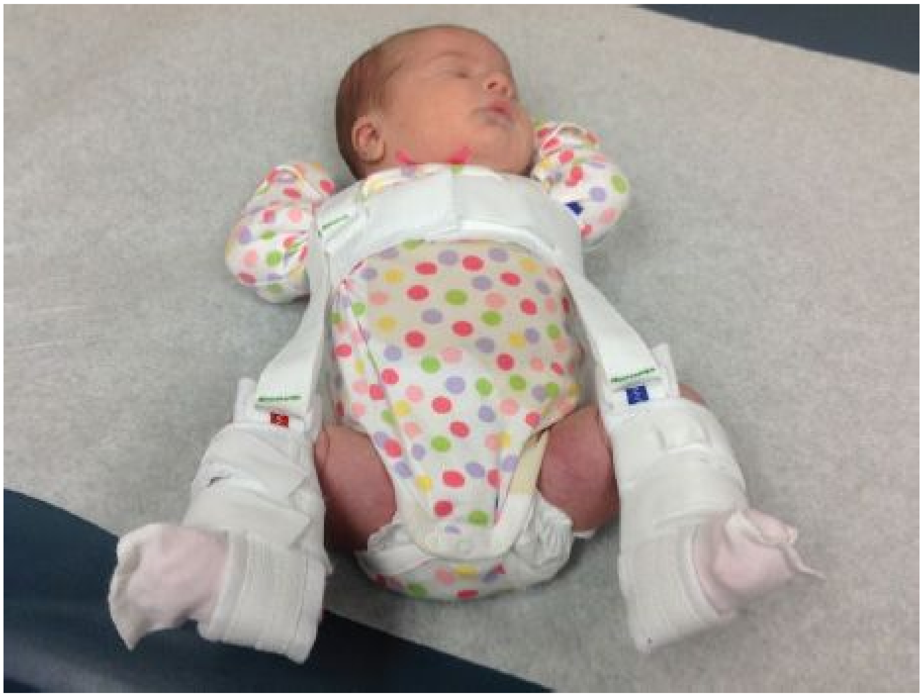


FIGURE 87-5 Pavlik harness for treatment of DDH in infants. The hips are held in 100-120 degrees of flexion and abducted to promote hip stability. (*Used with permission from R. Tracy Ballock, MD.*)

  - Typically worn for the following duration: (3 months + age at diagnosis).
  - Much less effective for infants older than 6 months.
- Observation for stable hips with isolated acetabular dysplasia.

COMPLIMENTARY/ALTERNATIVE THERAPY

- Double- or triple-diapering is not effective as a treatment modality for DDH.[2]

SURGERY

- Closed reduction, adductor lengthening tenotomy, spica casting (4 to 6 months of age).
- Open reduction, capsulorrhaphy (>9 months of age).
- Acetabuloplasty (>18 months of age).
    - If triradiate cartilage open—Salter (**Figure 87-6**) or Pemberton osteotomy.

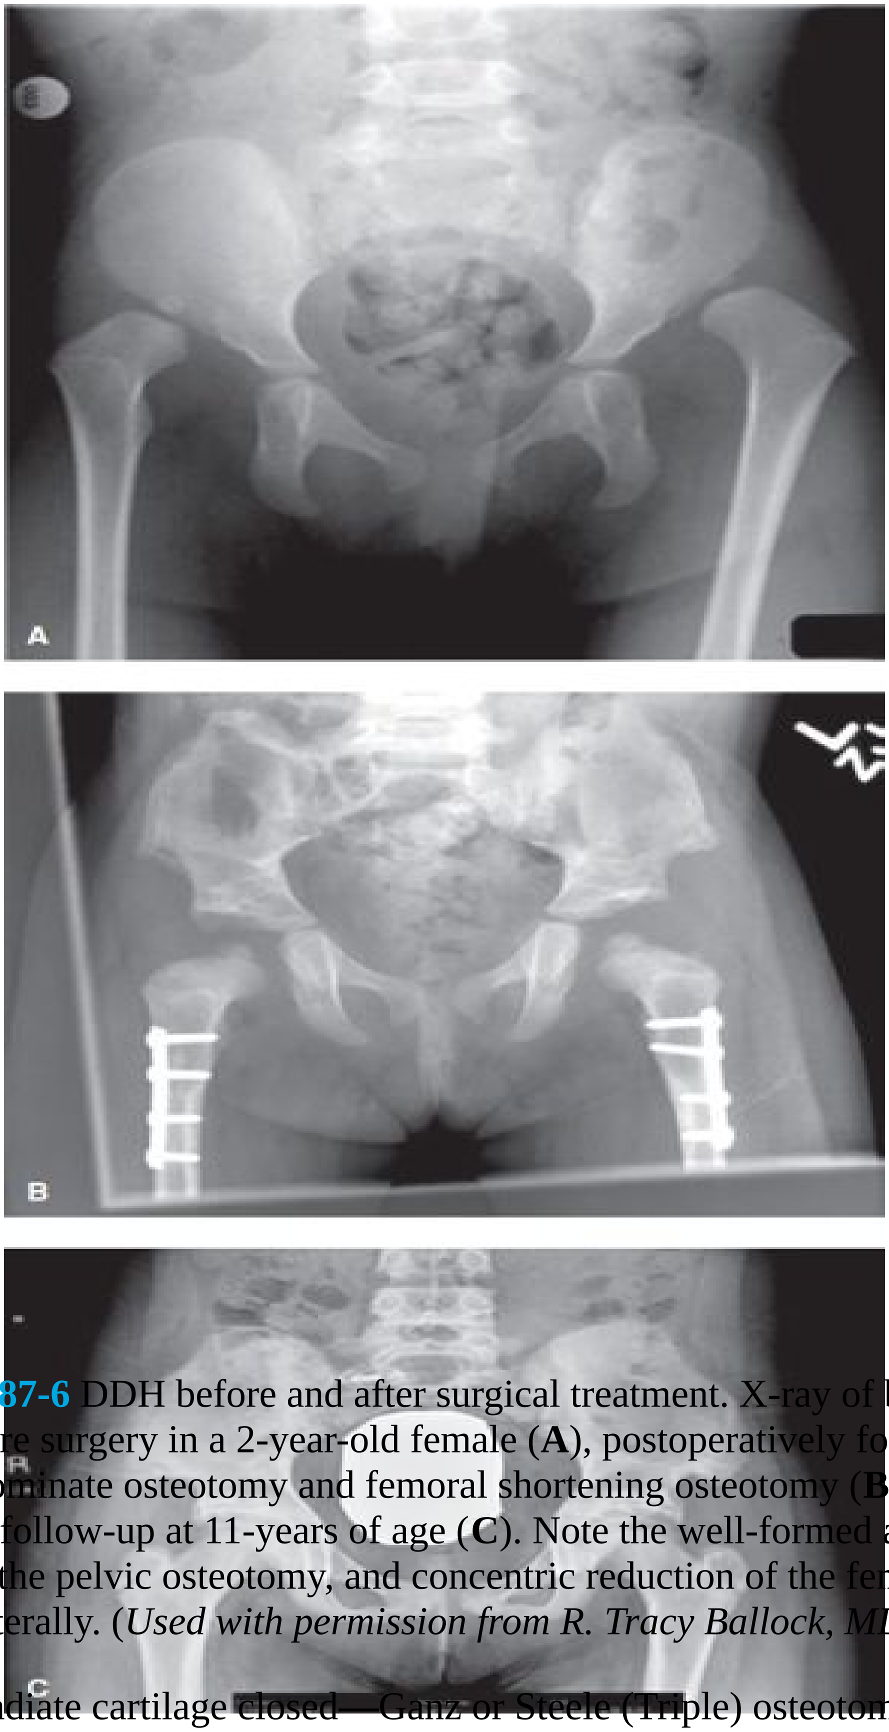

FIGURE 87-6 DDH before and after surgical treatment. X-ray of bilateral DDH before surgery in a 2-year-old female (**A**), postoperatively following Salter innominate osteotomy and femoral shortening osteotomy (**B**), and at long-term follow-up at 11-years of age (**C**). Note the well-formed acetabula following the pelvic osteotomy, and concentric reduction of the femoral heads bilaterally. (*Used with permission from R. Tracy Ballock, MD.*)

- If triradiate cartilage closed—Ganz or Steele (Triple) osteotomy.

  - Salvage procedures—Shelf acetabuloplasty, Chiari osteotomy.
- Femoral derotational osteotomy in older children to correct abnormal rotation, and shortening to allow for reduction of the hip joint without excessive stress (**Figure 87-6**).

REFERRAL

Referral to a pediatric orthopedic surgeon is appropriate when clinical signs of DDH are evident on physical examination.

SCREENING

- Every newborn should be screened by physical examination, and subsequently at every well-baby visit until the age of 12 months.[2]
- Children with risk factors including breech presentation in utero or positive family history should be screened with either an ultrasound at 6 weeks or radiograph at 3 months to detect silent acetabular dysplasia.[2]

PROGNOSIS

- Conservative treatment produces excellent results if DDH is diagnosed early.
- Pavlik harness success rate is 95 percent if instituted within the first 6 weeks of life.[1]

FOLLOW-UP

- Serial physical examination for children with risk factors for DDH.

- Pelvic radiographs every 3 to 6 months until age 3 for children with acetabular dysplasia, then every year until age 5, and every 3 years until skeletal maturity for clinical DDH.

88 LEGG-CALVÉ-PERTHES

Keith Bachmann, MD
Ryan C. Goodwin, MD

PATIENT STORY

A 7-year-old boy presents with his parents with a month-long history of "running funny" while playing baseball this season. He does not complain of any pain and has not had any problems like this in the past. The patient and family deny any trauma, fevers, or chills. Radiograph of his pelvis is obtained and shows the early stages of Legg-Calve-Perthes disease (**Figure 88-1**).

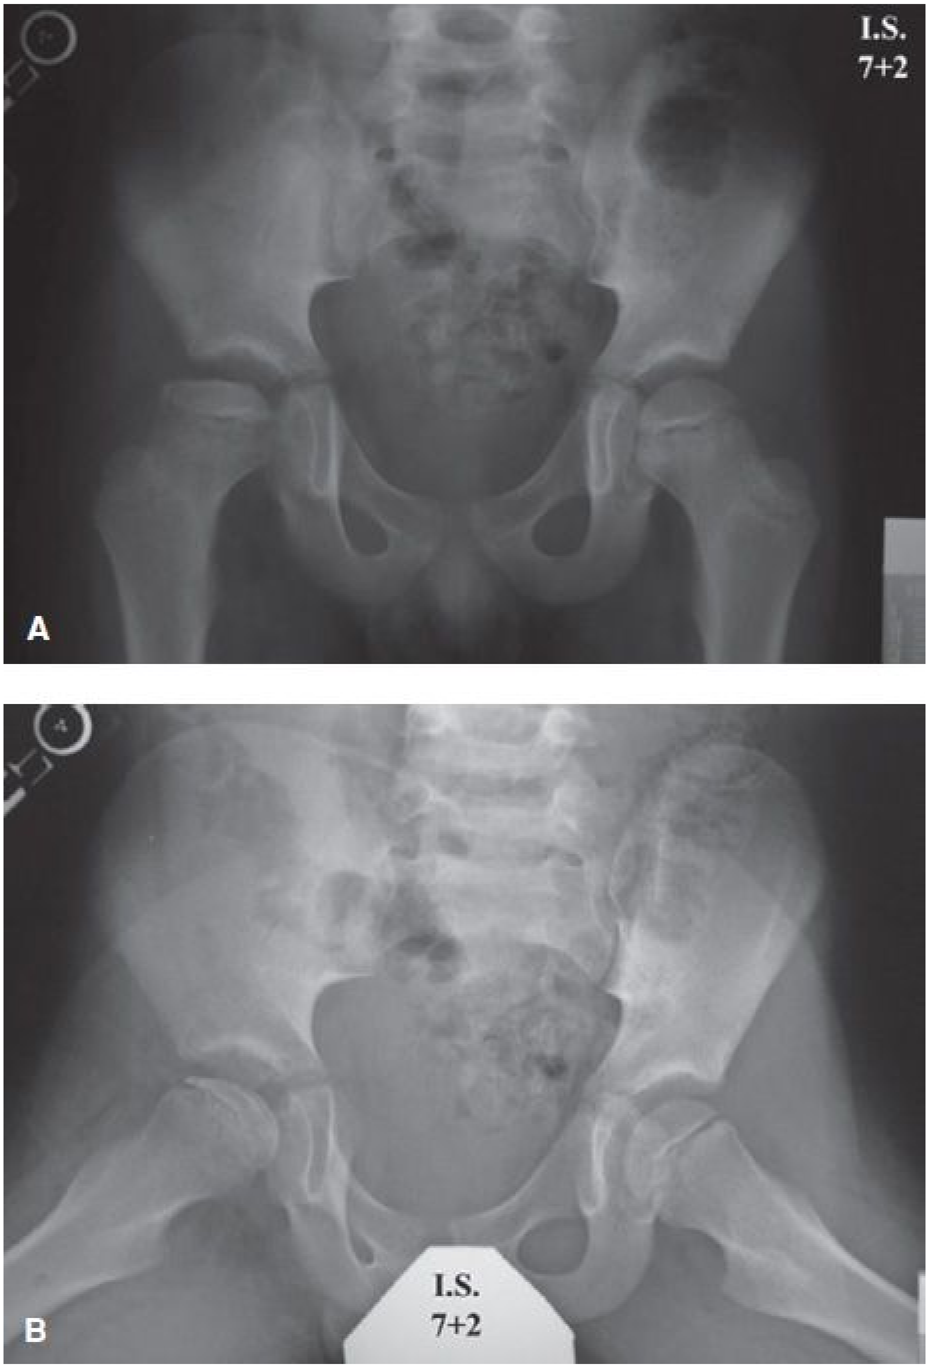

FIGURE 88-1 Initial stage of Perthes disease showing femoral head flattening of the right femoral head in a 7-year-old boy on AP (**A**) and Frog-leg lateral (**B**) radiographs of the pelvis. (*Used with permission from Ryan Goodwin, MD.*)

INTRODUCTION

Legg-Calvé-Perthes (LCP) disease is a juvenile form of idiopathic osteonecrosis of the femoral head. First described in 1910 as an entity separate from tuberculosis by Legg, Calvé, and Perthes in separate accounts. It still carries unresolved controversy regarding the etiology, pathogenesis, and management.

SYNONYMS

Perthes disease.

EPIDEMIOLOGY

- Can affect a wide age range of children aged 2 to 14 years, but most common at 5 to 8 years of age.
- Male to female ratio 5:1.
- Bilateral in 10 to 15 percent of cases.[1]
- Incidence is 5.1 to 16.9 per 100,000.[2]

ETIOLOGY AND PATHOPHYSIOLOGY[2]

ETIOLOGY

- Probably multifactorial, exact cause still uncertain.

- Possible factors—Trauma, susceptible child, hereditary factors, coagulopathy, hyperactivity, passive smoking, or collagen abnormality.[3]
- Unlikely factors—Endocrinopathy, urban environment, or synovitis.[3]
- Disruption of blood supply to the femoral head and a pathologic repair process cause imbalance of bone resorption and formation.[1]
- Current research focusing on cause of the vascular disruption including a missense mutation in the type II collagen gene in familial cases, thrombophilia also being investigated as possible cause although there are cases of LCP disease without either of these abnormalities.[1]

PATHOPHYSIOLOGY[1]

- Disruption of blood supply affects articular cartilage, bony epiphysis, physis, and metaphysis.
- Cartilage:
    - Necrosis especially in the deep layer, cessation of enchondral ossification, separation from underlying bone followed by revascularization and new accessory ossification.
- Bony Epiphysis:
    - Necrosis of marrow space, compression fractures of trabeculae, fibrovascular granulation tissue invasion, or osteoclastic resorption.
- Physis:
    - Focal areas of growth cartilage columns extending below the endochondral ossification line mostly in the anterior aspect of the femoral head.
- Metaphysis:
    - Physeal cartilage columns as mentioned above, fibrocartilage, fat necrosis, vascular proliferation, and fibrosis all described.

DIAGNOSIS

CLINICAL FEATURES

- Mild pain in groin, anterior hip, or around greater trochanter, knee pain.
- Limp exacerbated by activity that improves with rest.
- Insidious onset but commonly with antecedent trauma.
- Hip irritability (increased pain with motion) due to synovitis.
- Possible Trendelenburg gait (leaning over affected hip).
- Trendelenburg sign—Unaffected side of pelvis drops when standing on affected hip alone and body sways to affected side.
- Possible hip motion limitations depending on stage of disease—Lose abduction and internal rotation first. If in fragmentation stage severe restrictions:
    - Possible limb length discrepancy.
    - Possible thigh and calf muscle atrophy.

LABORATORY TESTING

- No laboratory abnormalities in LCP itself, may reveal an alternate diagnosis through laboratory studies.

IMAGING

- Plain x-rays, AP Pelvis, AP and Lateral views of the hip sufficient.
- Imaging classically involves four radiographic stages: initial (**Figures 88-1**), fragmentation (**Figure 88-2**), reossification, and healed.

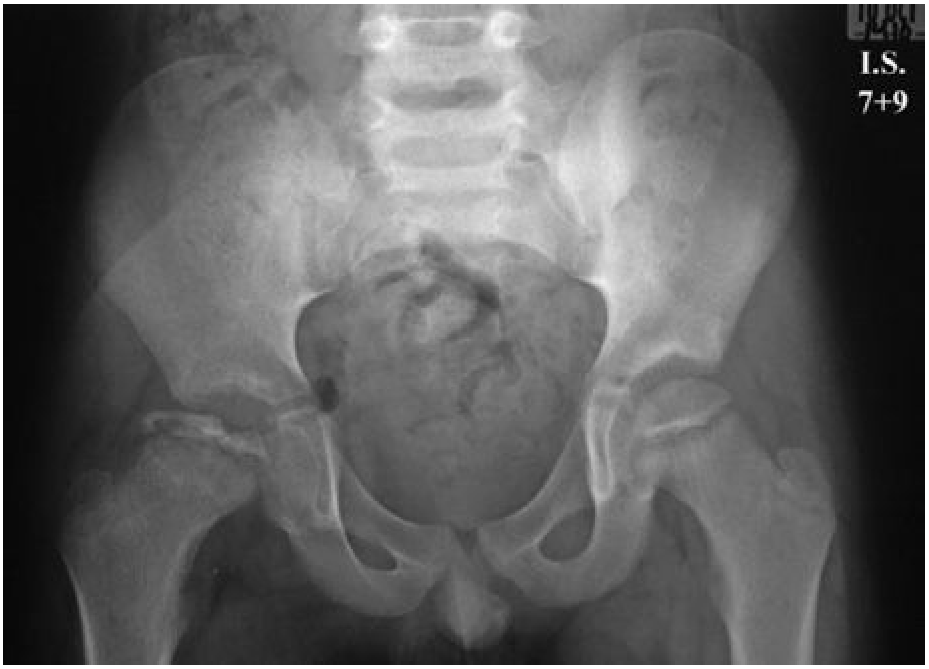

FIGURE 88-2 AP Pelvis radiograph of the same boy as in Figure 88-1 in the fragmentation stage, demonstrating some lateral subluxation of the right femoral head (*Used with permission from Ryan Goodwin, MD.*)

- During the initial and fragmentation stages may see flattening of the femoral head that may improve, worsen, or remain unchanged in the reossification stage.
- MRI can show changes in the perfusion of the femoral head potentially helping predict progression but this is still in the early stages of clinical use.
- X-rays in the healed phase may help classify the patient into the Stulberg classification:
  - Stulberg I: normal hip joint.
  - Stulberg II: Spherical head with enlargement, short neck, or steep acetabulum.
  - Stulberg III: Nonspherical head.
  - Stulberg IV: Flat head.
  - Stulberg V: Flat head with incongruent joint.

DIFFERENTIAL DIAGNOSIS[3,4]

Other causes of a limping child:

- Fracture (Toddler’s fracture, Stress Fracture, Physela Fracture)—Can usually be excluded based on history and radiographs.
- Osteomyelitis, Septic Arthritis, Diskitis—Usually accompanied by acute presentation, fever, and systemic symptoms.
- Slipped Capital Femoral Epiphysis—Usually apparent on plain radiographs.
- Arthritis (juvenile rheumatoid, Lyme disease)—Usually diagnosed clinically with the appearance of frank arthritis and evidence of inflammation on laboratory testing.
- Transient synovitis—Preceding upper respiratory tract infection is common.
- Osteochondritis dissecans (knee or ankle)—Knee and ankle pain more prominent.

Other causes of avascular necrosis include:

- Sickle cell disease and hemoglobinopathies—Secondary to vaso-occlusive disease. History of chronic disease usually apparent.
- Steroid use—History of prolonged steroid use usually apparent.
- Traumatic dislocation—History of trauma apparent.
- Iatrogenic—No clear pathogenetic mechanism.
- Epiphyseal Dysplasias including Multiple epiphyseal dysplasia, Spondyloepiphyseal dysplasia, mucopolysaccharidoses, or hypothyroidism—Chronic disorders apparent by history.

MANAGEMENT

NONPHARMACOLOGIC

- Rest followed by abduction exercises (physical therapy).
- Containment Bracing, most frequently studied is a Scottish Rite Orthosis (largely historical).
- Petrie casting (containment).

MEDICATIONS

- No medications to treat or reverse the disease process have been discovered.
- Symptomatic treatment with anti-inflammatory medications may be beneficial. SOR C
- Steroids can cause avascular necrosis and would not be recommended.

SURGERY[5]

- Options depend on age at presentation (see the following) and include:
  - Arthrogram.
  - Adductor tenotomy.
  - Petrie casting.
  - Femoral varus osteotomy.
  - Pelvic osteotomy (**Figures 88-3** and **88-4**).

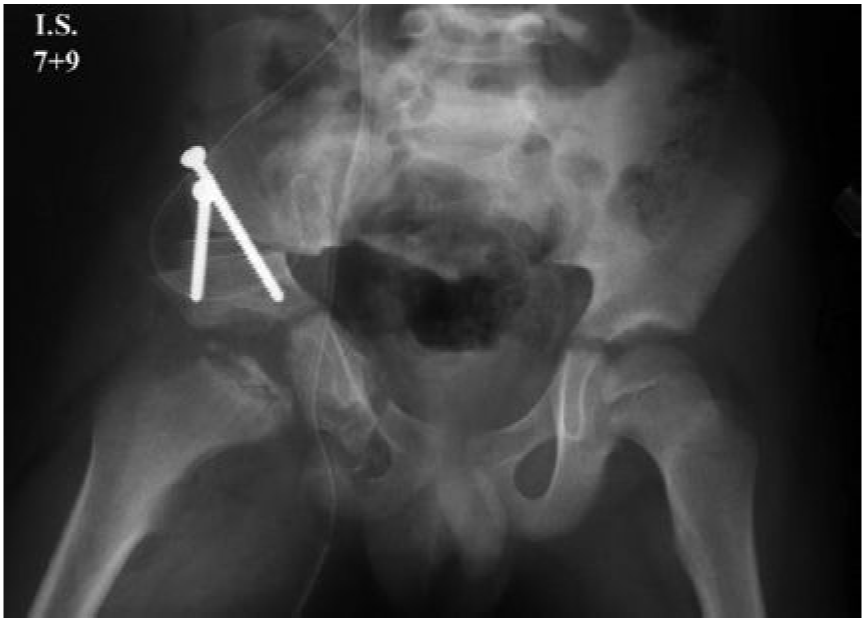

FIGURE 88-3 AP Pelvis radiograph of the same boy as in Figures 88-1 and 88-2 after undergoing a pelvic osteotomy to obtain better coverage and contain the right femoral head. (*Used with permission from Ryan Goodwin, MD.*)

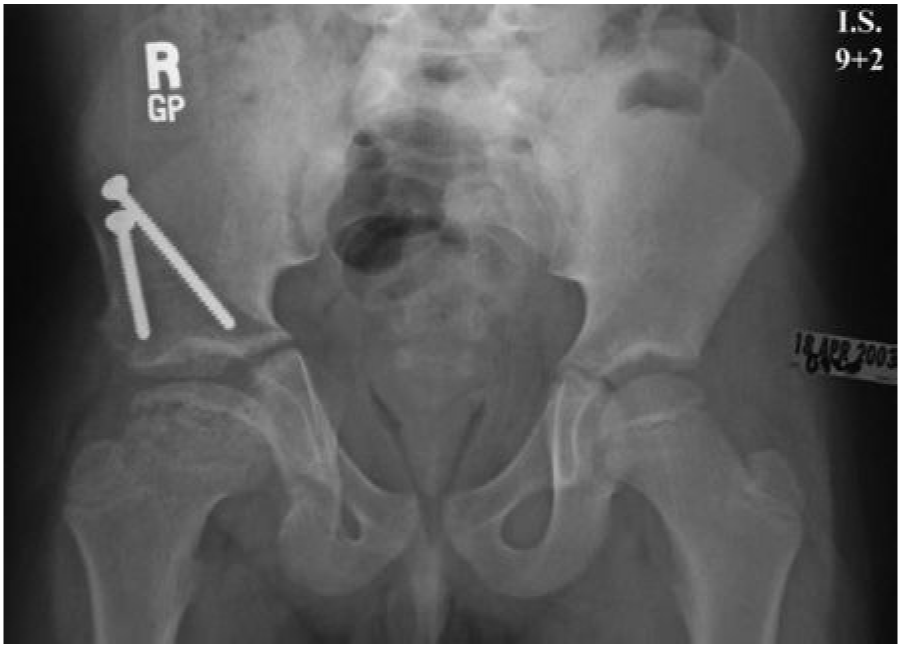

FIGURE 88-4 AP Pelvis radiograph of the same patient as in Figures 88-1 to 88-3 after healing with a final Stulberg II result. (*Used with permission from Ryan Goodwin, MD.*)

    - Combined procedure.
- Management depends on age at presentation.
    - Less than 6 years of age at onset.
        - Most (80%) achieve good results (Stulberg I/II hips) at maturity with physiotherapy or bracing.
        - This will still leave one to two out of every five patients with a poor outcome, but currently no ability to predict those who will have a poor outcome.
    - Age at onset between 6 and 8 years.
        - Results are mixed in current studies, one showing a significant difference in outcomes with better results obtained with surgical treatment[6] while another showed no difference.[7]
    - Age at onset >8 years.
        - Results in follow-up studies favors surgical management although even with this treatment results are still modest with 2/3 achieving Stulberg I/II hips. SOR C
- Long term follow-up from Iowa with mean 47.7 years follow up showed only 40 percent of patients with LCP maintained a good level of function, 40 percent underwent total hip arthroplasty (**Figures 88-5** and **88-6**), 10 percent had disabling pain, and 10 percent had poor function.[8]

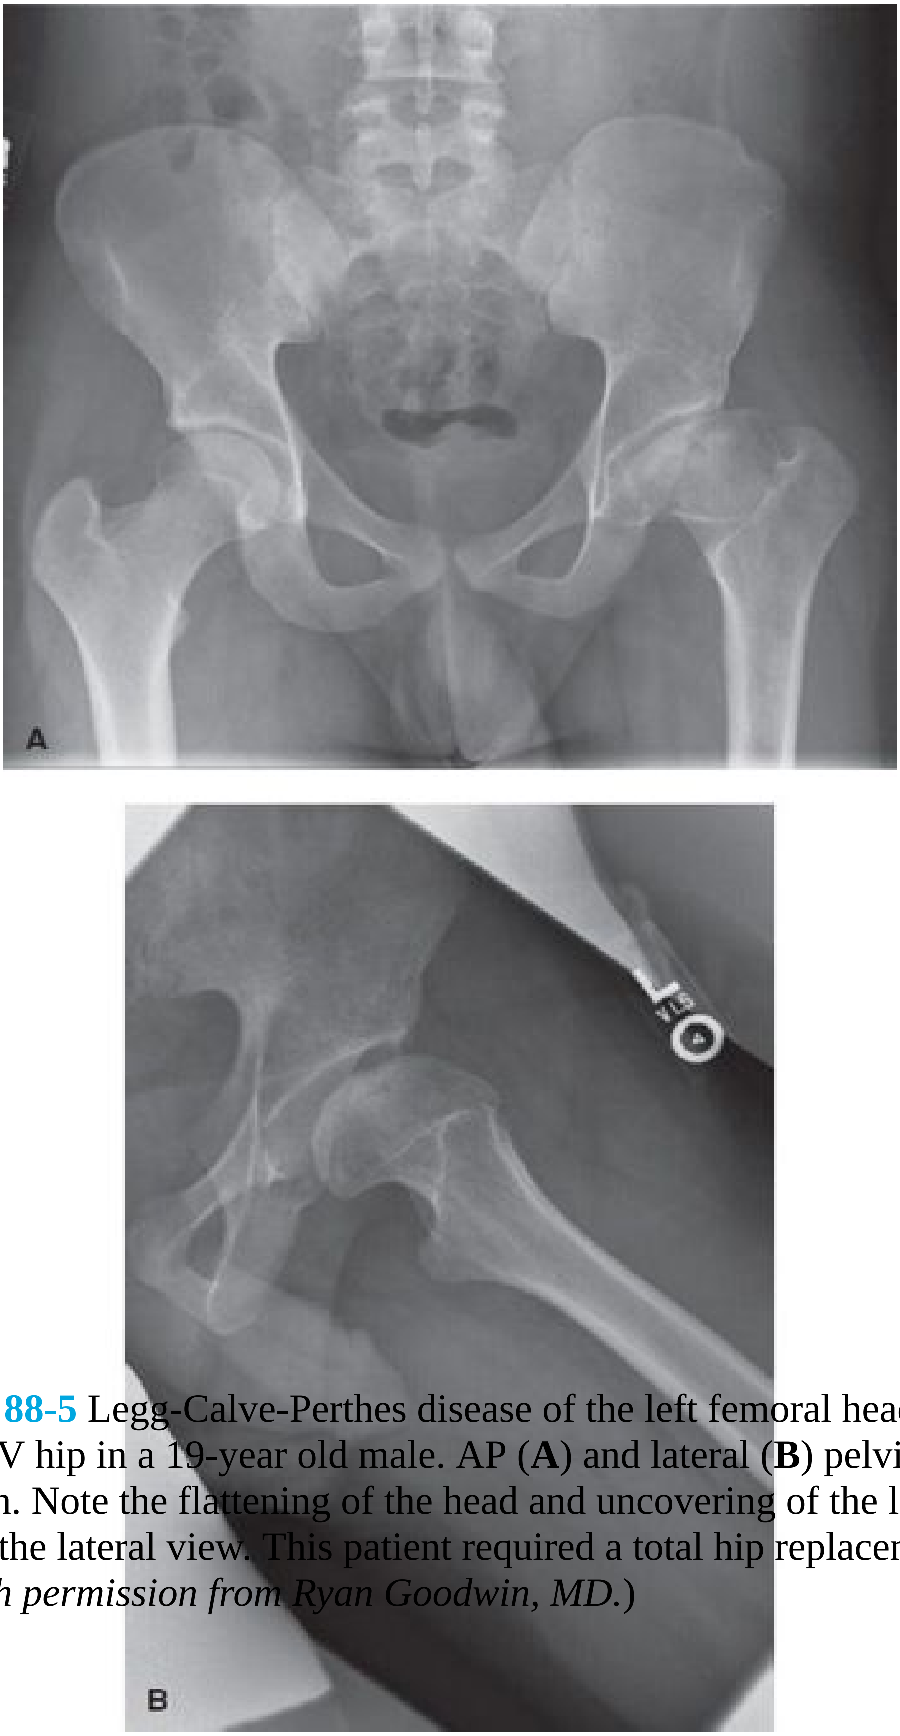

FIGURE 88-5 Legg-Calve-Perthes disease of the left femoral head with a Stulberg IV hip in a 19-year old male. AP (**A**) and lateral (**B**) pelvis radiograph. Note the flattening of the head and uncovering of the lateral aspect on the lateral view. This patient required a total hip replacement. (*Used with permission from Ryan Goodwin, MD.*)

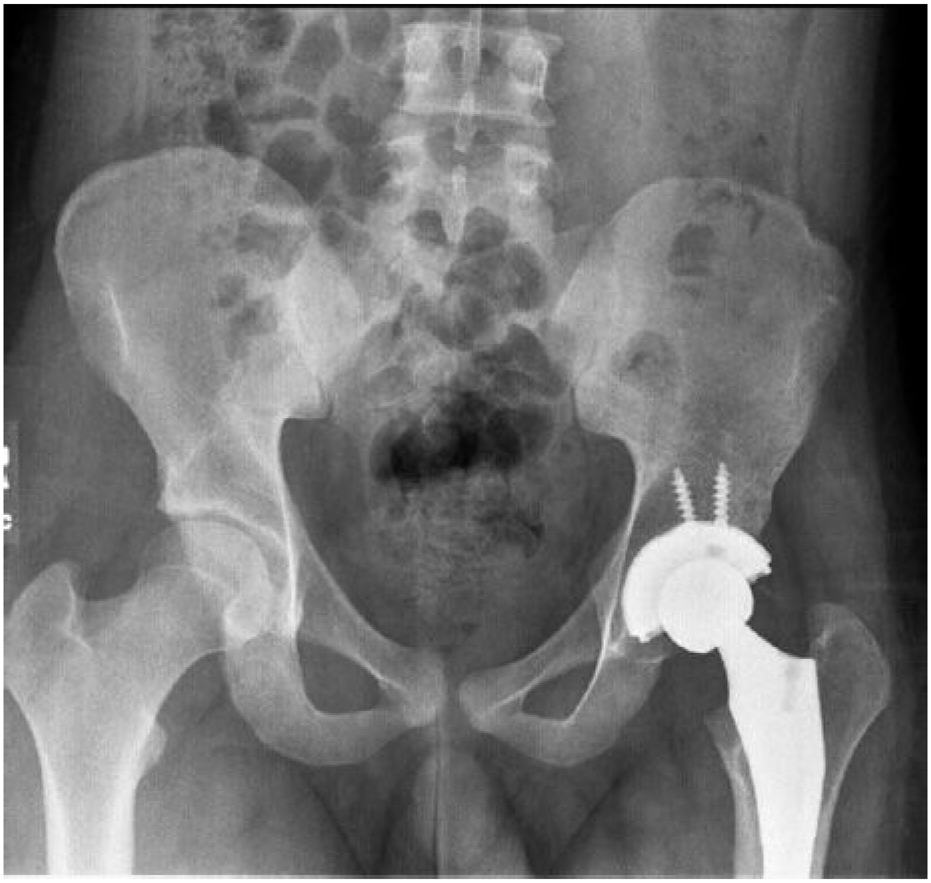

FIGURE 88-6 AP Pelvis radiograph of the patient from **Figure 88-5** after a total hip arthroplasty. (*Used with permission from Ryan Goodwin, MD.*)

REFERRAL

- A Pediatric orthopedic surgeon should be involved in the care of children with LCP to discuss options and institute the preceding therapies.

PREVENTION AND SCREENING

- A high degree of suspicion should be kept in relatives of patients with known LCP disease presenting with a typical story, but there is no routine screening recommended at this time, even in relatives of those with known disease.

FOLLOW-UP

- Should be with a pediatric orthopedic surgeon.
- The radiographic stage at presentation as well as age at presentation will determine treatment and further follow-up.

PATIENT EDUCATION

- Parents should be educated that LCP disease is an evolving clinical entity with multivariable etiology. It is not life-threatening and usually resolves without surgery.

89 SLIPPED CAPITAL FEMORAL EPIPHYSIS (SCFE)

Joel Kolmodin, MD
Paul M. Saluan, MD

PATIENT STORY

A 10-year-old male presents to your office with a 1-month history of left groin pain and intermittent left medial thigh pain as well. His symptoms are typically worse with activity, and his parents have noted that he limps. His parents relate that he has had a similar problems in the past. An x-ray of the left hip shows a slipped capital femoral epiphysis (**Figures 89-1** and **89-2**). The patient is made non-weight bearing, he is immediately admitted to the hospital and Pediatric Orthopedics is consulted for surgical management.

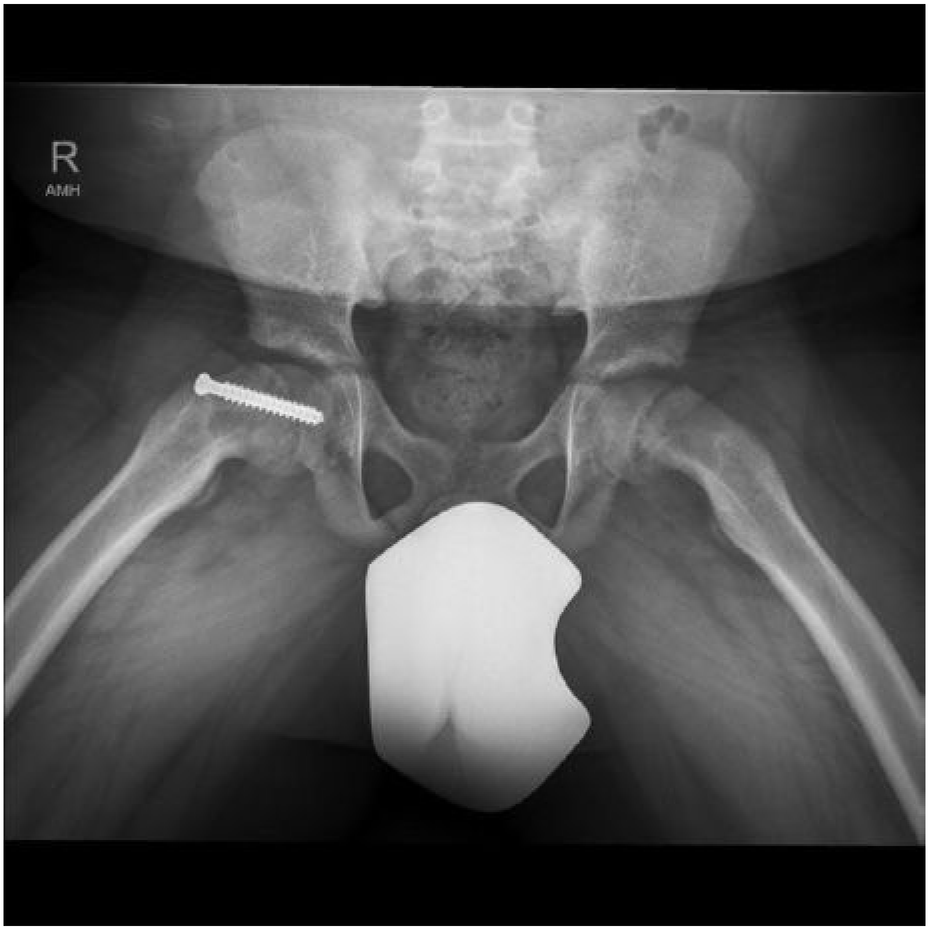

FIGURE 89-1 New slipped capital femoral epiphysis of the left hip in a 10-year-old boy on frog-leg view. Note that the slipped capital femoral epiphysis of the right hip was fixed surgically 18 months prior. (*Used with permission from Thomas Kuivila, MD.*)

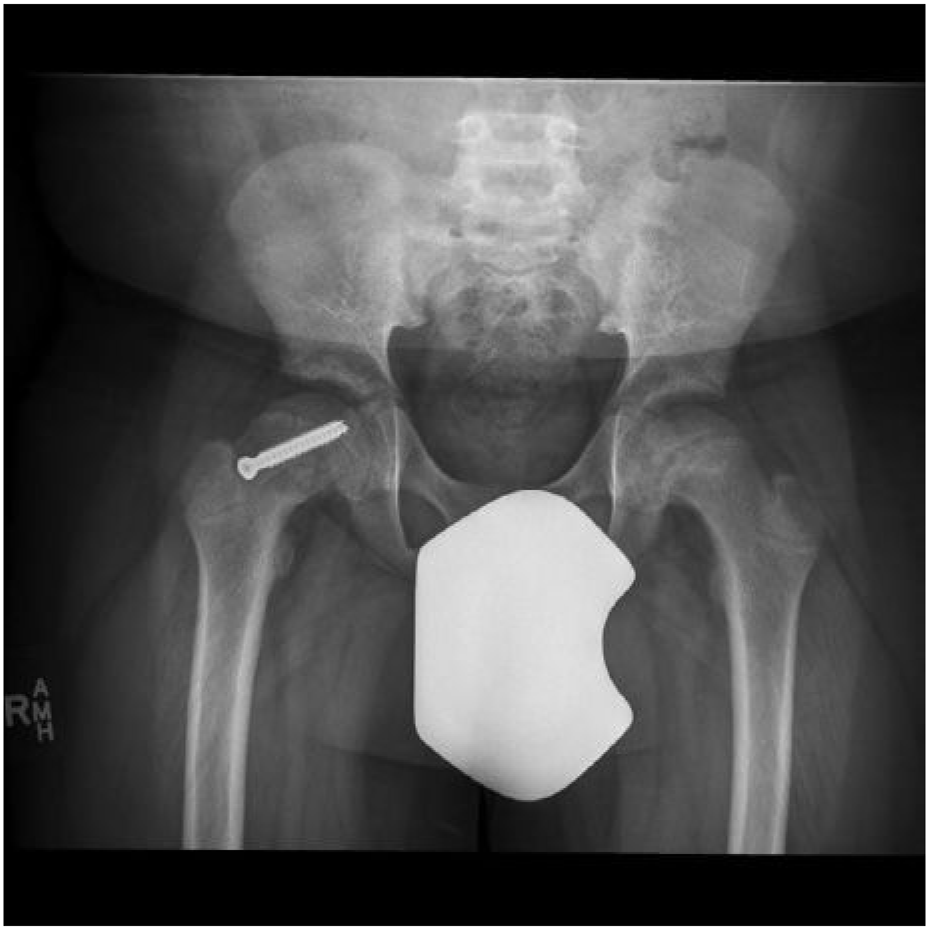

FIGURE 89-2 New slipped capital femoral epiphysis of the left hip on AP view of the same boy as in Figure 89-1. (*Used with permission from Thomas Kuivila, MD.*)

INTRODUCTION

Slipped capital femoral epiphysis (SCFE) is a relatively common disorder of the adolescent hip. "Skiffy" for short, SCFE is failure of the proximal femoral physis during periods of accelerated growth. This failure results in discontinuity arising between the head and neck of the femur. The femoral head stays located in the acetabulum, while the femoral neck migrates superiorly and anteriorly.

SYNONYMS

Slipped upper femoral epiphysis (SUFE).

EPIDEMIOLOGY

- SCFE most commonly occurs in adolescent boys between the ages of 10 and 16 years. It occasionally occurs in girls as well—usually between the ages of 12 and 14 years—but girls are half as likely as boys to have slips.[1]
- Annual incidence is estimated at 8.3 unilateral cases and 0.5 bilateral cases per 100,000 children.[2]
- Slips are more common in obese children[3] and they occur 2 to 4 times more frequently in black and Hispanic children than in white children.[1,4]
- The left hip is involved twice as frequently as the right hip. Bilateral slips occur 20 percent of the time,[1] usually within 12 to 18 months of the first slip.
- Interestingly, SCFE tends to show seasonal and regional variability. Slips tend to occur more frequently in warm months[5], and there is a predilection for slips to occur more frequently in the Northeastern and Western US.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiological factors for SCFE are thought to be numerous. They include local trauma, mechanical factors (physeal weakness during puberty, stress from obesity),[6,11] endocrine disorders (hypothyroidism, pituitary deficiency),[1] inflammatory conditions, and genetic factors.

- All proposed etiological factors result in a common condition: a weak physis that fails to resist displacement when subjected to sheering stress. Failure occurs in the hypertrophic zone of the physis.[7]

RISK FACTORS

Though the cause of SCFE is has not been fully elucidated, there are a few risk factors that have been identified:

- Male gender.[1]
- Adolescent age.
- Obese children.[3]
- Personal history of hyopothyroidism, growth hormone deficiency, and other pituitary axis abnormalities.[8]

DIAGNOSIS

CLINICAL FEATURES

- Patients with a SCFE will typically report hip, thigh (usually medial), or knee pain of a short duration. Medial thigh and knee pain is thought to be referred pain secondary to irritation of the obturator nerve.
- The pain is usually aggravated by activity and relieved with rest.
- Patients often walk with a limp.
- Patients with severe cases of SCFE are completely unable to bear weight, though this is uncommon.
- Often, the affected leg is externally rotated in comparison to the normal leg.

- On exam, there may be obligate external rotation of the affected hip as it is flexed (**Figures 89-3** and **89-4**). There may be a slight leg-length discrepancy. Although prior classification systems (based on duration of symptoms and severity of the slip) have been employed, the most commonly accepted system in use today recognizes slips as stable or unstable. Stable slips are those in which the patient is still able to bear weight; unstable slips are those that prevent any form of ambulation. This classification scheme has implications on prognosis and treatment method.[9]

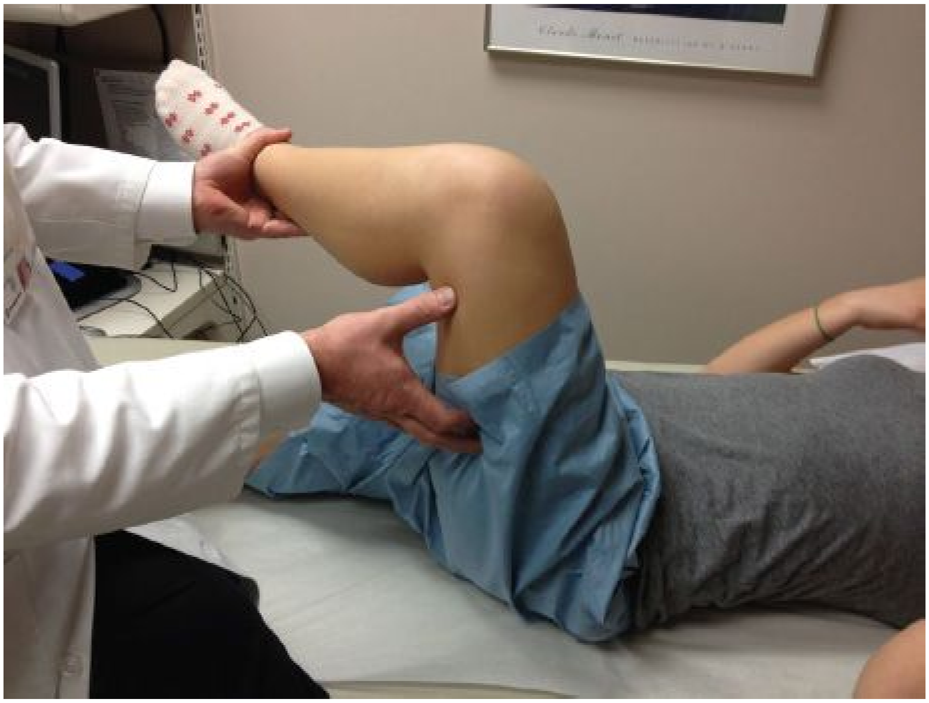

FIGURE 89-3 This patient has been treated for slipped capital femoral epiphysis. Note the obligate external rotation that is seen as the hip is flexed. The examiner is just flexing the hip and the external rotation is occurring spontaneously due to the abnormal anatomy. This is the result of femoral neck impingement on the acetabular rim during hip flexion. (*Used with permission from David Gurd, MD.*)

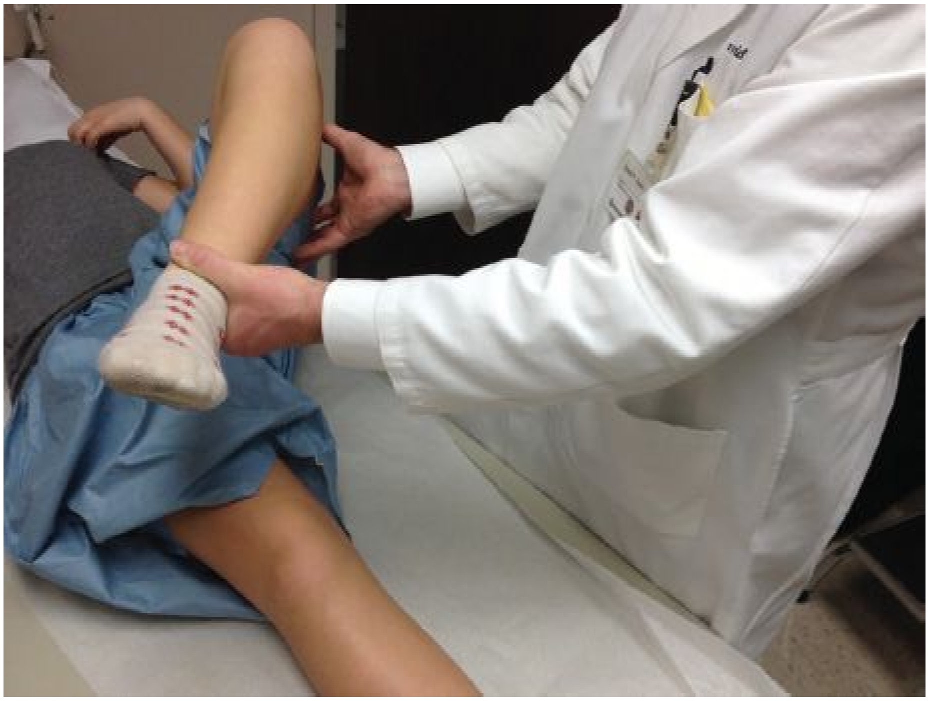

FIGURE 89-4 Obligate external rotation as the hip is flexed from the caudal view in the same boy as in Figure 89-3. (*Used with permission from David Gurd, MD.*)

LABORATORY TESTING

- No laboratory tests are necessary to diagnose SCFE.
- However, given the association with endocrine abnormalities, laboratory testing may be indicated if an endocrine etiology is thought possible.
- Pertinent lab tests include thyroid-stimulating hormone (TSH) to evaluate for hypothyroidism, basic metabolic panel to evaluate for renal abnormality, and Growth Hormone levels to evaluate for hypopituitarism, among others.
- Some authors have advocated TSH testing for all patient with SCFE, as well as selective pituitary testing for patients who are short for their age and have hypogonadism.[10]

IMAGING

- SCFE can typically be diagnosed with routine x-rays only. AP and frog-leg lateral views are the most effective ways of observing subtle slips (**Figures 89-1**, **89-2**, **89-5**, and **89-6**).

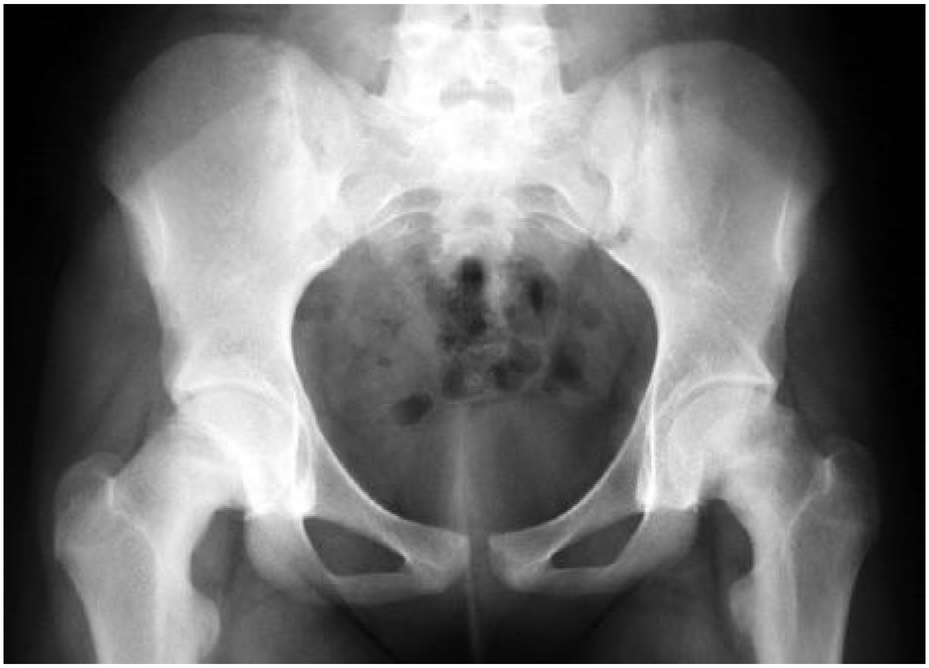

FIGURE 89-5 Bilateral slipped capital femoral epiphysis in a 12-year old boy on AP view. (*Used with permission from Ryan Goodwin, MD.*)

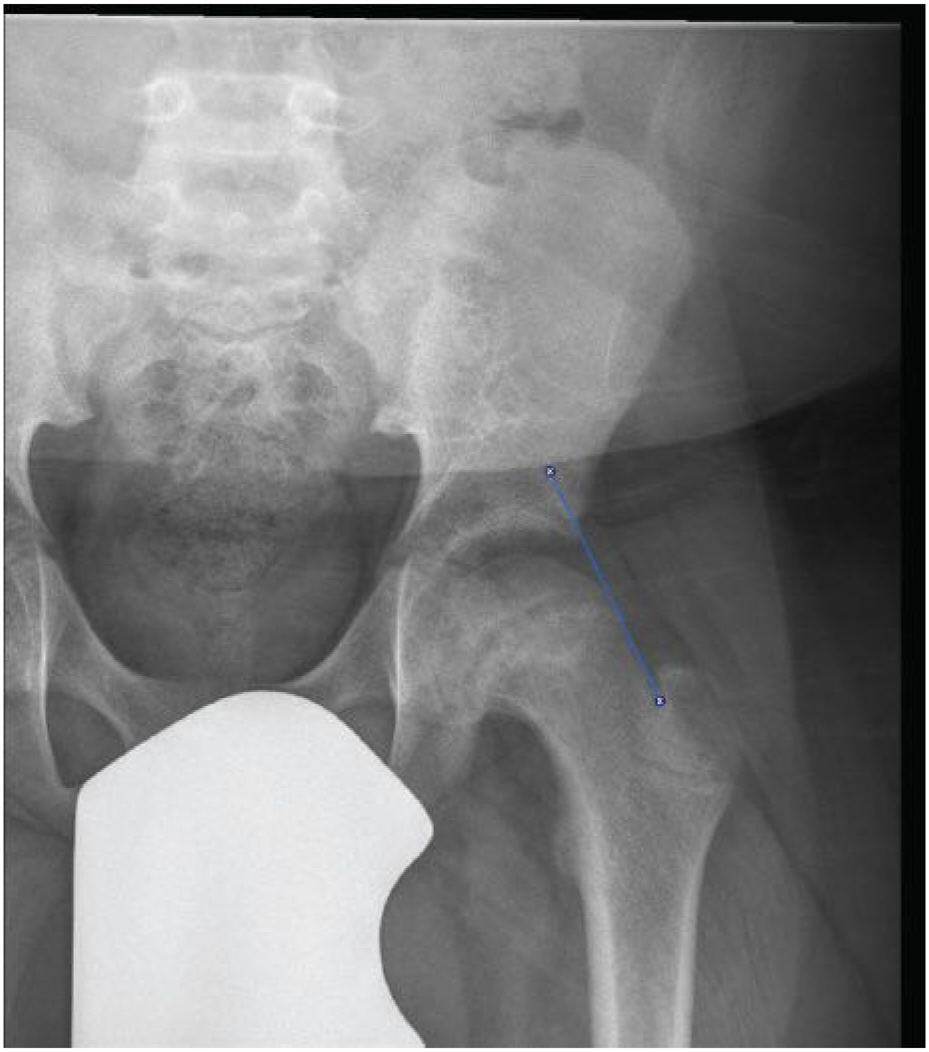

FIGURE 89-6 Klein’s line, which runs along the superior aspect of the femoral neck, as seen on AP view of the hip. Slipped capital femoral epiphysis is diagnosed when the line does not intersect any portion of the femoral head. (*Used with permission from Thomas Kuivila, MD.*)

- MRI is used very infrequently to identify slips that are not readily apparent on plain films.
- Ultrasound and CT are not routinely used for the diagnosis of SCFE.

DIFFERENTIAL DIAGNOSIS

- Avascular necrosis of the femoral head (Legg-Calve-Perthes or other etiologies)—Damage to the epiphyseal bone of the femoral head; usually the result of lack of blood supply, often for an unknown reason. This results in collapse of the overlying articular cartilage, which can lead to premature arthritis if the bone and cartilage are not able to repair and remodel (see Chapter 88, Leg-Calves-Perthes).
- Femoral neck fracture (as well as traumatic proximal femoral physeal fracture)—Fracture through the proximal femoral physis (growth plate fracture), immediately below the femoral head (subcapital femoral neck fracture), or at the base of the neck (basicervical femoral neck fracture). These fractures are almost exclusively traumatic in nature.
- Femoral neck stress fracture—Fracture through the femoral neck that is a result of overactivity or intense, repetitive activity (military recruits, etc.). Initial radiographs may be negative.
- Adductor strain—Strain of any of the adductor muscles of the thigh, particularly adductor brevis, adductor longus, and adductor magnus. These muscles take their origin from the pubic rami, giving the patient the impression that they have a “pulled groin” when strained.
- Osteitis Pubis—Noninfectious inflammation of the pubic symphysis and the surrounding muscle insertions. It is usually the result of microtrauma to the joint and surrounding muscle insertions during repetitive activities.
- Pelvic apophyseal injury—Avulsion of tendon from bone at the apophysis (a bony process that is the site of ligament or tendon attachment, associated with a growth plate), seen most commonly in the pediatric athlete. In pediatric patients, failure at the apophysis is common, as the growth plate tends to be weaker than its attached tendon or ligament.

MANAGEMENT

NONPHARMACOLOGIC

- Traction or casting has been used successfully in the past, but it is no longer used in current treatment due to its difficulty and complications.
- For obvious reasons, the highly restrictive hip spica cast is tolerated poorly in this demographic, as well as prolonged bedrest for traction.
- Additionally, past studies have shown that the incidence of chondrolysis is far greater in patients treated with casting than with patients treated surgically.[11,12]

MEDICATIONS

- Pain medications are used only for peri-operative pain management in SCFE patients. No medications are used for the treatment of the condition.

SURGERY

Surgical management is the standard of care for the management of SCFE.[11,12] SOR Ⓐ Numerous surgical management options are successfully employed, including percutaneous in situ pinning, open reduction and internal fixation, and osteotomy.

- In general, the slipped epiphysis is not reduced to its original state, as this maneuver causes increased risk of avascular necrosis due to disruption of blood supply.
- Reduction of the slip is only done if the femoral neck and head can be visualized during an open procedure.
- In most cases, the epiphysis is pinned where it lies in situ.
- Percutaneous in situ pinning with a single, large-diameter screw is now the most commonly used treatment option.
- Numerous studies have shown that a single threaded pin is comparable to two or three pins to maintain stability.[13,14] SOR Ⓐ

- For patients with unilateral SCFE, controversy exists over whether or not to pin the unaffected hip prophylactically. In general, it is recommended that prophylactic pinning of the unaffected hip occur in younger patients (with a low Oxford bone age score)[15] and in patients with a concomitant endocrine abnormality.

REFERRAL

- Diagnosis of SCFE should prompt direct admission to the hospital and strict non–weight-bearing status, followed by a consultation to pediatric orthopedic surgery.
- A patient with SCFE should not be sent home or told to follow up as an outpatient, as further activity and ambulation poses significant risks for further slippage.

PREVENTION AND SCREENING

- Routine screening for SCFE is not employed. However, the astute clinician should suspect SCFE in any adolescent or preadolescent pediatric patient presenting with knee, thigh, or hip pain.
- Indeed, many cases of SCFE have gone undiagnosed when a patient presents with pain outside the hip region.

PROGNOSIS

- The prognosis for stable slips is generally very favorable, with satisfactory results reported to be as high as 96 percent.
- Conversely, the prognosis for unstable slips is poor, with satisfactory results seen in only 1/2 of the patients.[16]

- Complications from SCFE include avascular necrosis of the femoral head and femoro-acetabular impingement (FAI).[3]

FOLLOW-UP

- After diagnosis and surgical management, patients with SCFE must be followed by their surgeon until the physis has become stable, evidenced by a bony bridge across the physis.
- Follow-up with a pediatric specialist may be indicated if a SCFE is found to occur concomitantly with another abnormality (i.e., hypothyroidism).

PATIENT EDUCATION

- Children diagnosed with SCFE need to be educated to not weight-bear between diagnosis and surgery. When the diagnosis is made the child should be evaluated immediately in a hospitalized setting with the parents helping to enforce the no weight-bearing rule.

90 OSGOOD-SCHLATTER

Kimberly Giuliano, MD
Ellen Park, MD

PATIENT STORY

An adolescent male presents with unilateral knee pain and swelling (**Figure 90-1**). His pain is worse after athletic participation and with kneeling. On examination, he has point tenderness and edema of the tibial tubercle. He is diagnosed with Osgood-Schlatter disease and treated with rest, ice, and non-steroidal anti-inflammatory medication. His symptoms improve but he continues to have mild flares of pain when he is more active.

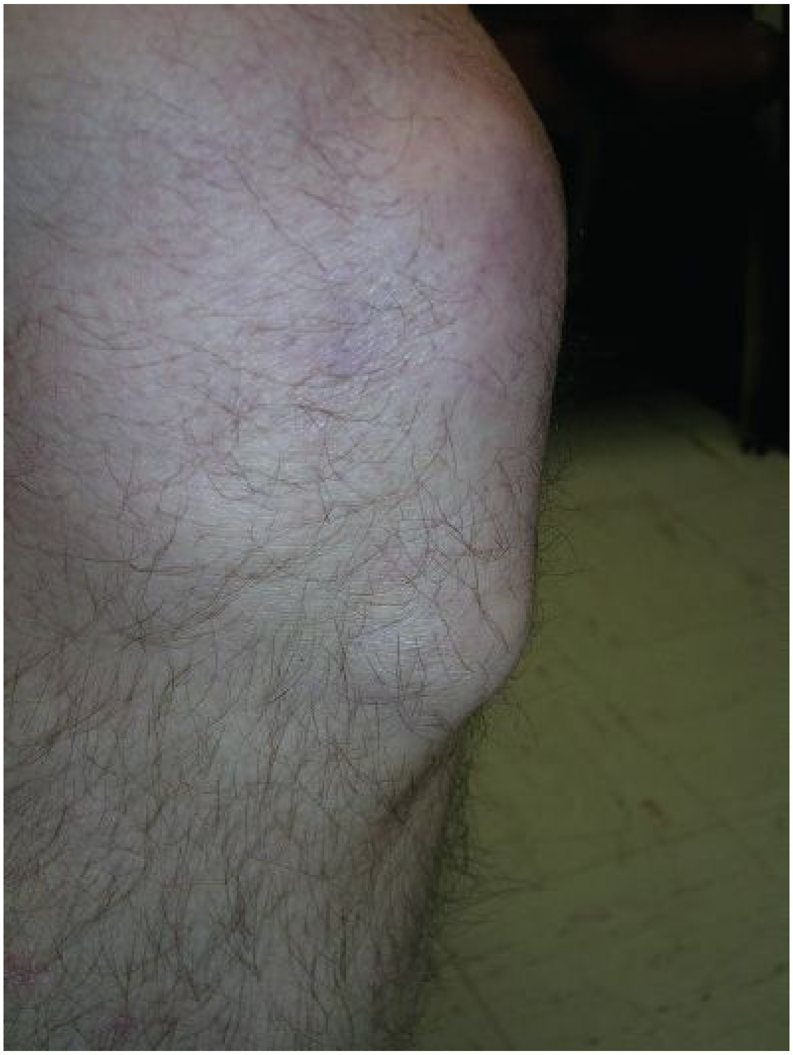

FIGURE 90-1 Prominence of the tibial tuberosity consistent with Osgood-Schlatter disease in an adolescent male. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Osgood Schlatter disease was described in 1903 by Dr. Osgood and Dr. Schlatter as pain and edema of the anterior tibial tubercle.[1,2] These clinical findings result from traction apophysitis at the patellar tendon insertion site on the proximal tibial tubercle.

SYNONYMS

Osteochondritis of tibial tubercle; tibial tuberosity avulsion.

EPIDEMIOLOGY

- Occurs in adolescents after a rapid growth spurt.
- More common in males than females (**Figure 90-2**).[3]

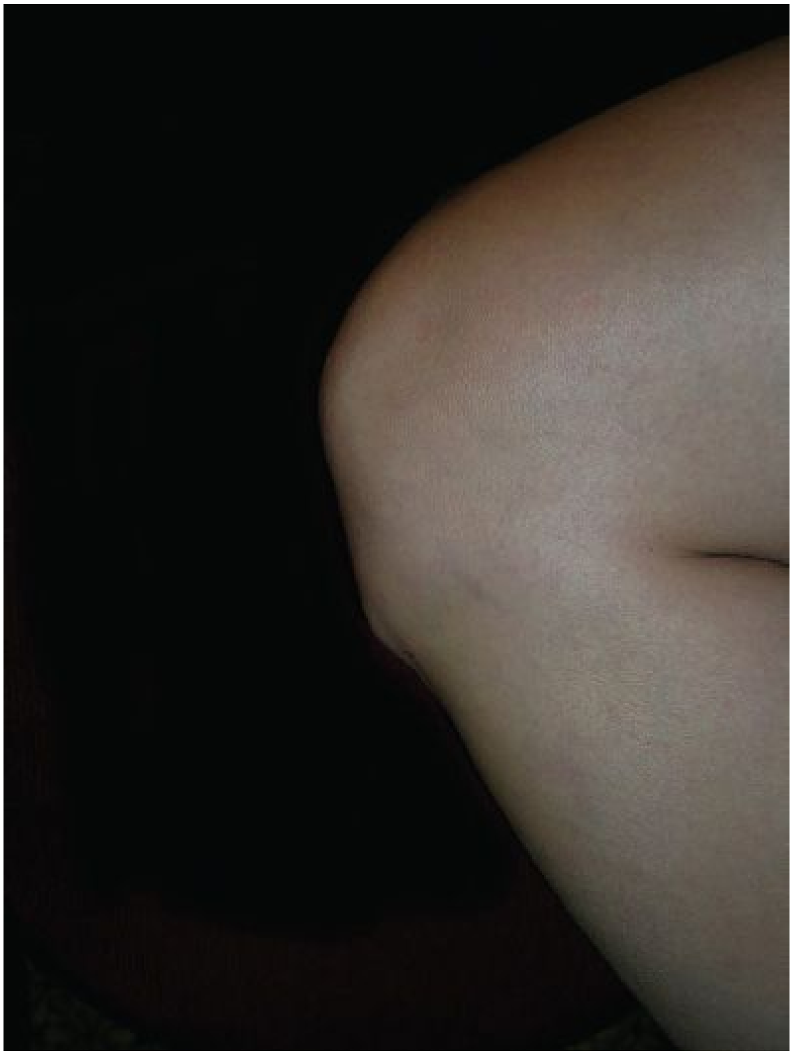

FIGURE 90-2 Prominent tibial tubercle in an adolescent female with Osgood-Schlatter disease. (*Used with permission from Richard P. Usatine, MD.*)

- More common in athletes (21.2%) than nonathletes (4.5%).[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- Overuse injury.
- Repetitive strain leads to chronic avulsion of tibial tubercle apophysis.
- Chronic avulsion results in separation and elevation of the patellar tendon insertion at the tibial tubercle.
- Callous formation during the healing process leads to a pronounced tibial tubercle.

RISK FACTORS

- Participation in athletic activities that involve repetitive running and jumping.
- Pubertal growth spurt.
- More proximal attachment of the patellar tendon.[5]
- Broad patellar tendon attachment at the tibia.[5]
- High riding patella.[6]

DIAGNOSIS

CLINICAL FEATURES

- Tenderness and prominence of the tibial tubercle.

DISTRIBUTION

- Typically unilateral but can have bilateral involvement.[4]

IMAGING

- Osgood-Schlatter is often a clinical diagnosis. Imaging is not indicated unless unusual features are present to suggest an alternate diagnosis.
- Plain films may demonstrate a spectrum of findings from normal to fragmentation and irregularity of the tibial tubercle, anterior knee soft tissue swelling, and patellar tendon thickening on the lateral knee x-ray (**Figure 90-3**). Plain films may not be helpful if tibial tubercle has not yet ossified (often between the ages of 9 and 11 years).

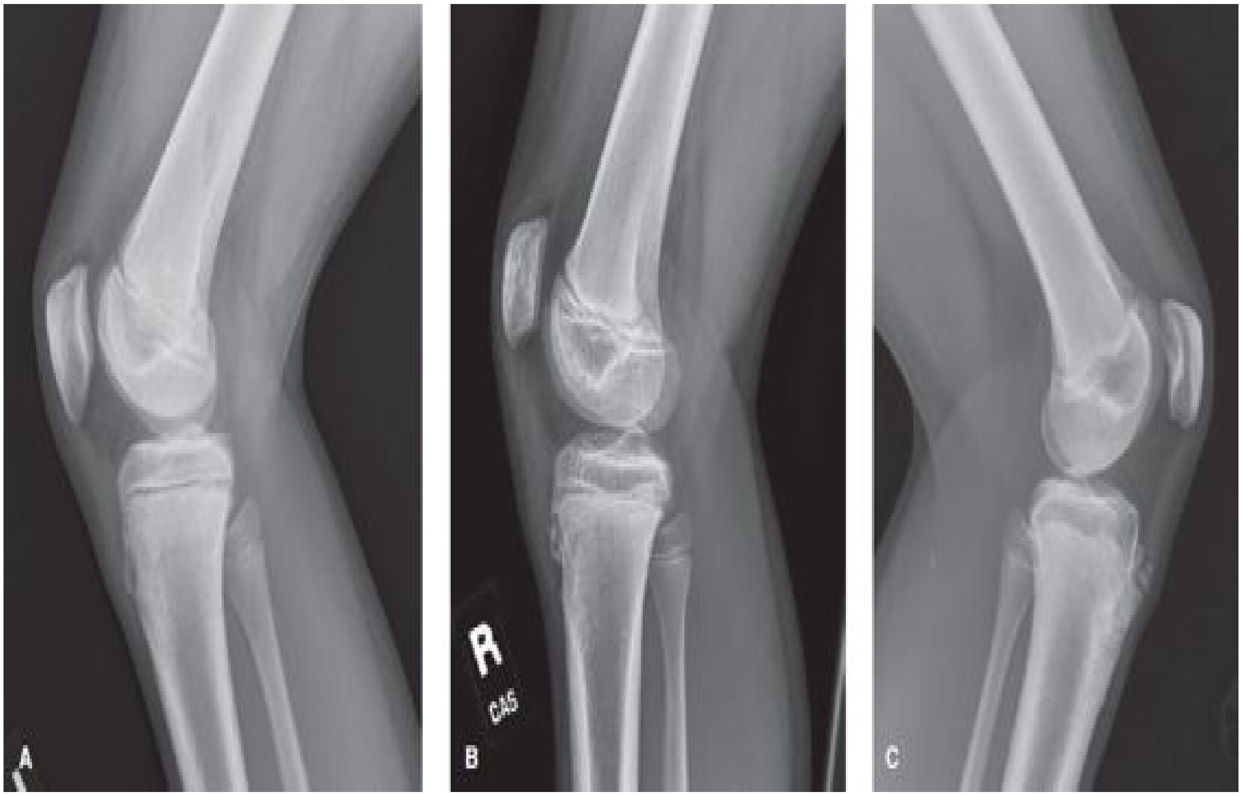

FIGURE 90-3 **A.** Mild changes of Osgood-Schlatter disease in an 11-year-old boy on left knee lateral radiograph. Note mild patellar tendon thickening and edema with slight irregularity of tibial tubercle. **B.** Mild changes of Osgood-Schlatter disease in right knee lateral radiograph with increased patellar tendon thickening, soft tissue edema and irregularity of tibial tubercle. **C.** Fragmentation of the tibial tubercle in Osgood-Schlatter disease. (*Used with permission from Ellen Park, MD.*)

- Computed tomography and magnetic resonance imaging (MRI) are not typically indicated. MRI is, however, the most sensitive form of imaging and will demonstrate spectrum of findings including soft tissue edema, infrapatellar fat pad edema, patellar tendon thickening, and bony changes (**Figure 90-4**).

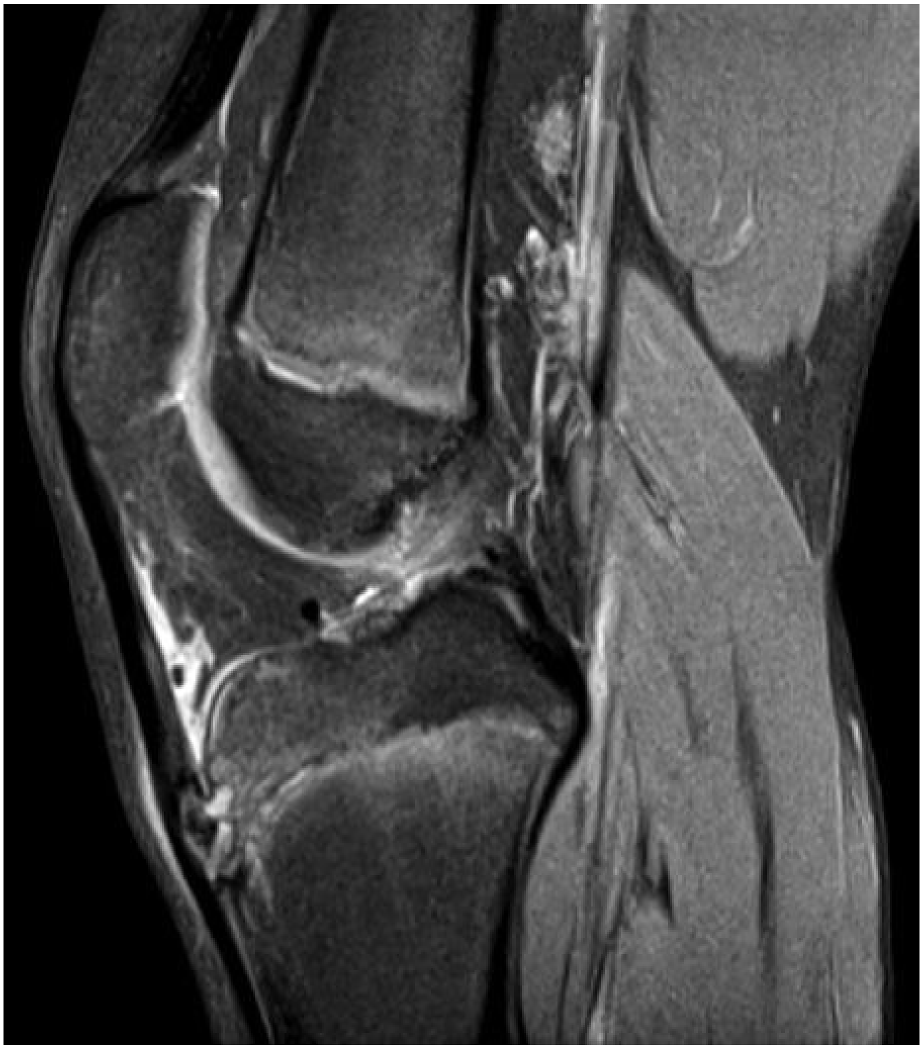

FIGURE 90-4 MRI (T2 weighted imaging) of knee in an 11-year-old with Osgood-Schlatter disease. Bone marrow edema and fragmentation of tibial tubercle is present along with edema of the adjacent soft tissues. (*Used with permission from Ellen Park, MD.*)

DIFFERENTIAL DIAGNOSIS

- Bone tumors—Tumors typically are associated with symptoms that are absent in Osgood-Schlatter (i.e., fever, pain at rest, night awakenings, systemic complaints).
- Osteomyelitis—Overlying erythema, calor and fever should prompt evaluation for infection as these symptoms are not typical for Osgood-Schlatter.
- Avulsion fracture of tibial tubercle—Acute pain with associated injury raises concern for avulsion fracture. Osgood-Schlatter typically presents with subacute pain without an identified injury.
- Arthritis—Edema within the knee joint is not consistent with Osgood-Schlatter. Juvenile Idiopathic Arthritis (JIA) and septic arthritis are not isolated to the tibial tubercle and are often associated with systemic symptoms (see Chapter 172, Juvenile Idiopathic Arthritis).
- Tibial stress fracture—Stress fractures generally do not occur within the tibial tubercle.
- Patellar tendonitis—Pain with palpation along the patellar tendon is consistent with tendonitis and is not present in Osgood-Schlatter.
- Sinding-Larsen-Johansson (traction apophysitis of inferior patella)—Pain is located at the inferior patella with traction apophysitis and the tibial tubercle is not involved.
- Plica syndrome (synovial fold inflammation)—Pain is located within the knee joint when the synovial folds are inflamed, but the tibial tubercle is non-tender.
- Hoffa disease (impingement of infrapatellar fat pad)—Fat pad impingement causes pain within the knee joint and does not involve the

tibial tubercle.

MANAGEMENT

NONPHARMACOLOGIC

- Rest the involved knee.[7–10] SOR Ⓑ
- Ice application. SOR Ⓒ
- Physical load restriction.[11] SOR Ⓑ
- Wearing a patellar tendon strap may reduce the pain.[12] SOR Ⓒ
- Wearing a knee pad may help protect the affected area from direct trauma. SOR Ⓒ
- Stretching the hamstring and quadriceps muscles. SOR Ⓒ
- Strengthening quadriceps muscles. SOR Ⓒ

MEDICATIONS

- Non-steroid anti-inflammatory drugs (NSAIDs).[789–10] SOR Ⓑ
- A small study showed improvement with dextrose injections for refractory cases of Osgood-Schlatter.[13] SOR Ⓒ

SURGERY

- Surgery is rarely necessary.
- Surgery can be considered for significant refractory Osgood-Schlatter symptoms after the patient reaches skeletal maturity.[14–18] SOR Ⓑ

REFERRAL

Conservative management by the primary care physician is usually sufficient. Referrals can be considered for refractory or atypical symptoms:

- Physical therapy.
- Sports medicine.
- Orthopedic surgeon.

PREVENTION

- Appropriate stretching of hamstrings and quadriceps prior to sport participation.
- Avoid repetitive jumping on hard surfaces.

PROGNOSIS

- Self-limited course.
- Complete recovery is expected for vast majority of patients upon reaching skeletal maturity.
- Tibial tubercle prominence may persist after symptoms resolve.
- Residual ossicles can result in continued pain after skeletal maturity.

FOLLOW-UP

- Patients should be instructed to follow up with their primary care physician if pain does not decrease with good adherence to conservative treatment measures; however, mild persistent pain is expected.

- Increased pain, night awakenings, overlying erythema, calor, or fevers should prompt further evaluation.

PATIENT EDUCATION

- Patients and parents should be reassured that this is a self-limited process and that adherence to conservative treatment measures is important to recovery from symptoms.

91 SCOLIOSIS

Joel Kolmodin, MD
David Gurd, MD

PATIENT STORY

A 12-year-old girl presents to the office after a routine school screening. She was told that she has an abnormal curvature of her spine, and she notes an unpleasant hump on the right side of her back. She is found to have a right sided prominence, shoulder height differences, and lateral curvature of her spine on examination (**Figures 91-1** and **91-2**). Neurological examination is normal. PA and lateral x-rays are taken, and the patient is referred to a Pediatric Orthopedic surgeon for evaluation and management.

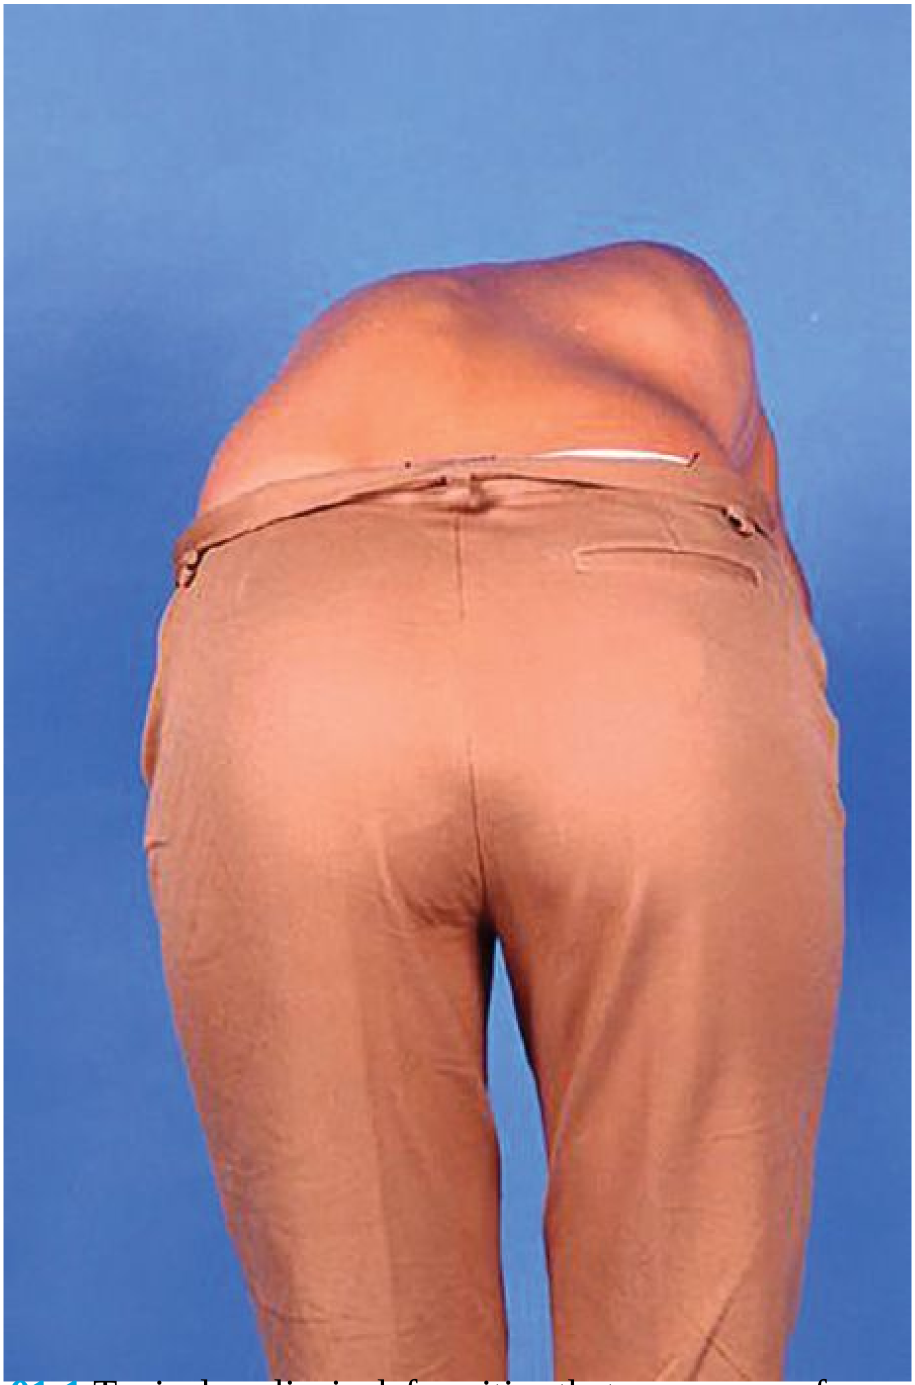

FIGURE 91-1 Typical scoliosis deformities that are seen on forward-bending clinical examination in a 12-year-old girl. Note the thoracic prominence on the right and the sloping angle from the right back to the left. (*Used with permission from David Gurd, MD.*)

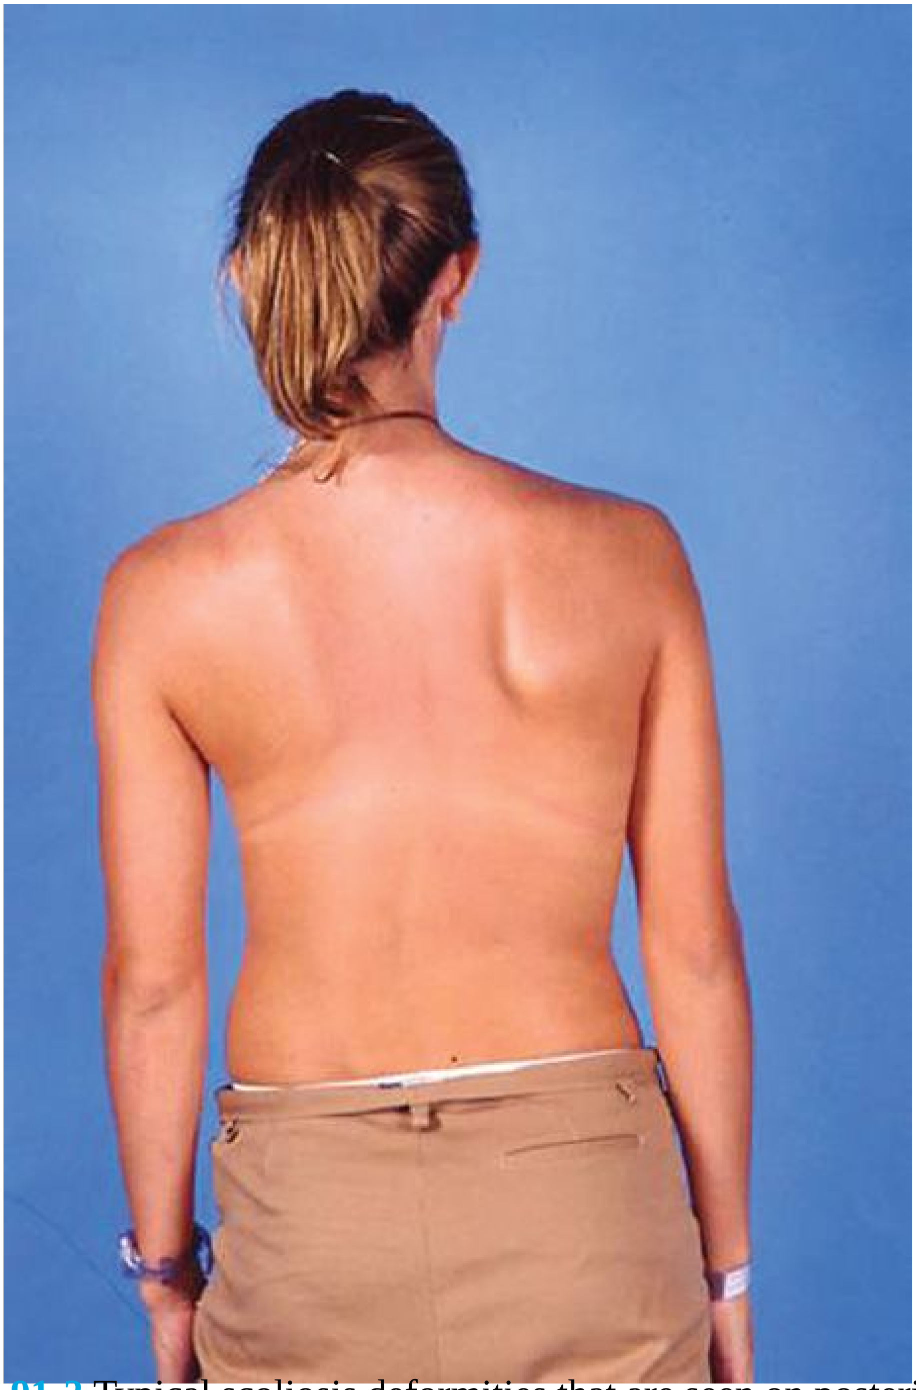

FIGURE 91-2 Typical scoliosis deformities that are seen on posterior clinical examination of the same girl as in Figure 91-1. Note the assymetry of the scapulae and the waist contours. The curvature of the spine is visible along with a slightly higher right shoulder too. (*Used with permission from David Gurd, MD.*)

INTRODUCTION

Scoliosis is a lateral curvature of the spine that is greater than 10 degrees in the coronal plane (**Figure 91-3**). It is often associated with rotational changes and hypokyphotic spinal deformity (flat thoracic spine when viewed from the side).[1]

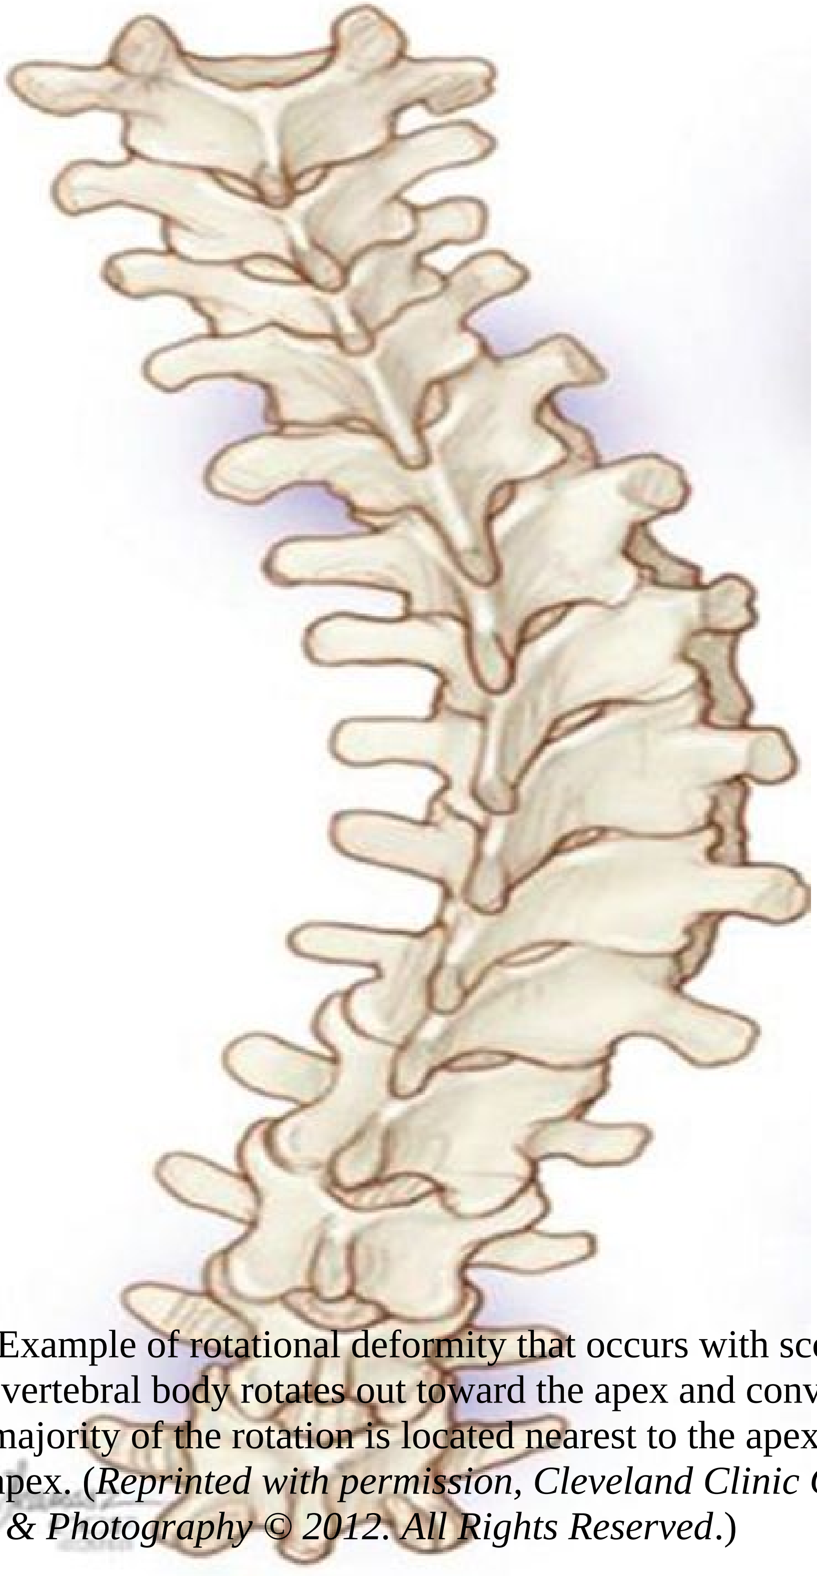

FIGURE 91-3 Example of rotational deformity that occurs with scoliosis. Notice how the vertebral body rotates out toward the apex and convexity of the curve. The majority of the rotation is located nearest to the apex, less away from the apex. (*Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2012. All Rights Reserved*.)

SYNONYMS

Back curvature; spine deformity; twisted spine.

EPIDEMIOLOGY

- Overall incidence in the population is 2 to 3 percent, with 0.1 to 0.3 percent of the population developing significant curves exceeding 20 degrees.[2]
- Scoliosis is classified as:
  - Congenital—Arising from congenital (as an infant) vertebral anomalies such as wedged vertebrae, hemivertebrae, and fused/unsegmented vertebrae.
  - Infantile Idiopathic Scoliosis—Scoliosis which is present between birth and 3 years of age without congenital change. This comprises 4 percent of all idiopathic scoliosis cases.[3]
  - Juvenile Idiopathic Scoliosis—Scoliosis which develops between 4 and 10 years of age. This comprises 10 to 15 percent of all idiopathic scoliosis cases.[4]
  - Adolescent Idiopathic Scoliosis (AIS)—Scoliosis which develops between 10 and 18 years of age. This is by far the most common form of scoliosis.

ETIOLOGY AND PATHOPHYSIOLOGY

- The vast majority of cases are idiopathic, as is the case with nearly all adolescents presenting with deformity.
- Numerous theories have been proposed for infantile and juvenile cases, including intrauterine molding, lying infants on their backs, and genetic

predisposition.[5]

RISK FACTORS

- There is a positive family history in approximately 30 percent of cases.

DIAGNOSIS

CLINICAL FEATURES

- Patients with scoliosis are typically asymptomatic. They may complain of intermittent back pain, but not more commonly than children without scoliosis. We do not believe that the scoliosis causes back pain unless the deformity is quite severe (**Figures 91-4** and **91-5**).[6] Patients and family members may report a deformity of the spine (curvature), rib cage (hump), shoulders (uneven), or pelvis (waist line asymmetry).

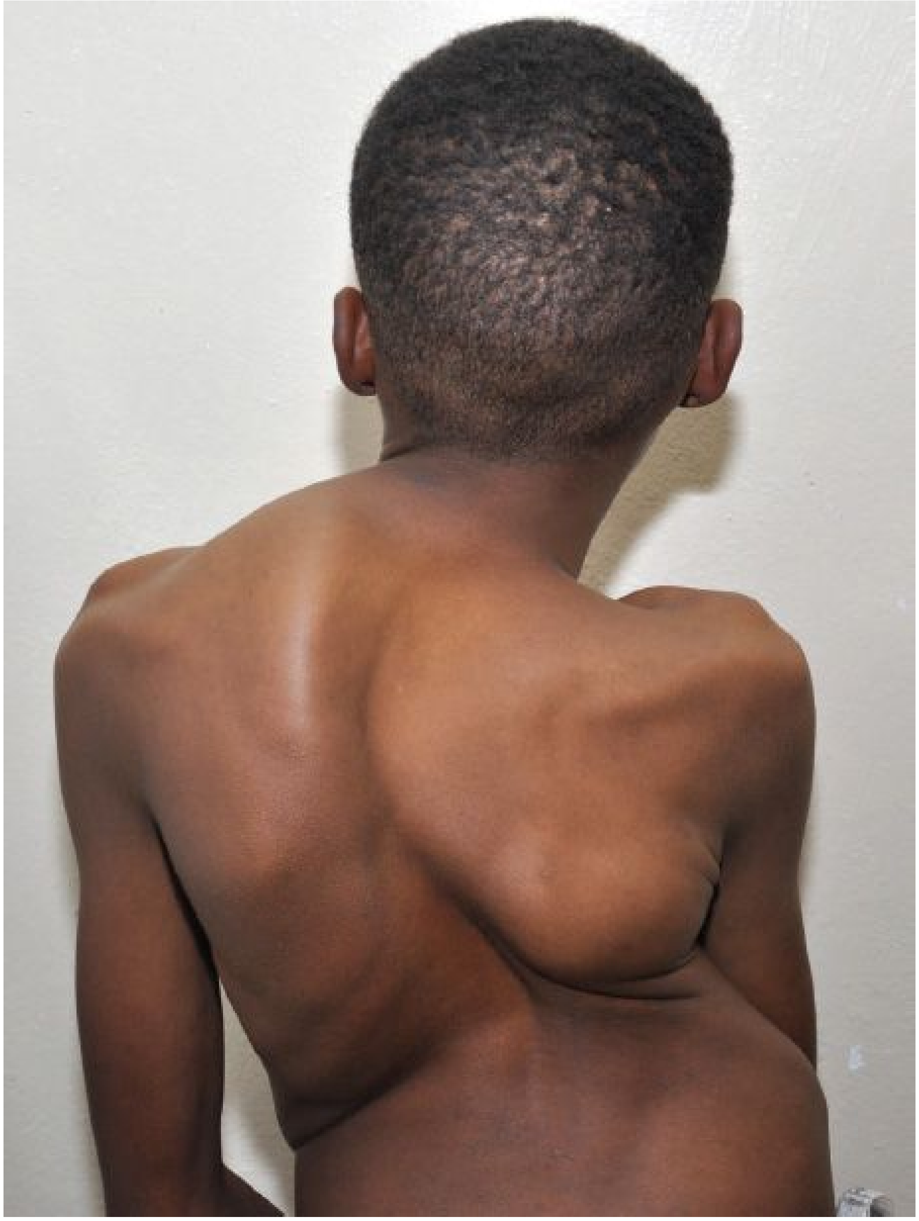

FIGURE 91-4 Severe scoliosis deformity. (*Used with permission from Richard Usatine, MD.*)

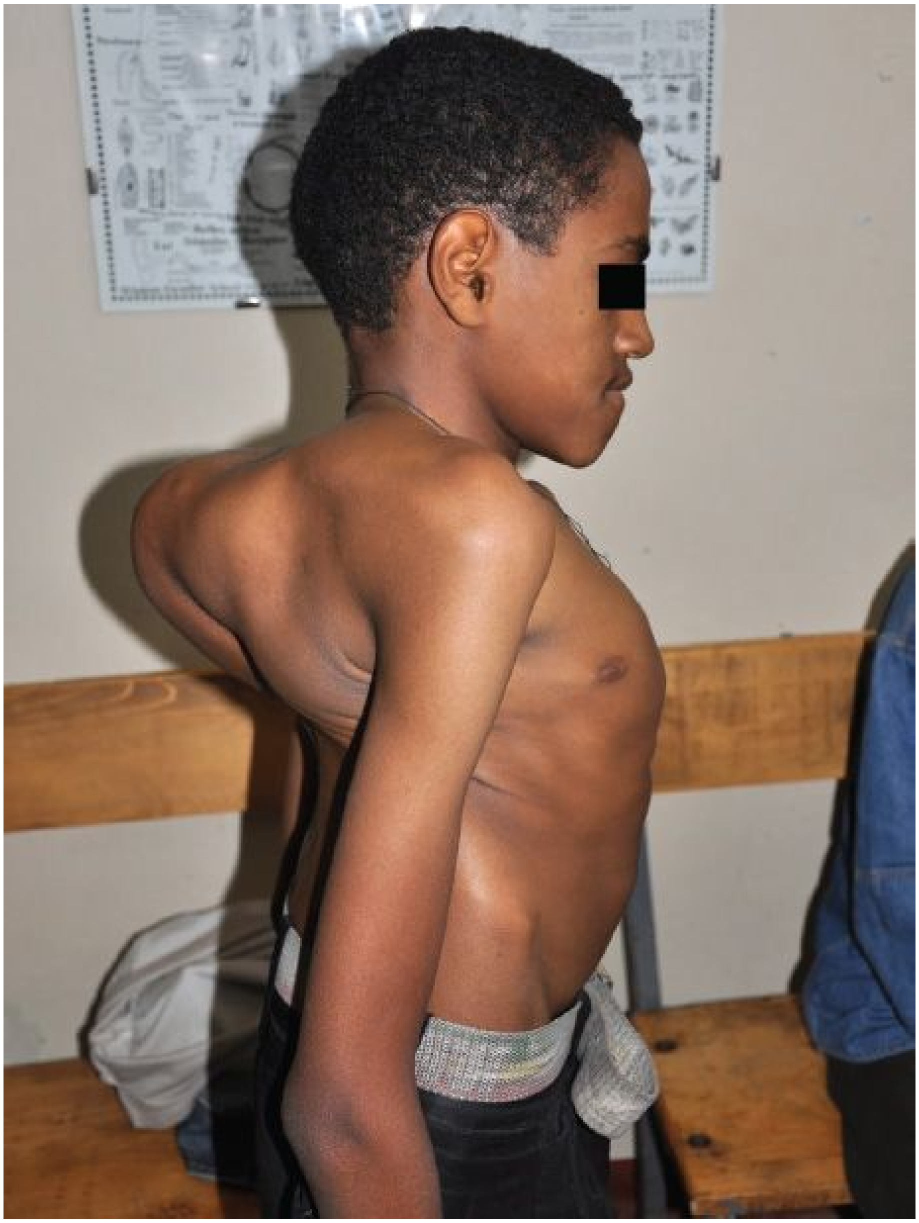

FIGURE 91-5 Severe scoliosis deformity of same patient in Figure 91-4 from lateral view. Note how the upper spine is almost horizontal. (*Used with permission from Richard Usatine, MD.*)

- The vast majority of curves are right-sided, meaning that the spine curves to the right when the patient is viewed from the back. Often there is a rib prominence noted when the patient bends forward. A curvature of the spine is more evident on forward bending. Patients will often notice unequal shoulder and/or iliac crest (pelvis) heights (**Figure 91-6**).

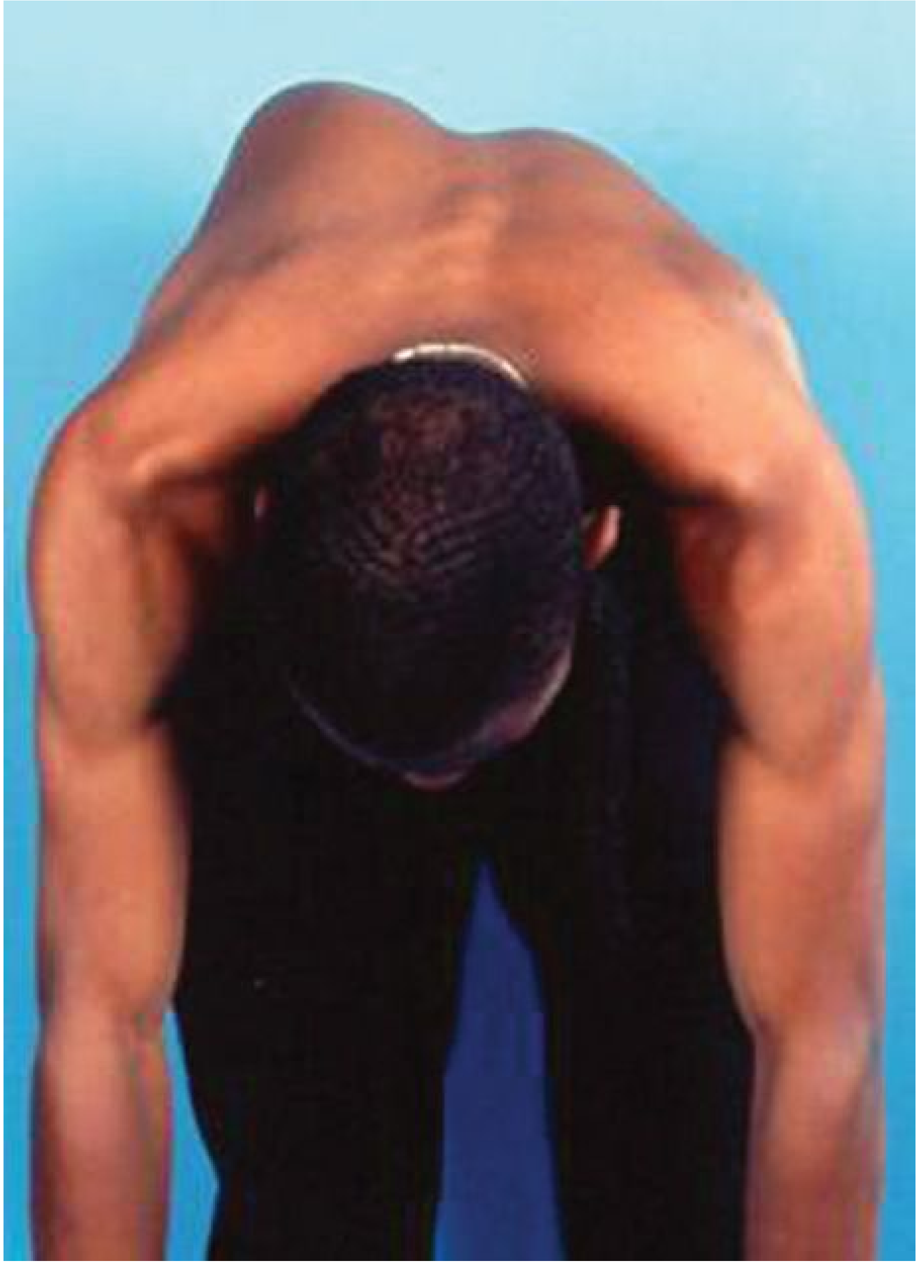

FIGURE 91-6 Typical scoliosis deformities seen on forward-bending clinical exam in a teenage male. (*Used with permission from David Gurd, MD.*)

- Neurologic deficit is uncommon, but it must be checked as scoliosis can be caused by neurological abnormalities. If there is a concern, an MRI can be helpful for assessment.

LABORATORY TESTING

- The SCOLISCORE™ Test is the first clinically validated and highly accurate genetic test for AIS curve progression.[7] It is based on a simple cheek swab. This test gives a numbered score determining likelihood of progression. The lower the score, the less likely for progression. Alternatively, the higher the score, the more likely for progression. There are no other laboratory tests currently available.

IMAGING

- Routine imaging includes PA and lateral x-rays (**Figures 91-7** and **91-8**). Lateral bending x-rays are ordered by an Orthopedic surgeon to assess the flexibility of the patient’s curve(s) and are typically only done preoperatively.

- MRI is not routinely ordered. It is ordered by the Orthopedic Surgeon only under specific circumstances to rule out such neurologic abnormalities as syrinx, tethered cord, and Chiari malformation. In a patient with known scoliosis, any abnormality found on neurological exam mandates an MRI.

DIFFERENTIAL DIAGNOSIS

- Kyphosis—Abnormally large forward curvature of the thoracic spine. It is normal to have kyphosis of the thoracic spine, but it is considered abnormal when the kyphosis angle exceeds 50 degrees. As scoliosis can be associated with some degree of abnormal kyphosis, the two diagnosis can mimic one another.
- Postural change—Slouching or hunching over in an asymmetric was can give the appearance of a scoliotic curve. The asymmetry resolves, however, when the patient corrects their incorrect posture.
- Sprengle deformity—Failure of caudal migration (descent) of one scapula during development, resulting in asymmetric scapular heights. This asymmetry can cause a patient to appear to have unequal shoulder heights when viewed from the back (which is also seen in scoliosis), though there is no curvature to the spine.
- Leg length inequality—When one leg is longer than the contralateral side, pelvic obliquity results. This abnormal tilting of the pelvis can cause a compensatory curvature of the spine as the body attempts to keep the keep centered over the sacrum.
- Pectus carinatum and excavatum—Both are common deformities of the anterior chest wall that can occur with or without scoliosis. Most often they occur without scoliosis. Pectus carinatum causes a protrusion of the sternum and anterior chest and usually appears during the adolescent growth spurt. It is less common than pectus excavatum in which the anterior chest appears sunken. Both conditions can be asymmetric, giving the appearance of a scoliotic curvature.

MANAGEMENT

NONPHARMACOLOGIC

- Physical therapy has not been shown to prevent the progression of scoliotic curves in any way. It can be helpful, however, in providing the patient some physical benefit in the form of core strengthening to address asymmetry in torso rotation strength,[8] stretching, cardiovascular training, symptom relief, and so on.
- Though its efficacy has been debated in Orthopedic circles, bracing is presently the mainstay of non-operative management of scoliosis.[9] The goal of bracing is to prevent the progression of curves; it is not used to correct curves. Bracing is instituted by an orthopedic surgeon when a patient reaches his/her growth phase and has a curve magnitude of 25 to 40 degrees.[10] SOR B
- The most active growth phase occurs when a patient (1) has not yet begun menstruating, (2) has a low Risser score,[11] and (3) has open triradiate cartilages.
- There are many forms of braces, some of which are worn under clothing for up to 23 hours per day and others of which are only worn at night. Bracing is continued until the active growth phase is completed—usually 2 years after menstruation or when the patient has a Risser score of 4 or 5.[11]
- With early-onset scoliosis, every effort is made to delay surgery until after 10 years of age, a point at which the thoracic cage has adequately developed such that fusion will not confer significant respiratory compromise.
- Surgical management is not medically necessary if the curve can be kept below 45 degrees.[12,13] SOR A

MEDICATIONS

- There are no medications for the treatment of scoliosis.
- Although scoliosis is painless in the cast majority of cases, pain medications (NSAIDs), or anti-spasmotics (cyclobenzaprine, methocarbamol, or diazepam) are infrequently used to treat intermittent

symptoms of back pain and/or muscle spasm associated with the diagnosis. SOR Ⓒ

COMPLIMENTARY/ALTERNATIVE THERAPY

- Generally, alternative therapies are ineffective in managing scoliosis.
- Specifically, studies have shown that chiropractic manipulation, biofeedback, acupuncture, and electrical stimulation[14] do not prevent the progression of scoliosis. SOR Ⓑ
- They may have a role for these modalities in the treatment of pain or muscle spasm in symptomatic scoliosis.

SURGERY

- Surgery is sometimes employed as a way to manage those patients with early-onset scoliosis where progression is rapid. Growing rods, or metal rods that are attached to the most superior and inferior portions of the curvature, can be lengthened as a child grows. In this way, definitive posterior spinal fusion can be delayed until 10 years of age or later.[15]
- Surgery in the form of posterior spinal fusion is indicated when a curve reaches 45 degrees or more.[12] SOR Ⓐ The large majority of curves that are 45 to 50 degrees or greater at skeletal maturity will progress as the patient ages, typically at 1 degree per year.[12]
- The goals of surgery are (1) to halt the progression of the deformity, (2) to safely correct the curve, and (3) to address cosmetic deformity such as rib cage prominence. Halting the progression of the curve is the most important goal, as studies have shown that large curves (greater than 90 degrees) can be painful and have a significant impact on respiratory function.[13]
- Surgical treatment utilizes metal implants that are inserted into the spine. These are most often in the form of pedicle screws or hooks and two metal rods that are inserted posteriorly through a midline incision in the back (**Figure 91-9**). Anterior approaches are used as well, though less

frequently due to adverse effects on the lungs. This instrumentation is used to correct the coronal curve and any rotational deformity, after which the spine is fused with an allograft and/or autograft. The role of metal instrumentation is to hold the spine in its corrected position until bony fusion occurs. Neuro-monitoring is used throughout the case to ensure that there are no changes to neurologic status during the correction.[16] This recent advance has made all corrections more safe and has allowed more aggressive correction of large curves.

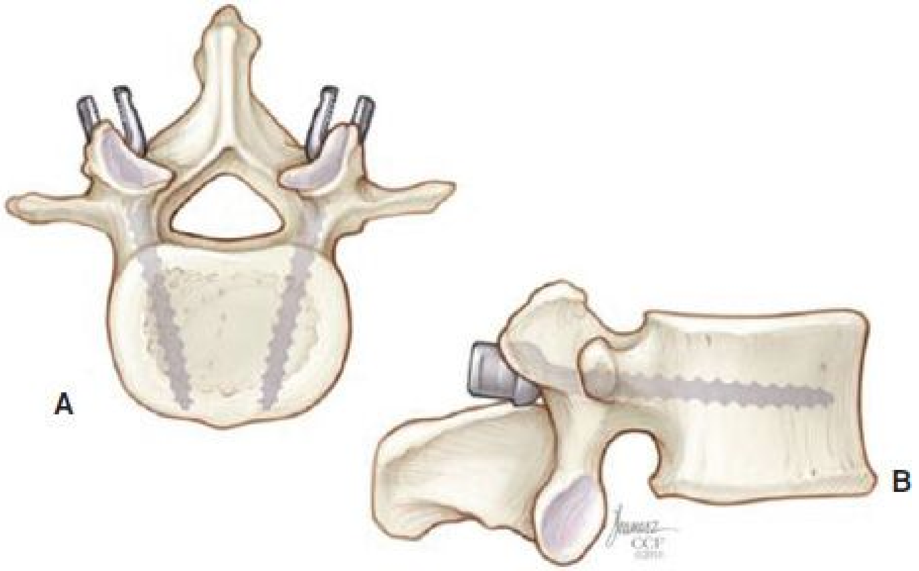

FIGURE 91-9 **A.** Illustration of pedicle screws within the pedicle of a thoracic vertebral body. Just medial to the pedicle is the neural canal and lateral is the rib and pleura. **B.** Same screw from the lateral view. (*Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2012. All Rights Reserved*.)

- Postoperatively, there are typically no braces or casts used (**Figure 91-10**).

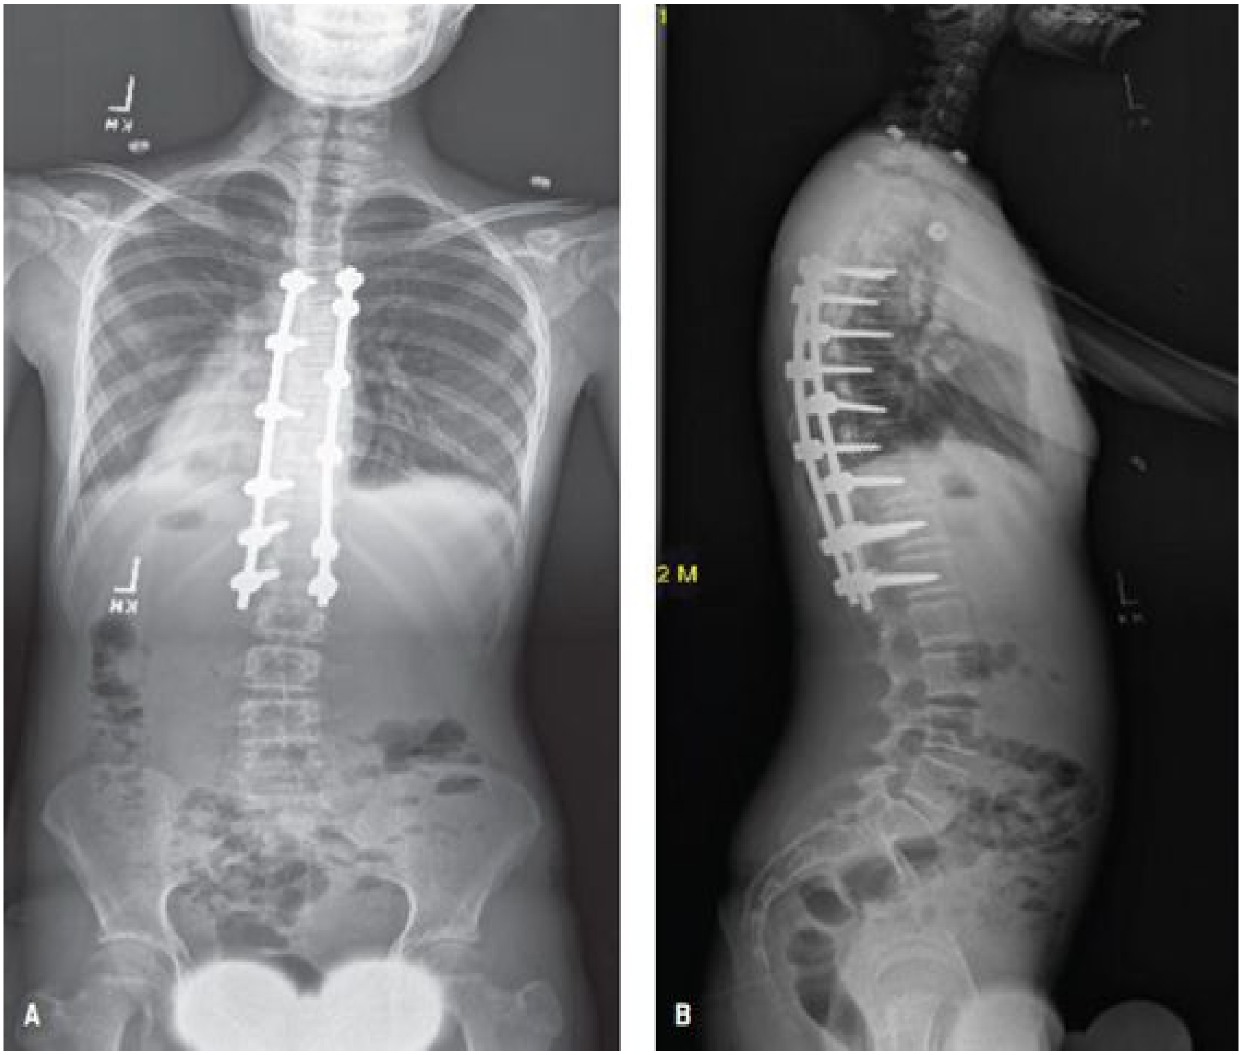

FIGURE 91-10 Postoperative imaging with radiographs of the same 12-year-old girl in Figure 91-1 and 91-2. **A.** PA view **B.** Lateral view. (*Used with permission from David Gurd, MD.*)

- The patient is encouraged to mobilize the first day after surgery.
- Bending, lifting, and twisting are generally discouraged for up to 6 months, though routine activities are started immediately.
- It is usually safe to return to noncollision sports 6 months post-operatively.

REFERRAL

- Referral to an Orthopedic surgeon is recommended for any scoliotic curve that is found in infancy or early childhood.
- It is recommended for any child that is found to have a curve greater than 20 degrees and has not yet reached their age of peak growth.

PREVENTION AND SCREENING

- School screening programs are universally in place and they typically start in the elementary school setting, prior to the age at which children reach their peak growth velocity.[17]
- Additionally, scoliosis screening should be performed at yearly well-child check-ups performed by a pediatrician.

PROGNOSIS

- Prognosis is related to the type of scoliosis that the patient has. Infantile scoliosis is known to spontaneously resolve in 20 to 80 percent of cases.[18]
- The prognosis for juvenile and adolescent idiopathic scoliosis is generally favorable if proper screening, conservative management, and definitive treatment are undertaken as they become warranted.
- Curves of all types that are kept below 90 degrees are generally associated with no respiratory compromise, organ dysfunction, or painful sequelae.[13]

FOLLOW-UP

- Once a patient has been found to have scoliosis, regular follow up with a Pediatric Orthopedic surgeon is necessary.

- Children outside their peak growth age can sometimes be followed as infrequently as once per year.
- Patients that are growing rapidly or are treated in a brace are followed as frequently as every 3 to 4 months, but typically every 6 months.

PATIENT RESOURCES

- The Scoliosis Research Society has a helpful site that is easy to navigate and is very informative—**www.srs.org/patient_and_family/scoliosis**.
- The National Institute of Health also has a helpful site, which even gives links to scholarly articles—**www.nlm.nih.gov/medlineplus/scoliosis.html**.
- The Pediatric Orthopedic Society of North America provides a complete patient guide—**www.settingscoliosisstraight.org/education**.

PROVIDER RESOURCES

- The Scoliosis Research Society website has specific links for providers—**www.srs.org/professionals/conditions_and_treatment**.
- The American Academy of Orthopedic Surgery provides up-to-date information and scholarly articles—**www,orthoportal.aaos.org/oko/default**.
- Free patient handouts are provided at the National Institute of Health website—**www.nlm.nih.gov/medlineplus/ency/article/001241.htm**.

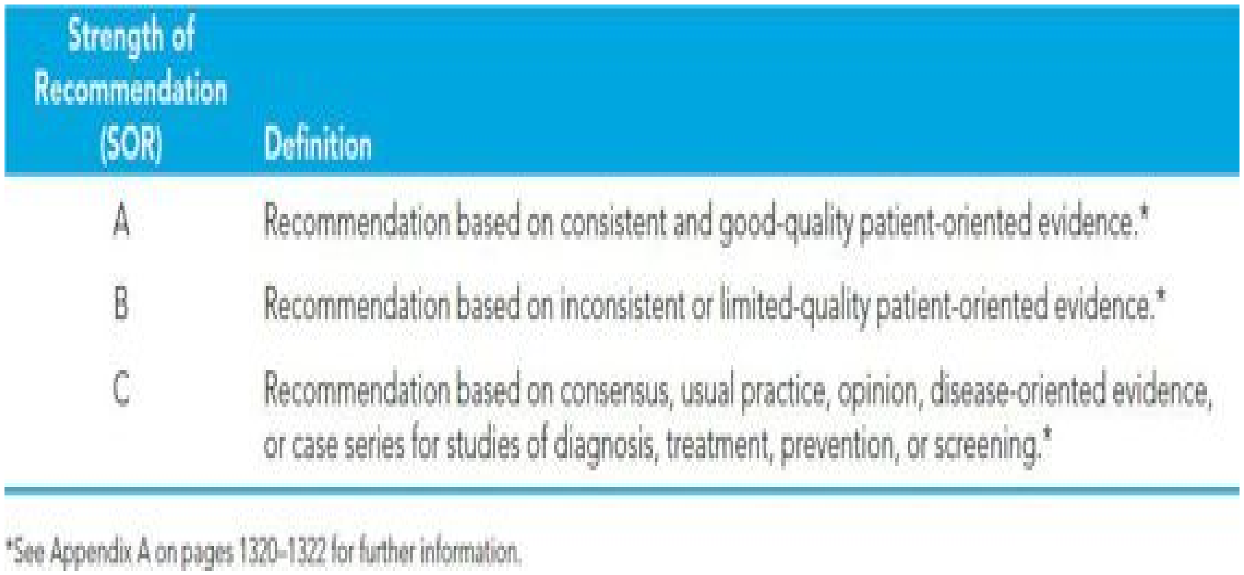
DERMATOLOGY



Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1320–1322 for further information.

SECTION 1 EARLY CHILDHOOD DERMATOLOGY

92 NORMAL SKIN CHANGES OF INFANCY

Mindy Smith, MD, MS
Cristina Fernandez, MD

PATIENT STORY

A 2-week-old infant is brought to the office for her first well-baby check. The parents noticed a rash on the face. You diagnose the white spots on the bridge of the nose as milia and neonatal acne on the cheeks. The parents are happy to hear that the neonatal acne and milia will go away without treatment (**Figures 92-1** and **92-2**).

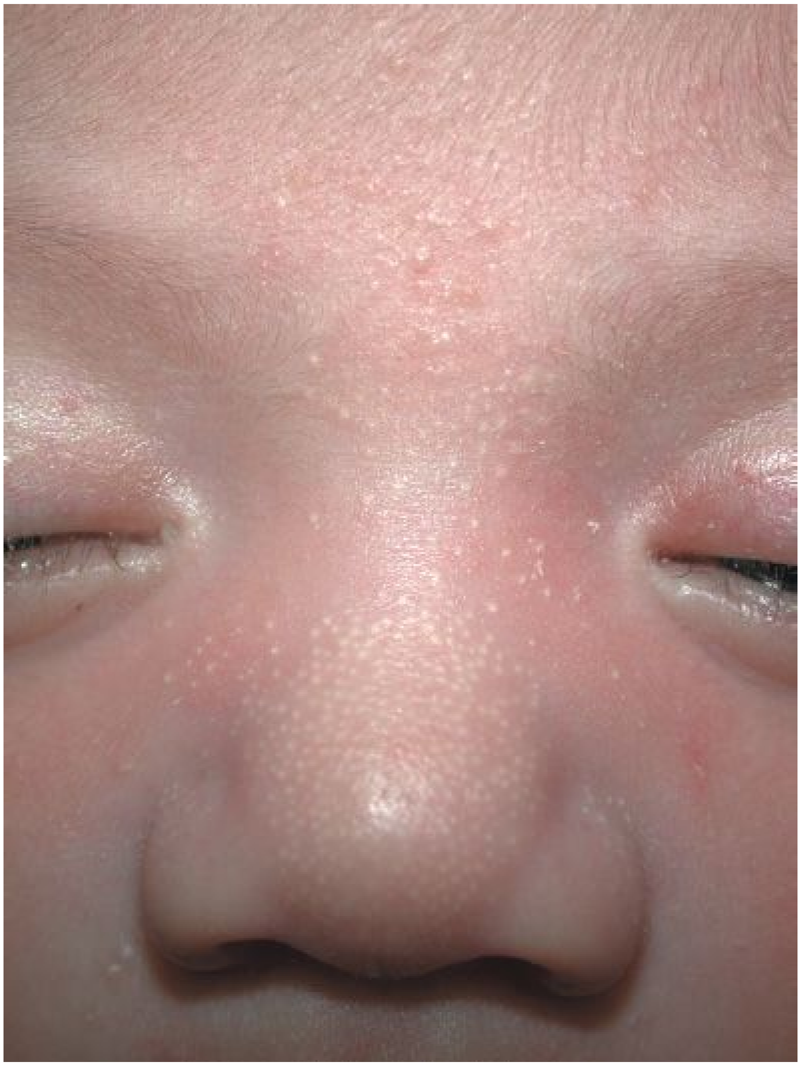


FIGURE 92-1 Milia on the face of a 2-week-old infant with greatest number of milia on the nose. (*Used with permission from Richard P. Usatine, MD.*)

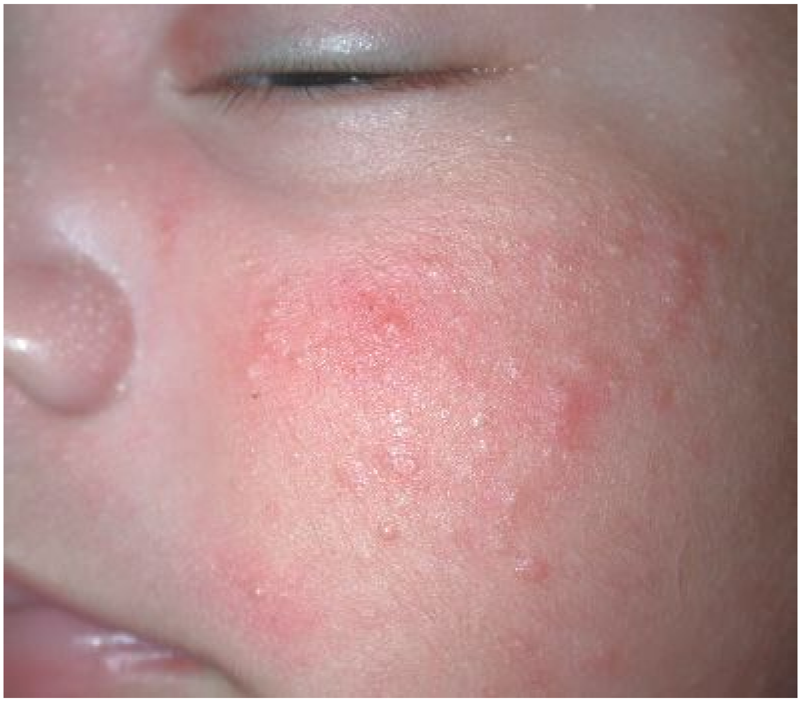

FIGURE 92-2 Neonatal acne on the same infant as in Figure 92-1. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

- Rashes are common in newborns. Physicians will be consulted frequently as they are a common parental concern. Almost all newborn rashes are benign; however, a few are associated with more serious conditions. A newborn’s skin shows a variety of changes during the first 2 months of life and most are self-limited. Physicians must be prepared to identify common rashes and provide advice to parents.[1]
- Milia are inclusion cysts that appear as tiny white papules in the skin (**Figure 92-1**) or on the roof of the mouth.
- Neonatal acne is an acneiform eruption appearing as small red papules or whiteheads with surrounding erythema on the skin of newborns (**Figure 92-2**).

- A mongolian spot is a hereditary, congenital macule of bluish-black or bluish-gray pigment usually in the sacral area, back, and buttocks of infants (**Figures 92-3** and **92-4**).

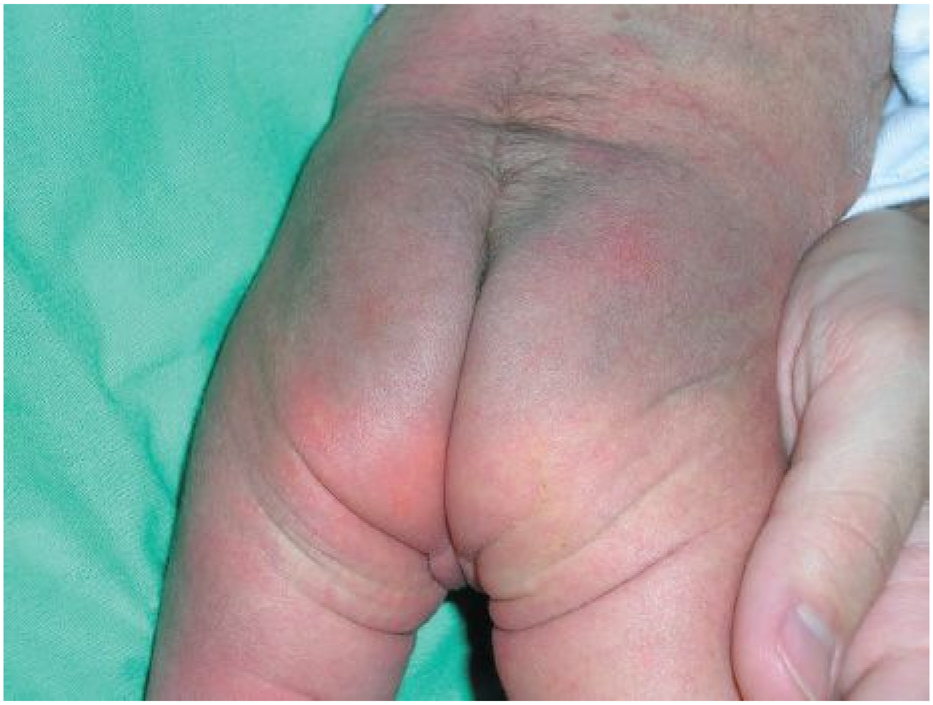

FIGURE 92-3 Large mongolian spots covering the buttocks and back of a Hispanic infant. (*Used with permission from Richard P. Usatine, MD.*)

- Erythema toxicum neonatorum (ETN) is a benign, self-limited skin eruption appearing as small yellow-white papules or vesicles with surrounding skin erythema (**Figures 92-5** and **92-6**).

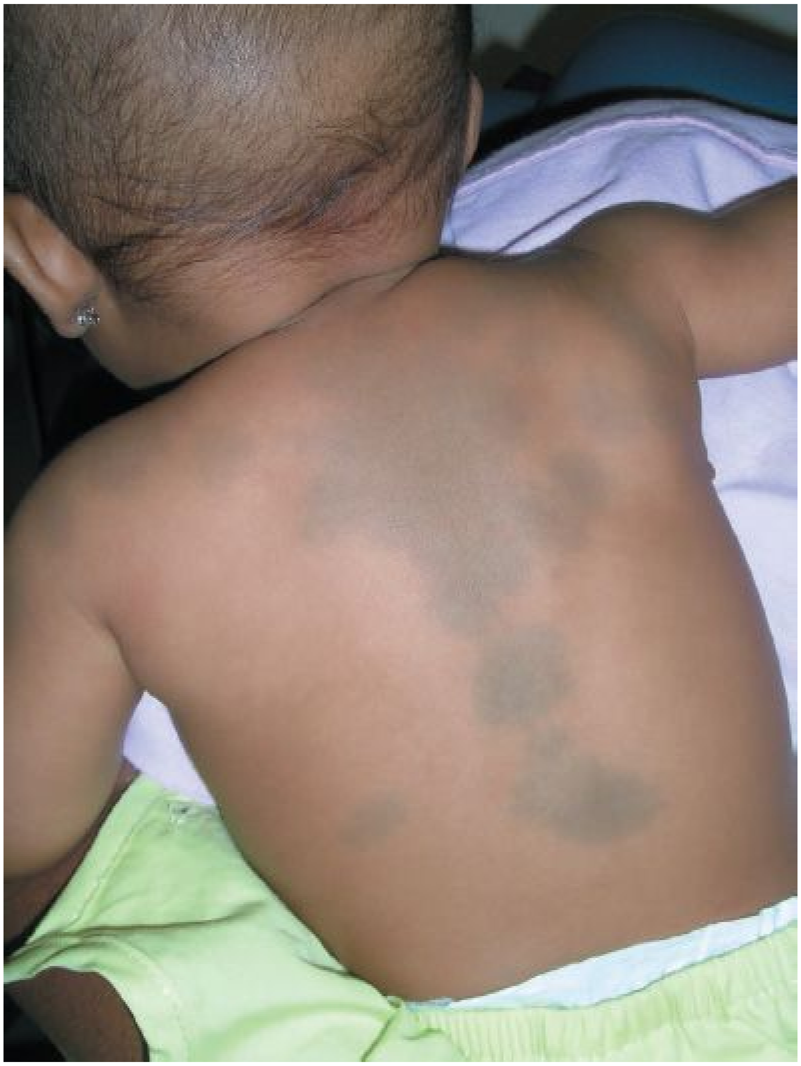

FIGURE 92-4 Prominent mongolian spots on the back of a 1-year-old black child. (*Used with permission from Richard P. Usatine, MD.*)

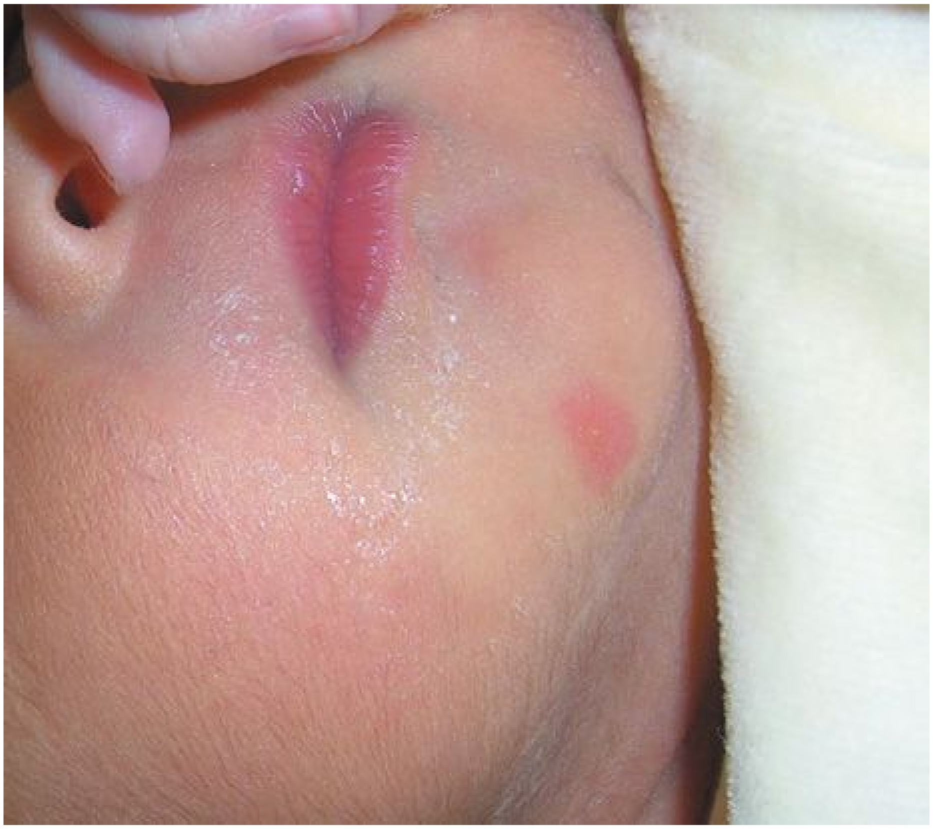

FIGURE 92-5 One small spot of erythema toxicum neonatorum (ETN) on a 2-day-old infant. (*Used with permission from Richard P. Usatine, MD.*)

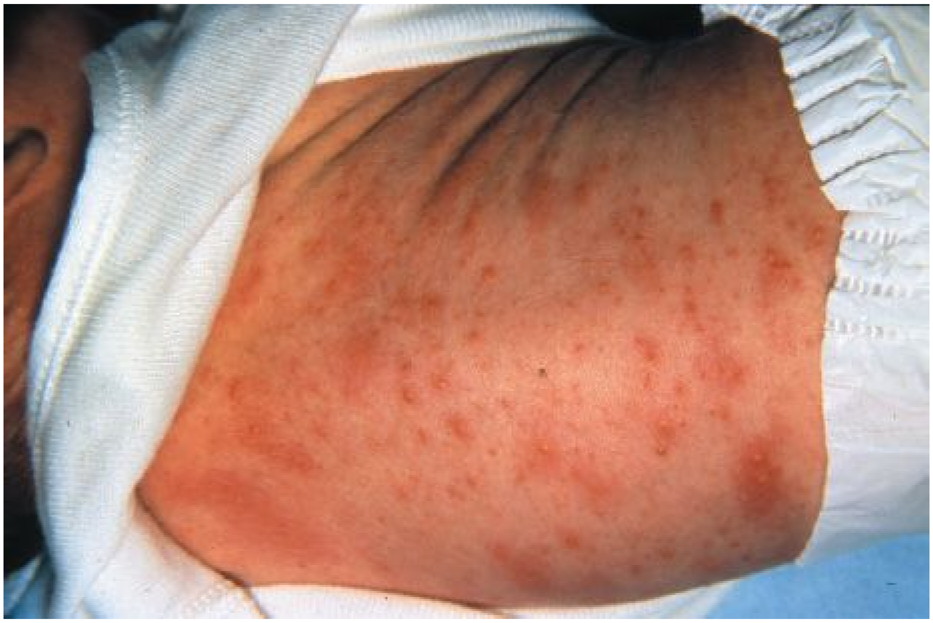

FIGURE 92-6 More widespread case of erythema toxicum neonatorum (ETN) covering the infant. ETN is completely benign and will resolve spontaneously. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

SYNONYMS

- Milia are also called milk spots or oil seed.
- Neonatal acne is also called acne neonatorum.
- Mongolian spots are also known as mongolian blue spots, congenital dermal melanocytosis, and dermal melanocytosis.

EPIDEMIOLOGY

- Approximately 40 percent of newborn infants in the US develop milia.[2] This condition is mainly associated with newborns carried to full term or near term.
- Neonatal acne occurs in up to 20 percent of the newborns. It typically consists of close comedones of the forehead, nose, and cheeks, although other locations are possible. It is most frequent in boys in the first week of life and is 5 times more common in boys than girls.[3]
- The prevalence of mongolian spots varies among different ethnic groups. They have been reported in approximately 96 percent of black infants, 90 percent of Native American infants, 81 to 90 percent of Asian infants, 46 to 70 percent of Hispanic infants, and 1 to 10 percent of white infants.[2,4,5]
- ETN occurs in 30 to 70 percent of full-term infants and in 5 percent of premature infants. The incidence rises with increasing gestational age and birth weight.[6,7]

- In one case series of infants in the first 48 hours of life in San Diego (N = 594), the incidence of milia was 8 percent and ETN, 7 percent.[8] A prevalence rate of ETN of 16.7 percent was found within the first 72 hours in 1,000 Spanish infants.[9]

ETIOLOGY AND PATHOPHYSIOLOGY

- Milia are inclusion cysts that contain trapped keratinized stratum corneum surrounded by a dense lymphocytic infiltrate. Milia are caused by retention of keratin within the dermis. They may rarely be associated with other abnormalities in syndromes such as epidermolysis bullosa and the orofacial digital syndrome (type 1).[2,10]
- Neonatal acne was thought to be due to maternal androgenic hormones stimulating sebaceous glands; more recently it is theorized that neonatal acne is caused by an increase in dehydroepiandrosterone (DHEA) production causing enlargement and possibly hyperactivity of the fetal adrenal gland.[3]
    - Histologic examination shows hyperplastic sebaceous glands with keratin-plugged orifices.
- The mongolian spot is a hereditary, congenital, developmental condition exclusively involving the skin. It results from entrapment of melanocytes in the dermis during their migration from the neural crest into the epidermis.
    - Mongolian spots are associated with cleft lip, spinal meningeal tumor, melanoma, and phakomatosis pigmentovascularis types 2 and 5.[2,11]
    - A few cases of extensive mongolian spots have been reported with inborn errors of metabolism, the most common being Hurler syndrome, followed by gangliosidosis type 1, Niemann-Pick disease, Hunter syndrome, and mannosidosis. In such cases, they are likely to persist rather than resolve.[2,4]
- The etiology of ETN is not known. ETN is thought to be an immune system reaction; the condition is associated with increased levels of

immunologic and inflammatory mediators (e.g., interleukins 1 and 8, eotaxin).[12]

  - The eosinophilic infiltrate of ETN suggests an allergic-related or hypersensitivity-related etiology, but no allergens have been identified. Newborn skin appears to respond to any injury with an eosinophilic infiltrate.
  - Because ETN rarely is seen in premature infants, it is believed that mature newborn skin is required to produce this reaction pattern.

DIAGNOSIS

CLINICAL FEATURES

- Milia are characterized as tiny, pearly white papules (**Figure 92-1**) that are actually small inclusion cysts ranging from 1 to 2 mm in diameter. No visible opening is present.[2]
  - Milia usually appear after 4 to 5 days of life in full-term newborns. Manifestations of milia may be delayed from days to weeks in infants born before term.[11,12]
- Neonatal acne (**Figure 92-2**) includes comedones (i.e., whiteheads), papules, and pustules.
  - Papules and pustules are the most frequent types of lesions (72.7%), followed by comedones only (22.7%).[2]
- A mongolian spot (**Figures 92-3** and **92-4**) is a bluish-black macule or patch typically a few centimeters in diameter, although much larger lesions also can occur. Lesions may be solitary or numerous.
  - Generalized mongolian spots involving large areas covering the entire posterior or anterior trunk and the extremities have been reported.
  - Several variants exist including:[2,4]
    - Persistent mongolian spots—These are larger, have sharper margins, and persist for many years (**Figure 92-4**).

        - Aberrant mongolian spots involve unusual sites such as the face or extremities.
        - Persistent aberrant mongolian spots also are referred to as macular-type blue nevi.

- ETN commonly presents with a blotchy, evanescent, macular erythema (**Figures 92-5** and **92-6**).
    - The macules are irregular, blanchable, and vary in size.
    - In more severe cases (**Figure 92-6**), pale yellow or white wheals or papules on an erythematous base may follow. In approximately 10 percent of patients, 2- to 4-mm pustules develop.[7]
    - ETN occurs within the first 4 days of life in full-term infants, with the peak onset within the first 48 hours following birth. Rare cases have been reported at birth.
    - Delayed onset can rarely occur in full-term and preterm infants up to 14 days of age.
    - Infants with ETN otherwise are healthy and lack systemic symptoms.

TYPICAL DISTRIBUTION

- Milia are found on the forehead, nose, upper lip, cheeks, and scalp. They can, however, occur anywhere and may be present at birth or appear subsequently. The milia on the child in **Figure 92-1** were present at birth.

- Neonatal acne occurs on the face with the cheeks being the most common site (81.8%) (**Figure 92-2**).[2]

- Mongolian spots most commonly involve the lumbosacral area (**Figure 92-3**), but the buttocks, flanks, and shoulders (**Figure 92-4**) may be affected with extensive lesions.

- ETN sites of predilection include the forehead, face, trunk, and proximal extremities, but lesions may occur anywhere, including the genitalia. Involvement of the mucous membranes and palms and soles rarely occurs (**Figures 92-5** and **92-6**).

LABS AND IMAGING

- No laboratory studies are required.
- In extensive mongolian spots involving the back, radiographic studies are needed to rule out a spinal meningeal tumor or anomaly.[4]
- ETN is often diagnosed clinically, based on history and physical examination, but a peripheral smear of intralesional contents can be done to confirm the diagnosis.[2,7]
  - A Tzanck smear or Gram stain shows inflammatory cells with greater than 90 percent eosinophils and variable numbers of neutrophils.
  - A complete blood count (CBC) also shows eosinophilia (up to 18%) in approximately 15 percent of patients. Eosinophilia may be more pronounced when the eruption shows a marked pustular component.

DIFFERENTIAL DIAGNOSIS

Other diagnoses that can be confused with milia, neonatal acne, and ETN include:

- Miliaria—Heat rash (prickly heat) with tiny papules that can be red (miliaria rubra) or clear (miliaria crystallina) or pustular (miliaria pustulosa) (**Figure 92-7**). Miliaria results from sweat retention caused by partial closure of eccrine structures. Both milia and miliaria result from immaturity of the skin structures, but they are clinically distinct entities.

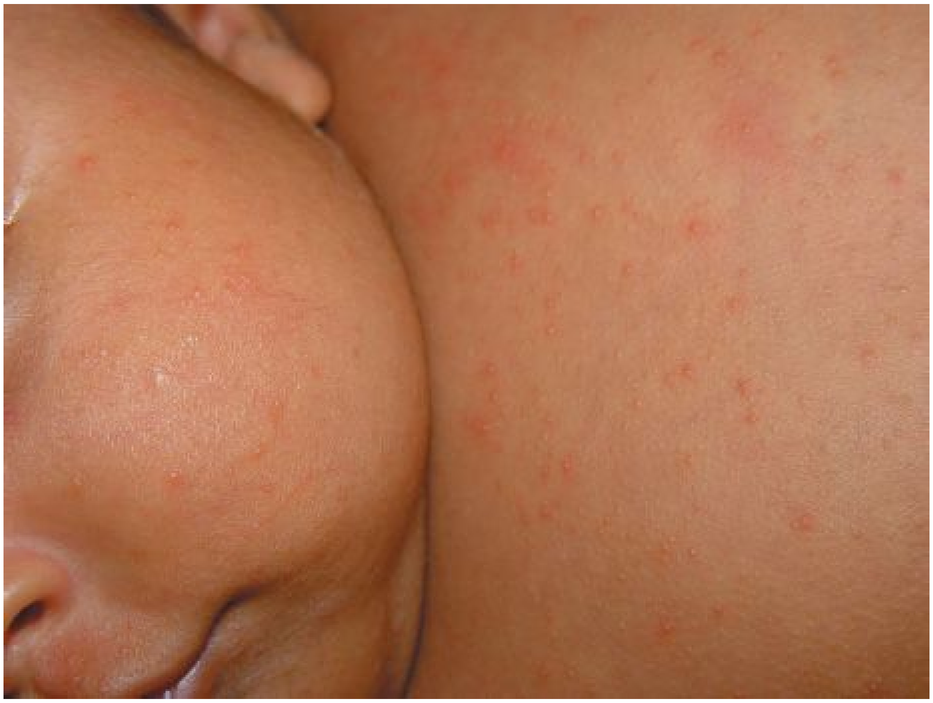

FIGURE 92-7 Miliaria (heat rash) in a 6-month-old infant on a warm summer day. (*Used with permission from Richard P. Usatine, MD.*)

- Neonatal pustular melanosis—This eruption, present at birth, consists of 2- to 4-mm nonerythematous vesicles filled with a milky fluid. This rash occurs in 5 percent of African American newborns and in less than 1 percent of white newborns, and fades in the first 3 to 4 weeks of life (see Chapter 94, Pustular Diseases of Childhood).
- Drug reaction (maternal medication or infant)—History of drug administration and can be more widespread.

Mongolian spots may be confused with the following lesions also present at birth or shortly after:

- Congenital melanocytic nevi—These lesions are much less common (1 to 2% of newborns). They are of variable color from tan or brown to red or black, often within a single lesion and the pigment may fade off into surrounding skin. The borders are often irregular and the lesion can appear slightly raised over time (although a macular portion is usually found at the edges). Most congenital melanocytic nevi have a darker color and more discrete borders than mongolian spots. A biopsy is only needed if melanoma is suspected (see Chapter 144, Congenital Nevi).

- There are reports of Mongolian spots being confused for the bruising that occurs in child abuse. A good history and a clear knowledge of the pattern of mongolian spots should help to differentiate between these two entities.

ETN can also be confused with the following:

- Miliaria—See preceding information.
- Folliculitis—Primary lesion is a papule or pustule pierced by a central hair, although the hair may not always be visualized. Deeper lesions present as erythematous, often fluctuant, nodules. Folliculitis rarely occurs in the first few days of life when ETN is most commonly seen (see Chapter 100, Folliculitis).
- Herpes simplex virus—A single vesicle or crops of vesicles on an erythematous base are often the first manifestations of neonatal herpes simplex virus infection, which is associated with a high morbidity and mortality. The appearance of these lesions may mimic ETN. Any vesicular rash in the newborn should be evaluated for the possibility of herpes simplex virus infection (see Chapter 187, Congenital Infections).
- Chickenpox—The characteristic rash appears in crops of lesions beginning with red macules and passing through stages of papule, vesicle (on an erythematous base), pustule, and crust. Simultaneous presence of different stages of the rash is a hallmark. Infants are mostly born with adequate maternal antibodies to varicella, so that timing should differentiate between these two conditions (see Chapter 108, Chickenpox).
- Cutis marmorata (**Figure 92-8**) is reticulated mottled skin with symmetric involvement of the trunk and extremities produced by a vascular response to cold; the change resolves with heat. This entity can persist for weeks or months. No treatment is indicated.

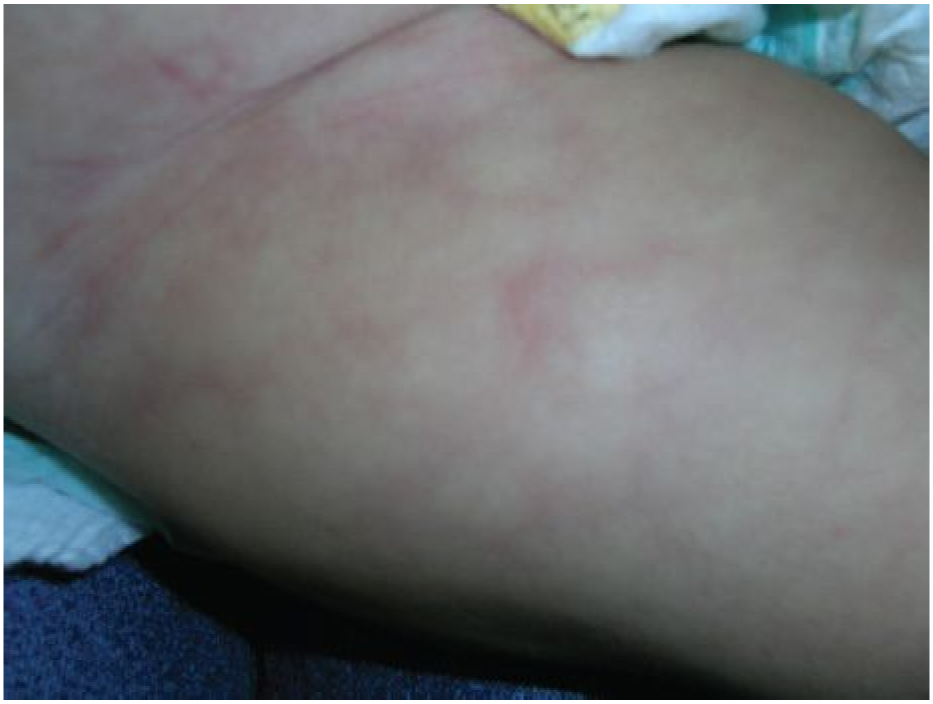

FIGURE 92-8 Cutis marmorata in a 4-month-old infant in a cold exam room. Notice the reticular pattern. This resolved when the infant was warmed. (*Used with permission from Richard P. Usatine, MD.*)

- Harlequin color change affects 10 percent of full-term babies and occurs when the newborn lies on one side and erythema develops on one side of the body, while blanching is seen on the contralateral side. The color change fades after 30 seconds to 20 minutes and resolves with increased muscle activity or crying. It begins between the second to fifth days of life and lasts up to 3 weeks.[13]
- Neonatal lupus is a rare syndrome in which maternal autoantibodies are passively transferred to the baby producing well-demarcated, erythematous, scaling patches that are often annular, predominately on the scalp, neck or face (**Figure 92-9**). The condition is self-limited and resolves without scarring by 6 to 7 months of age. It is associated with congenital heart block. Treatment includes photoprotection; mild topical steroids may be helpful.

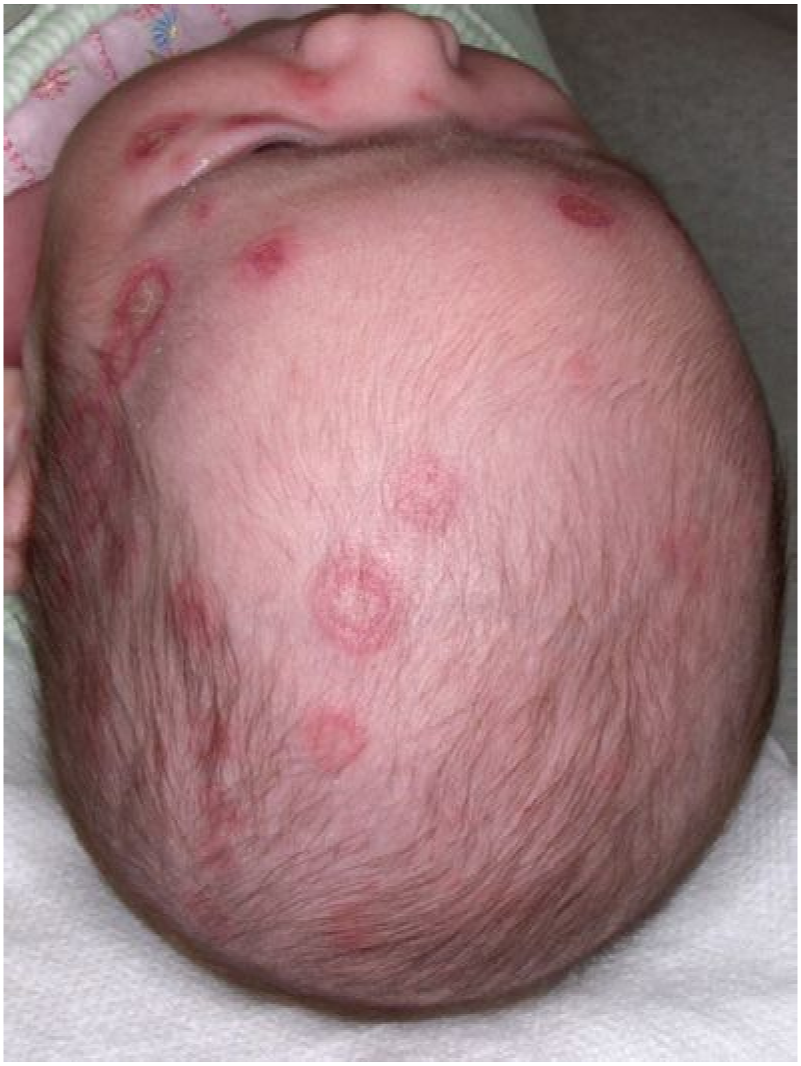

FIGURE 92-9 Neonatal lupus from acquired antibodies through transplacental transmission from the mother with active systemic lupus erythematosus (SLE). Note the annular patterns of scale. (*From Warner AM, Frey KA, Connolly S. Photo rounds: annular rash on a newborn. J Fam Pract. 2006;55(2):127-129. Reproduced with permission from Frontline Medical Communications*.)

MANAGEMENT

- Milia, neonatal acne, mongolian spots, and ETN are benign conditions and parents should be reassured that they resolve with time.

- Although acne treatment generally is not indicated, infants can be treated with a topical ketoconazole 2 percent cream twice daily for 1 week.[3] If acne persists more than 4 weeks, infantile acne is likely and 2.5 percent benzoyl peroxide lotion can be used.[3]

PROGNOSIS

- Milia usually disappear within several weeks.
- Neonatal acne may come and go until the baby is between 4 and 6 months of age.
- Mongolian spots may persist for many years but usually disappear within 3 to 5 years and almost always by puberty.
- ETN usually lasts for several days but can change rapidly, with lesions appearing and disappearing in different areas over hours.

PATIENT EDUCATION

- Milia is a benign self-limiting rash that disappears within a few months without leaving any scars. No drug therapy is required and use of nonprescription rash medications is not recommended.
- Neonatal acne resolves on its own in weeks. Oils and lotions do not help and may actually aggravate the acne.
- Mongolian spots are likely to fade over time and may disappear by age 7 to 13 years.
- ETN will usually disappear within 2 weeks.

93 CHILDHOOD HEMANGIOMAS AND VASCULAR MALFORMATIONS

Richard P. Usatine, MD
Megha Madhukar, MD

PATIENT STORY

A baby girl is brought to the office because her mother is concerned over the growing strawberry hemangioma on her face. Her mother is reassured that most of these childhood hemangiomas regress over time and that there is no need for immediate treatment (**Figure 93-1**).

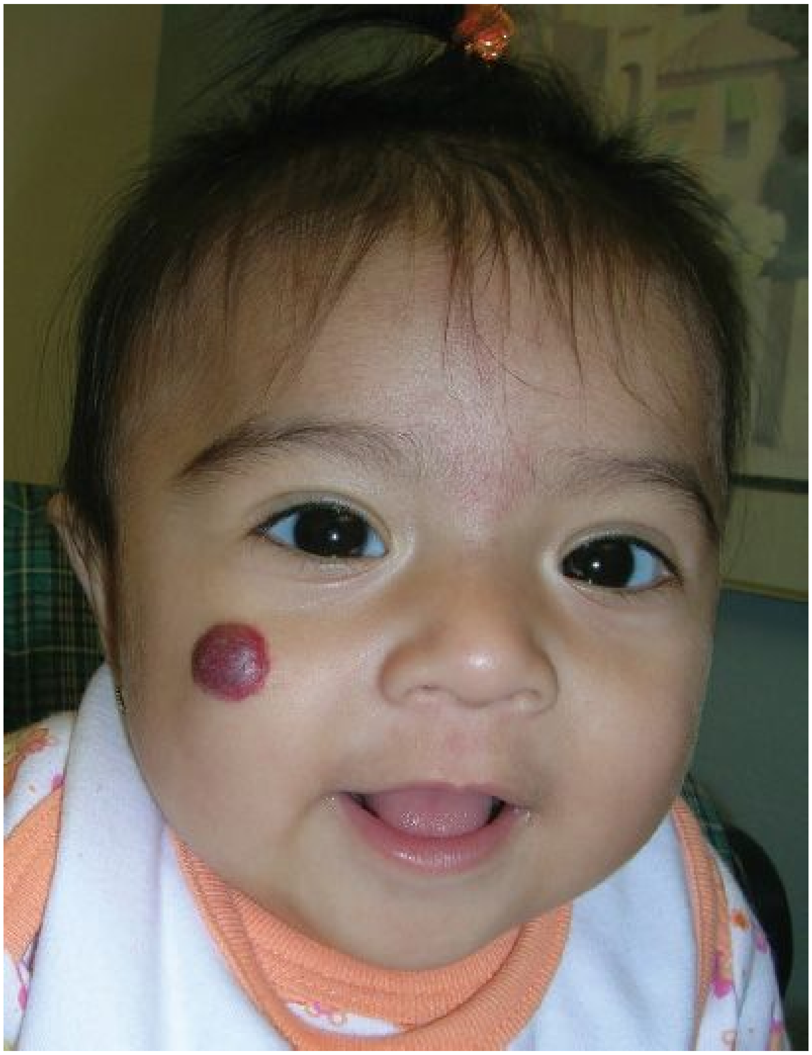

FIGURE 93-1 Strawberry hemangioma on the face causing no functional problems. Treatment is reassurance and watchful waiting. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Hemangiomas are the most common benign tumors of infancy. They can be problematic if they block vision or interfere with any vital function. Most hemangiomas are small and of cosmetic concern only.

SYNONYMS

Infantile hemangiomas, angiomas. Strawberry hemangiomas are also called superficial hemangiomas of infancy. Cavernous hemangiomas are also called deep hemangiomas of infancy.

EPIDEMIOLOGY

- Approximately 30 percent of hemangiomas are present at birth; the other 70 percent appear within the first few weeks of life.
- Hemangiomas occur more commonly in fair-skinned, premature, female infants. In one study, the mothers of children with hemangiomas are of higher maternal age, have a higher incidence of preeclampsia and placenta previa, and are more likely to have had multiple gestation pregnancies.[1]
- There is an increased incidence of vascular anomalies in the families of children born with hemangiomas.[1]
- The data are mixed as to whether chorionic villus sampling may play a role in the formation of hemangiomas.[1]
- Females are affected more often than males (2.4:1).[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Hemangiomas consist of an abnormally dense group of dilated blood vessels. Most childhood hemangiomas are thought to occur sporadically.
- Hemangiomas are characterized by an initial phase of rapid proliferation, followed by spontaneous and slow involution, often leading to complete regression. Most childhood hemangiomas are small and innocuous, but some grow to threaten a particular function (**Figure 93-2**) or even life.

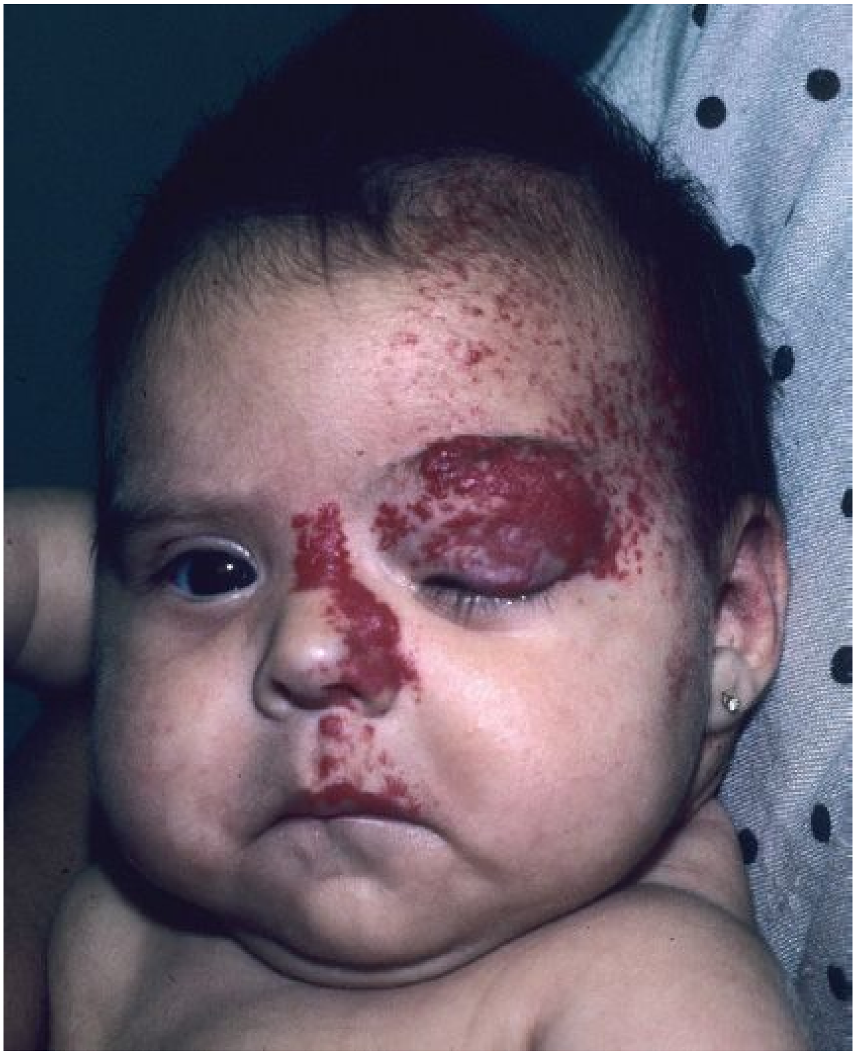

FIGURE 93-2 Large hemangioma on the face needing immediate treatment to prevent amblyopia in the left eye. Although this hemangioma follows the V1 dermatome, this is not a port-wine stain and the patient does not have Sturge-Weber syndrome. (*Used with permission from Richard P. Usatine, MD.*)

- Rapid growth during the first month of life is the historical hallmark of hemangiomas, when rapidly dividing endothelial cells are responsible for the enlargement of these lesions. The hemangiomas become elevated and may take on numerous morphologies (dome-shaped, lobulated, plaque-like, and/or tumoral). The proliferation phase occurs during the first year, with most growth taking place during the first 6 months of life. Proliferation then slows and the hemangioma begins to involute.

- The involutional phase may be rapid or prolonged. No specific feature has been identified in explaining the rate or completeness of involution. However, in one type of hemangioma, the rapidly involuting congenital hemangioma, the proliferation phase occurs entirely in utero such that the lesion is fully developed at birth, followed by complete involution during the second year of life.[1]
- A good rule of thumb is 50 percent of childhood hemangiomas will involute by age 5 years, 70 percent by age 7 years, and the remainder of childhood hemangiomas will take an additional 3 to 5 years to complete the process of involution.[1]
- Of the lesions that have involuted by age 6 years, 38 percent will leave residual evidence of the hemangioma in the form of a scar, telangiectasia, or redundant, “bag-like” skin. The chance of a permanent scar increases the longer it takes to involute. For example, of the lesions that involute after age 6 years, 80 percent may exhibit a cosmetic deformity.[1]

DIAGNOSIS

CLINICAL FEATURES

Early lesions may be subtle, resembling a scratch or bruise, or alternatively may look like a small patch of telangiectasias or an area of hypopigmentation. Hemangiomas can start off as a flat red mark, but as proliferation ensues, it grows to become a spongy mass protruding from the skin. The earliest sign of a hemangioma is blanching of the involved skin with a few fine telangiectasias followed by a red macule. Rarely, a shallow ulceration may be the first sign of an incipient hemangioma.[1] Hemangiomas are typically diagnosed based on appearance, rarely warranting further diagnostic tests.

Hemangiomas may be superficial, deep, or a combination of both. Superficial hemangiomas are well defined, bright red, and appear as nodules or plaques located above clinically normal skin (**Figures 93-1** to **93-3**). Deep hemangiomas are raised flesh-colored nodules, which often have a bluish hue and feel firm and rubbery (**Figure 93-4**).

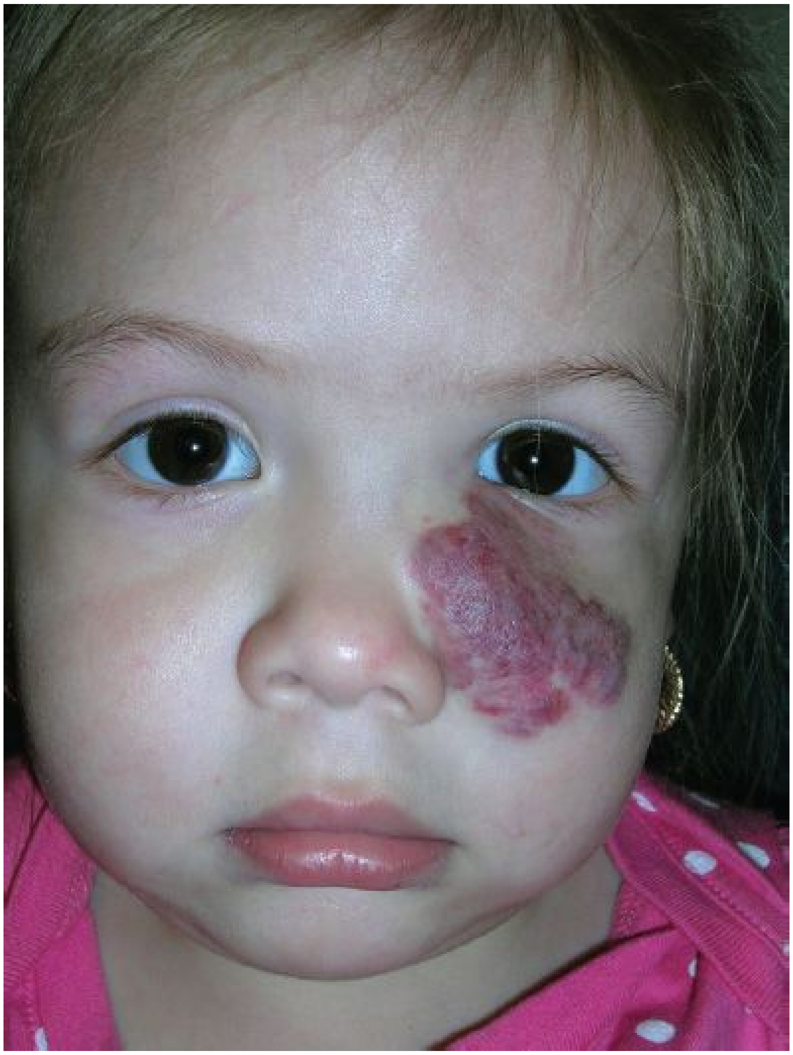

FIGURE 93-3 Strawberry hemangioma present since birth on the face of a 22-month-old girl. Although it is close to her eye, her vision has never been occluded. She has been followed by ophthalmology and no active treatment was recommended. The hemangioma grew larger during the first year of life and is now beginning to involute without treatment. (*Used with permission from Richard P. Usatine, MD.*)

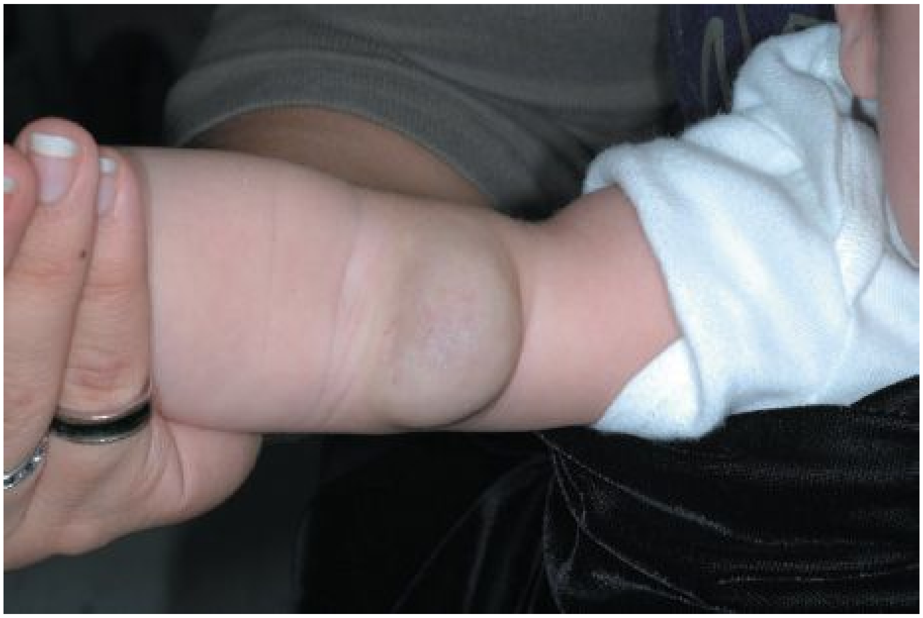

FIGURE 93-4 Deep (cavernous) hemangioma on the arm in a 9-month-old child. Treatment is watchful waiting. (*Used with permission from Richard P. Usatine, MD.*)

Most are clinically insignificant unless they impinge on vital structures, ulcerate, bleed, incite a consumptive coagulopathy, or cause high output cardiac failure or structural abnormalities. Blocking vision is a common reason needed for treatment (**Figure 93-2**).

TYPICAL DISTRIBUTION

Anywhere on the body, most often on the face, scalp, back, or chest.

IMAGING

Most hemangiomas of infancy do not need imaging. If the hemangioma is very large, deep or undefined, MRI with and without IV gadolinium helps delineate the location and extent of the hemangioma while also differentiating them from high flow vascular lesions, like arteriovenous malformations.[1] Ultrasound is a useful tool to differentiate hemangiomas from other subcutaneous structures such as cysts and lymph nodes as well as from other soft-tissue masses.[1]

Plain radiography may be useful for evaluating hemangiomas that impinge on an airway.[1]

BIOPSY

Biopsies are rarely needed and can be risky because vascular lesions may bleed profusely. If a biopsy is being considered, it might be best to refer to a specialist.

DIFFERENTIAL DIAGNOSIS

- Superficial capillary malformations that are frequently seen in infants include those above the eyelids and nape of the neck. These are called *salmon patches* and are not dangerous. The “angel’s kisses” on the eyelids usually disappear by age 2 years. The “stork bites” may last into adulthood but are rarely an issue because they often get covered by hair (**Figures 93-5** and **93-6**). These capillary malformations are a variant of nevus flammeus or port-wine stain. They are macular, sharply circumscribed, pink to purple, and varied in size (see Chapter 170, Hereditary and Congenital Vascular Skin Lesions).

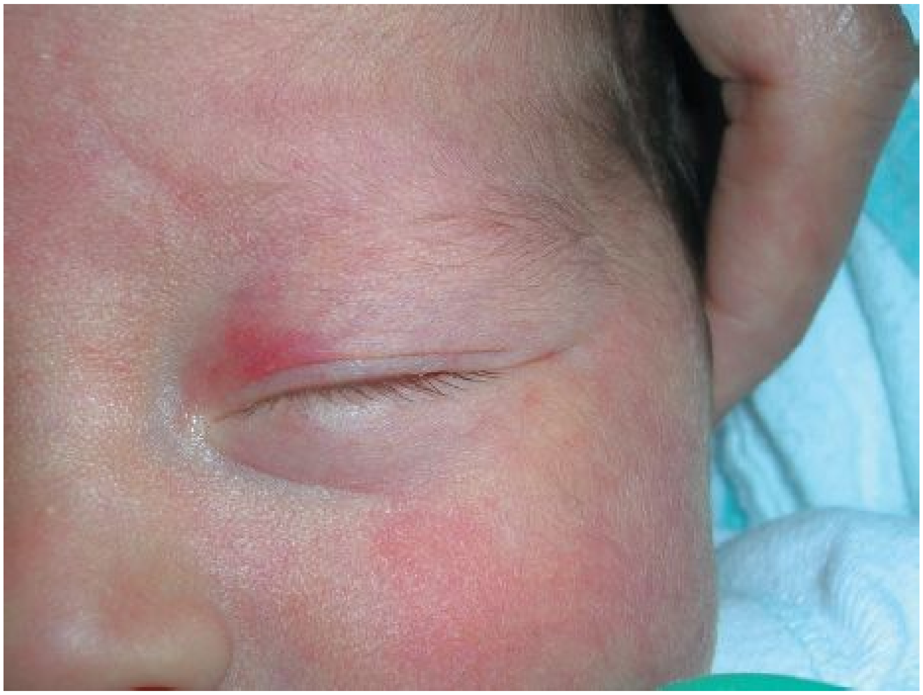

FIGURE 93-5 Salmon patch (a variant of nevus flammeus) on the upper eyelid called an “angel’s kiss.” These resolve by age 2 years. (*Used with permission from Richard P. Usatine, MD.*)

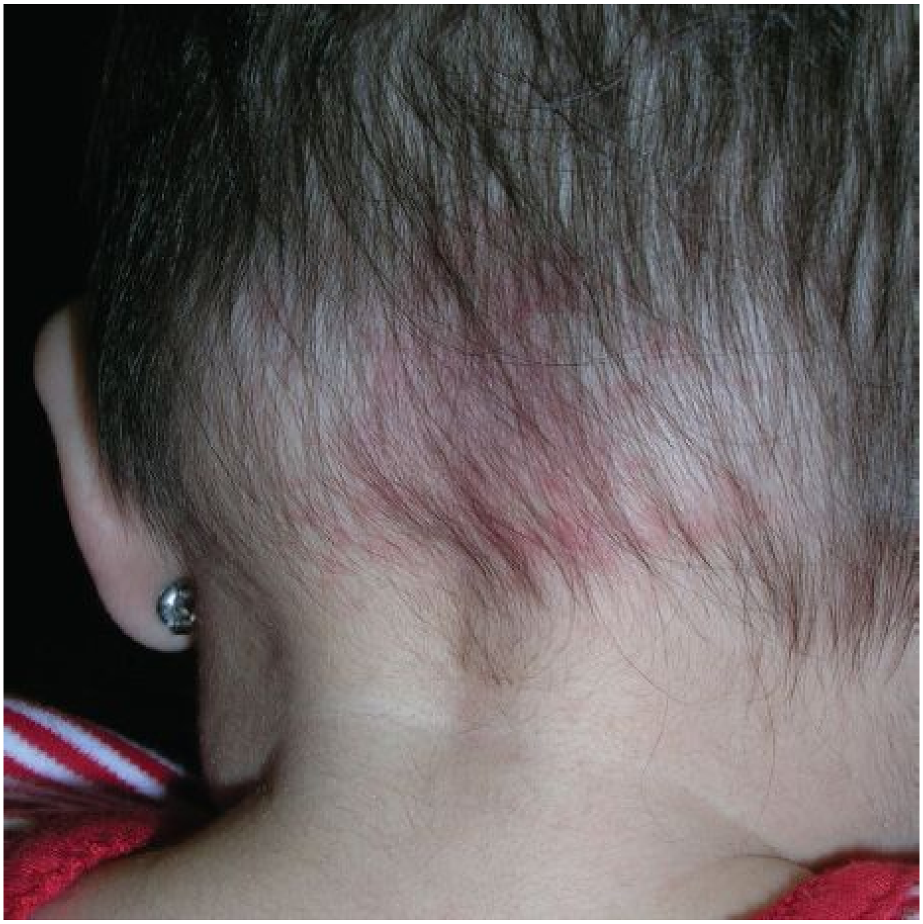

FIGURE 93-6 Salmon patch (a variant of nevus flammeus) on the neck of this young child called a “stork bite.” These vascular malformations persist into adulthood. (*Used with permission from Richard P. Usatine, MD.*)

- Blue rubber bleb nevus syndrome—Bluish cutaneous vascular malformations that empty with pressure, texture resembles rubbery nodules, similar to deep hemangiomas.[2]
- Maffucci syndrome—Rare congenital nonhereditary mesodermal dysplasia characterized by multiple enchondromata, cutaneous hemangiomas, and more recently spindle cell hemangiomas.[3] It is important to identify Maffucci syndrome early because it is associated with an increased risk of malignancy. May appear as multiple vascular malformations of the skin with a “grape-like” appearance (see Chapter 170, Hereditary and Congenital Vascular Skin Lesions).

- Arteriovenous malformation—Benign, single red papules on head or neck, may be cutaneous or mucosal.[4]
- Infantile fibrosarcoma—A rare and highly malignant tumor of childhood that may take on the form of a highly vascularized mass, resembling a hemangioma, especially after a hemangioma has ulcerated as a result of rapid proliferation.[5]

MANAGEMENT

- The majority of hemangiomas will eventually involute without complications and require no treatment, but approximately 20 percent cause complications like ulcerations, irreversible cutaneous expansion, or threaten vital structures such as the eyes, nose, or airways.[6]
- Any large segmental hemangioma on the face could be part of the PHACE (posterior fossa malformations, hemangiomas, arterial anomalies, coarctation of aorta, cardiac defects, eye abnormalities) syndrome and therefore will need evaluation of the eyes, central nervous system (CNS), and heart (see Chapter 227, PHACE syndrome).
  - **P**osterior fossa—Brain malformations present at birth.
  - **H**emangioma—Segmental hemangioma covers a large area on the head or neck (greater than 5 cm).
  - **A**rterial lesions—Abnormalities of the blood vessels in the neck or head.
  - **C**ardiac abnormalities/aortic coarctation.
  - **E**ye abnormalities.
  - Sternal cleft/pit and supraumbilical raphe may also be present.
- Any lower face or beard hemangioma can be a marker for laryngeal hemangiomatosis. Snoring in such a child can be a bad sign. Refer to a head and neck surgeon.
- Hemangiomas in trauma-prone areas are most likely to ulcerate. These include the diaper area (**Figure 93-7**) and the back of the head. Small ulcerations can be treated with topical mupirocin in morning and metronidazole gel in the evening. SOR C

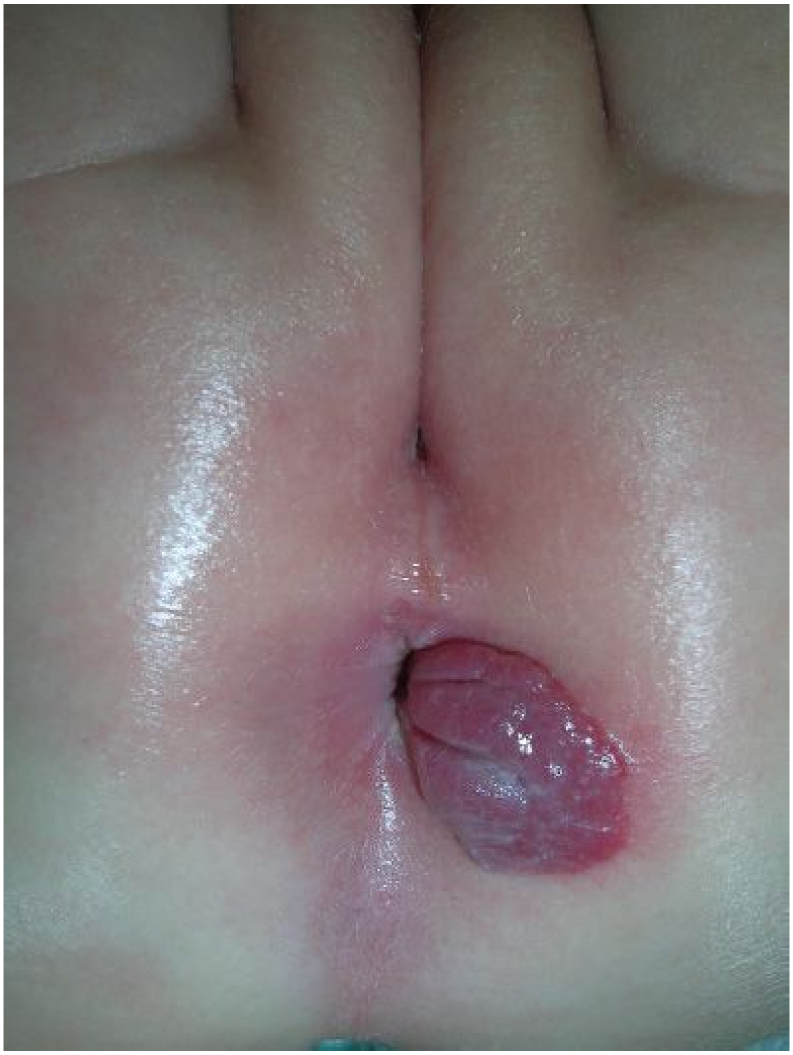

FIGURE 93-7 Strawberry hemangioma in the perianal area of a 5-month-old girl. This is at high risk of ulceration. (*Used with permission from Richard P. Usatine, MD.*)

- Propranolol is now the first line of therapy for function-impairing and rapidly proliferating infantile hemangiomas.[2–4] It has been successfully used to treat periorbital infantile hemangiomas and other problematic infantile hemangiomas (**Figure 93-8**).[2–4] SOR Ⓑ

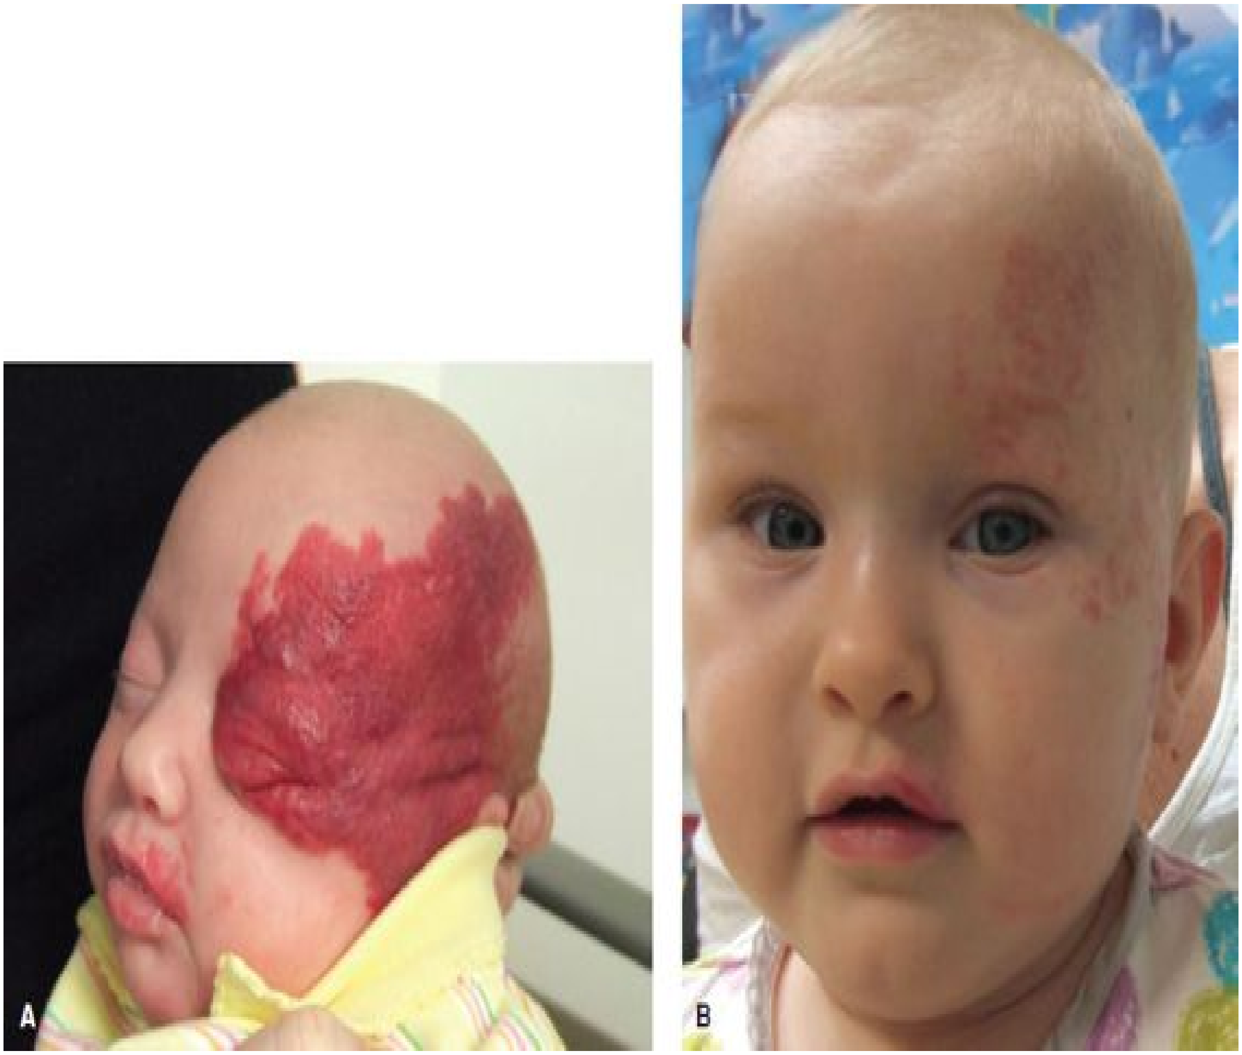

FIGURE 93-8 Large infantile hemangioma in which the child does not have the PHACE syndrome. However, urgent therapy was needed to shrink this hemangioma. **A.** Before propranolol therapy. **B.** After propranolol therapy. (*Used with permission from John Browning, MD.*)

- Propranolol (20 mg/5 mL) is given orally starting with 1 mg/kg per day divided into qid dosing. It is advisable to monitor for hypoglycemia and low blood pressure even though this treatment has been found to be safe in a number of studies.[2–4] If the child is tolerating the treatment well, the dose may be increased to the recommended maintenance dose of 1.5 to 2 mg/kg per day in divided doses.[2,4] Treatment should be maintained until the lesion is completely involuted or the child is 1 year of age.

- Prior to the discovery of the benefits and safety of propranolol as a first-line treatment, prednisone 3 to 5 mg/kg per day had been shown to provide an effective and rapid way of treating hemangiomas.[7] SOR B In a study, 68 percent of patients receiving systemic corticosteroid treatment with oral prednisone experienced rapid and virtually complete involution of hemangiomas.[7] Another 25 percent experienced significant regression, and treatment demonstrated no effect in 7 percent of patients. The authors recommended treating with oral prednisone for 6 to 8 weeks, and in more severe cases, for 12 weeks. Side effects include moon facies and irritability, which resolved once therapy was discontinued.[7] Growth may be retarded temporarily.
- Ultrapotent topical corticosteroids have been found especially helpful in the treatment of small hemangiomas, especially periocular hemangiomas and those at sites prone to ulceration and disfigurement. Seventy-four percent of patients demonstrated good or at least partial response to treatment with the majority experiencing cessation of growth before what would have been expected for their age. Thinner, more superficial hemangiomas demonstrated better improvement than thicker, deeper lesions.[8] SOR B
- Intralesional corticosteroid injections, composed of a mixture containing triamcinolone acetonide (20 mg average dose) and betamethasone acetate (3 mg average dose) with varying number of injections, have been found to successfully treat head and neck childhood hemangiomas in properly selected infants. In a research study, 13 percent of the hemangiomas treated with intralesional injections almost completely involuted, 32 percent showed greater than 50 percent reduction in volume, 32 percent showed definite but less than 50 percent reduction in volume, and 23 percent showed little to no decrease in size.[9] SOR B Avoid intralesional steroids around eye.
- Treatment with flashlamp-pumped pulsed-dye laser has been found to be an effective treatment method for superficial cutaneous hemangiomas at sites of potential functional impairment and on the face. In a study, 76 percent of patients were found to have excellent or good results with the flashlamp-pumped pulsed-dye laser. Hemangiomas with a deep component do not seem to benefit from flashlamp-pumped pulsed-dye

laser therapy to the same degree as a truly superficial hemangioma, as the laser is limited by its depth of vascular injury.[10] SOR B

- Facial hemangiomas causing severe functional disturbance and serious psychological distress are strong reasons to consider surgical excision before the child reaches the expected age of spontaneous regression. SOR C
- Large periocular hemangiomas demand prompt treatment to prevent debilitating consequences such as amblyopia (**Figure 93-2**). Early treatment is also recommended for proliferative labial tumors because not only do they have a tendency to bleed, but they also make eating difficult. Additionally, early treatment with a consideration for surgery is advised for hemangiomas located on the nasal tip as they regress slowly and may ultimately result in distortion of the nasal framework.[11]
- Laser surgery may be considered for selective ablation of vascular tissue, like ulcerated hemangiomas and thin superficial hemangiomas, especially when their locations may result in psychosocial distress for the patient, that is, facial hemangiomas. The pulsed-dye laser seems especially promising with its ability to selectively damage blood vessels with minimal damage to surrounding tissues.[12] This procedure is also associated with decreased pain and increased healing.[12] SOR B
- Surgical excision of involuted hemangiomas is not uncommon to remove the residual tissue that may be causing cosmetic or functional impairment. Excision is performed in late involution to reduce the risk of hemorrhage.
- Depending on the location and how complex the hemangioma is, consultations with pediatric dermatologists, ophthalmologists, otolaryngologists, plastic surgeons, and pediatric neurosurgeons may be necessary to ensure proper care.

NEW TOPICAL THERAPY

- Topical timolol ophthalmic gel or solution has been shown in a number of studies to effectively treat infantile hemangiomas (**Figure 93-9**).[13–15] SOR B One of the studies noted that predictors of better response were superficial type of hemangioma ($p = 0.01$), 0.5 percent timolol concentration ($p = 0.01$), and duration of use longer than 3 months (p =

0.04).[14] SOR B Another study using 0.5 percent ophthalmic solution 3 to 4 times daily in patients with small superficial hemangiomas found that treatment was most effective in the early proliferative stage.[13] SOR B

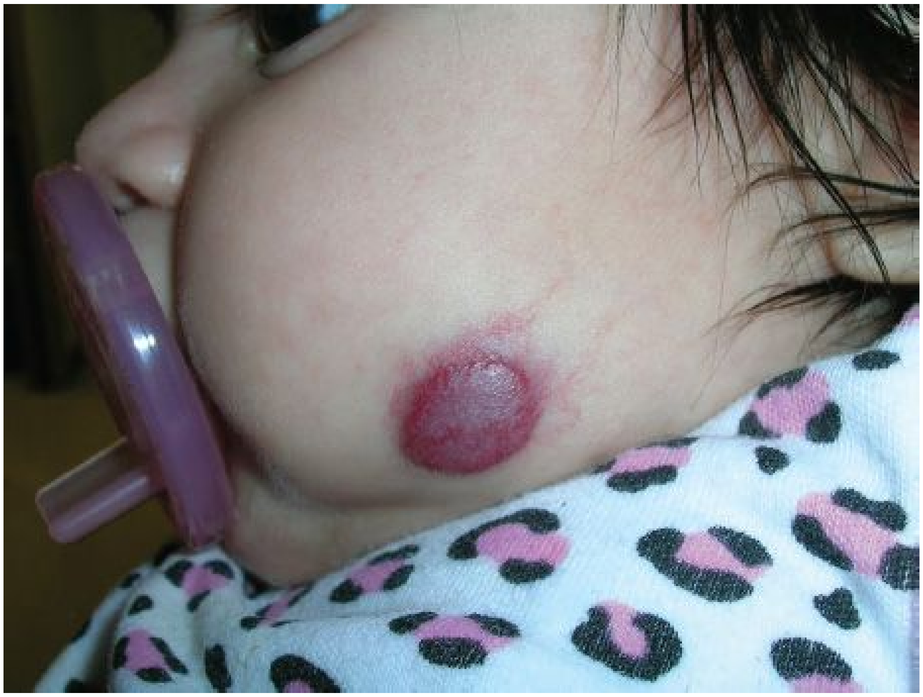

FIGURE 93-9 Strawberry hemangioma on the face causing no functional problems in a 3-month-old girl. The parents requested treatment and a course of topical timolol gel 0.5 percent was initiated. While the hemangioma was in the beard area, the child had no problems with breathing or snoring. A referral to ENT was not needed to investigate for laryngeal hemangiomatosis. (*Used with permission from Richard P. Usatine, MD.*)

FOLLOW-UP

Watchful waiting and serial observations during well-child examinations are recommended for uncomplicated hemangiomas of infancy. Hemangiomas with complicating factors need close follow-up on an individual basis.

PATIENT EDUCATION

Hemangiomas are benign and not cancer. They are common and up to 1 in 10 white babies will have one. Most hemangiomas will go away spontaneously and not need treatment. For those needing treatments, there are new treatments that are safe and effective (oral propranolol and topical timolol).

94 PUSTULAR DISEASES OF EARLY CHILDHOOD

Andrew Shedd, MD
Richard P. Usatine, MD
Heidi Chumley, MD

PATIENT STORY

A 1-year-old boy is brought for a second opinion about the recurrent pruritic vesicles and pustules on his hands and feet. This is the third episode, and in both previous episodes, the physicians thought the child had scabies. The child was treated with permethrin both times and within 2 to 3 weeks the skin cleared. No other family members have had lesions or symptoms. **Figures 94-1** to **94-3** demonstrate a typical case of infantile acropustulosis that is often misdiagnosed as scabies. Although the condition can be recurrent, it is ultimately self-limited and will resolve.

INTRODUCTION

Acropustulosis and transient neonatal pustular melanosis (TNPM) are pustular diseases that typically present in infancy. Acropustulosis is a pruritic vesiculopustular disease presenting between 2 and 10 months of age and remitting spontaneously by 36 months of age. TNPM is present at birth and characterized by 2- to 3-mm hyperpigmented macules and pustules. Acropustulosis may require symptomatic treatment of pruritus, but otherwise both illnesses are self-limiting.

EPIDEMIOLOGY

Acropustulosis:

- Rare, intensely pruritic, vesiculopustular disease of young children.[1]
- Typically begins in the second or third months[1] of life and as late as 10 months of age.[2]
- Occur slightly more often in darker-skinned patients and males.[1]
- Typically spontaneously remits by 6 to 36 months of life.[2]

Transient neonatal pustular melanosis:

- A disease of newborns.[3]
- Equal male-to-female ratio.[3]
- Seen in 4.4 percent of black infants and 0.6 percent of white infants.[4]
- Early, spontaneous remission.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

Acropustulosis:

- The exact cause and mechanism have yet to be determined.[5]
- Some physicians speculate that it is a persistent reaction to scabies ("postscabies syndrome"). Suggestive of this infectious etiology, infantile acropustulosis will occasionally be concurrently present among siblings. Also, patients diagnosed with this disorder frequently have received prior treatment for scabies, which may either provide evidence of an infectious etiology or demonstrate the frequent misdiagnosis, as in the previous patient. Odom et al. concludes that in some cases, this disease may represent a hypersensitivity reaction to *Sarcoptes scabiei*.[4]

Transient neonatal pustular melanosis:

- The etiology is uncertain;[6] however, it may result from an obstruction of the pilosebaceous orifice.[3]

DIAGNOSIS

- Acropustulosis—A workup to rule out potentially serious infectious causes should be considered whenever confronted with a new pustular dermatosis early in a child's life. A workup might include a scraping for scabies and KOH preparation as rapid diagnostic tests. If these studies are negative, the diagnosis may be made clinically as described below.
- TNPM—This diagnosis can often be made clinically. However, if performed, a Wright stain of the exudate will reveal a predominance of neutrophils with an occasional eosinophil, and the Gram stain will be negative.[3]

CLINICAL FEATURES

Acropustulosis:

- These vesiculopustular lesions begin around the second or third months of life and are typically concentrated on the hands and feet (**Figures 94-1** to **94-3**).[1]
- They begin acutely as small pink papules and progress within 24 hours to pustules[1] of less than 5 mm in diameter.[2]
- Recurrent episodes of these intensely pruritic lesions typically last 10 days and may recur every 2 to 5 weeks,[1,2] decreasing in frequency and severity[2] until spontaneous remission around 3 years of age.[1]
- There may be a residual scale and postinflammatory hyperpigmentation.[2]

Transient neonatal pustular melanosis:

- This condition is characterized by the presence at birth of 2- to 3-mm macules and pustules[4] on a nonerythematous base (**Figures 94-4** to **94-7**).[7]

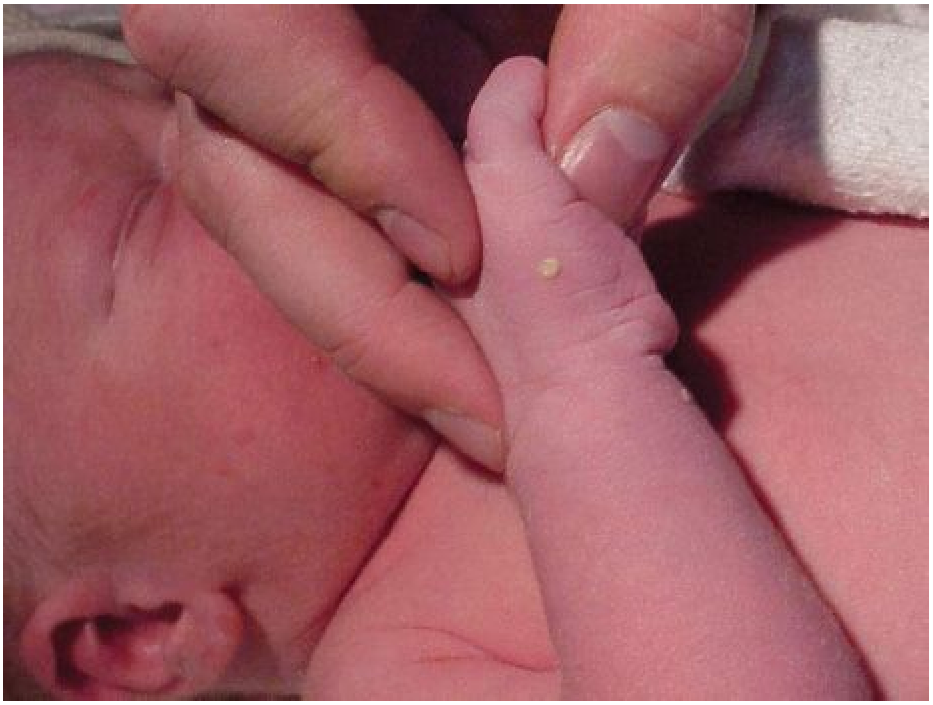

FIGURE 94-4 Transient neonatal pustular melanosis on the hand of a newborn. Note the pustule does not have surrounding erythema. (*Used with permission from Dan Stulberg, MD.*)

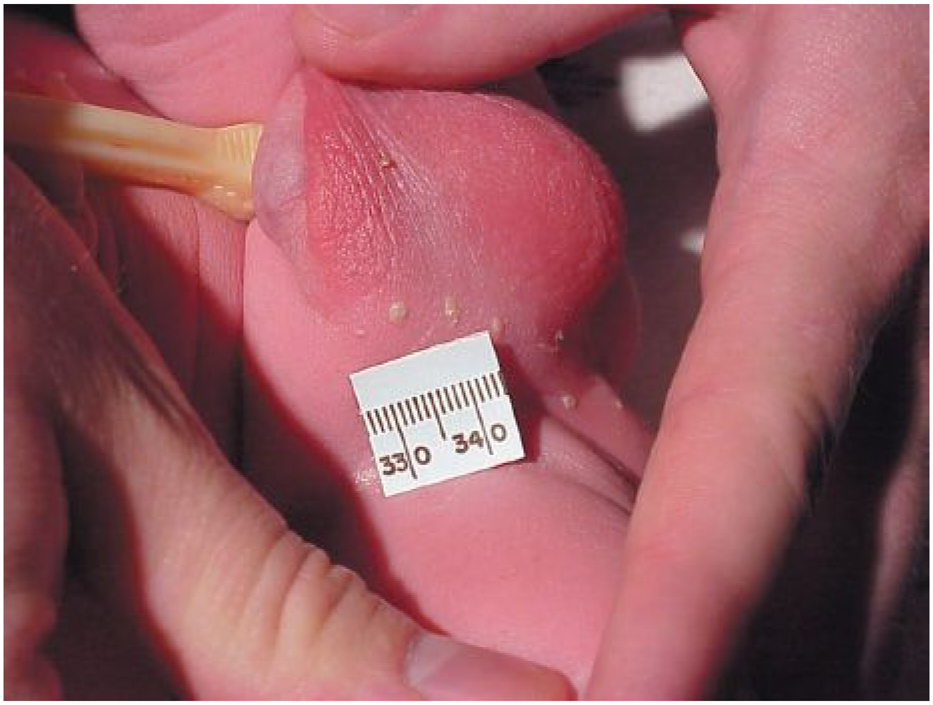

FIGURE 94-5 Transient neonatal pustular melanosis on scrotum of the same newborn with multiple pustules and no erythema. (*Used with permission from Dan Stulberg, MD.*)

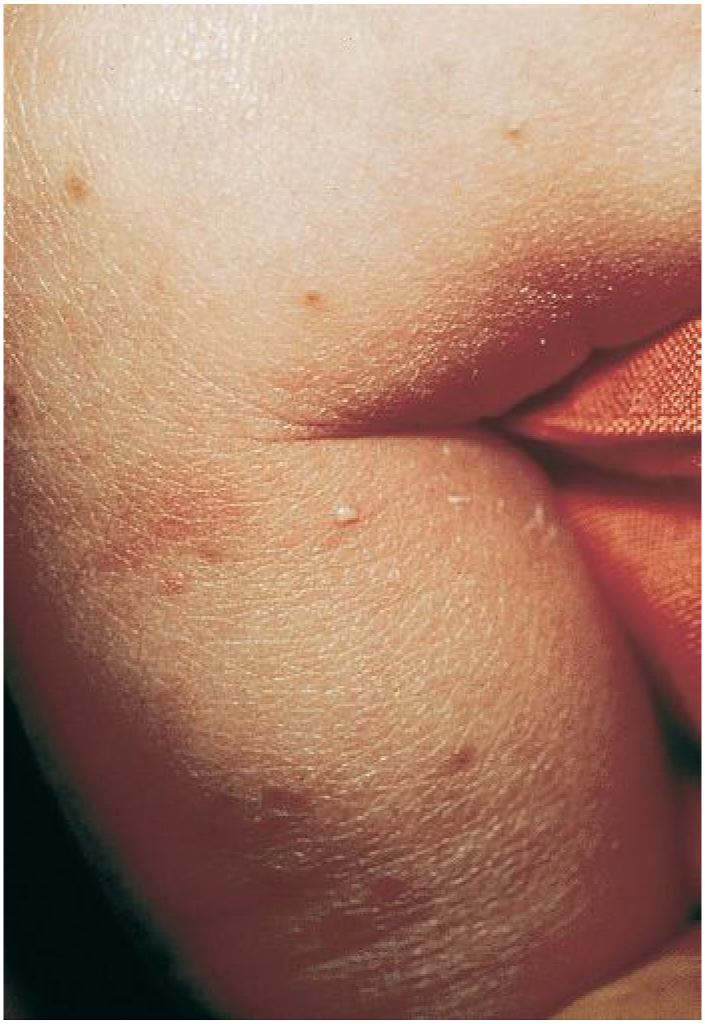

FIGURE 94-6 Transient neonatal pustular melanosis on the leg of a newborn. Note the hyperpigmented macules where the pustules have resolved. (*Used with permission Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas and Synopsis of Pediatric Dermatology, 2nd edition, FIGURE 1-8, McGraw-Hill, 2009*.)

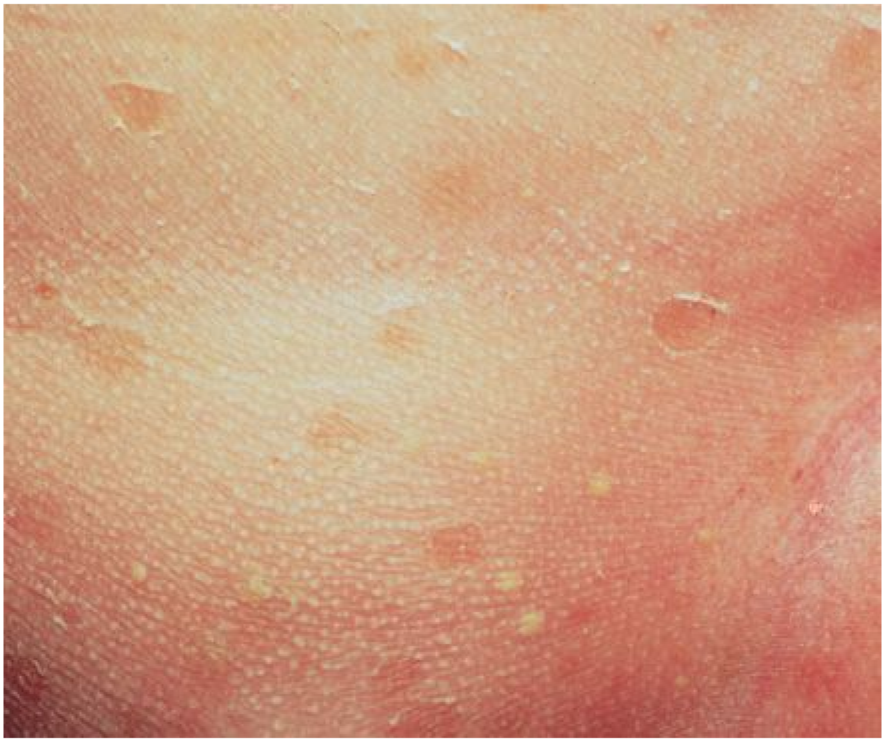

FIGURE 94-7 Transient neonatal pustular melanosis with a number of intact pustules and some hyperpigmented macules with a rim of scale where the previous pustules had ruptured. (*Used with permission from Weinberg SW, Prose NS, Kristal L, Color Atlas of Pediatric Dermatology, 4th edition, Figure 1-3, New York, NY: McGraw-Hill, 2008*.)

- The lesions probably evolve prenatally[7] and subsequently rupture postnatally in 1 to 2 days.
- They heal with hyperpigmented macules that fade by 3 months of age,[3] with lighter-skinned patients experiencing less hyperpigmentation (**Figures 94-6** and **94-7**).[7]
- Sometimes, the only evidence of the disease is the presence of small, brown macules with a rim of scale at birth (**Figure 94-7**).[7]

TYPICAL DISTRIBUTION

- Acropustulosis—Although most commonly found on the palms and soles, the pustules may also be found on the dorsal surfaces of the hands and feet and occasionally the face, scalp, and trunk.[5]

- TNPM—They are most common on the face and chin; however, they may also be present on the neck, chest, sacrum, abdomen, and thighs.[7]

LABORATORY TESTING

- Acropustulosis—A blood count is not needed but might reveal a slight leukocytosis and frequently an eosinophilia. Stained smears of the lesions are also not needed but will demonstrate many neutrophils,[1] with some eosinophils possible early in the course.[2]
- TNPM—A Wright stain will reveal numerous neutrophils and some eosinophils, with a negative Gram stain.[3] Blood counts should be normal and no laboratory workup is generally indicated.

DIFFERENTIAL DIAGNOSIS

- Scabies infestation—Characterized by pruritic, intraepidermal burrows and vesicles with scale and crust, most commonly found in the web spaces of the digits, wrists, elbow, genitals, and lower extremities. May be present in other family members, and is not present at birth. Microscopic examination of the scrapings of the burrows may reveal mites, feces, eggs, or all of the preceding.[3] Acropustulosis will be refractory to all scabies therapies but scabies therapy may appear to work because each episode of acropustulosis is self-limited (see Chapter 128, Scabies).
- Erythema toxicum neonatorum—Appearing on the neonate 1 to 2 days after birth, this disease of unknown etiology causes 2- to 3-cm diffuse blotchy macules with 1- to 4-mm central vesicles or pustules. The lesions, which spare the palms and soles, contain a predominance of eosinophils and resolve spontaneously by 2 weeks of age (see Chapter 92, Normal Skin Changes).[3]

- Impetigo—A superficial infection of the skin with vesicles, bullae, and honey-colored crusts, caused by group A *Streptococcus*, or *Staphylococcus aureus*. Gram stain and culture should be positive (see Chapter 99, Impetigo).[3]
- Cutaneous candidiasis—Slightly pruritic areas of intensely erythematous papules, pustules, and plaques, possibly with white exudate, found around the genitals and folds of skin. *Candida* yeast forms present on KOH preparation or culture (see Chapter 121, Candidiasis).[3]
- Varicella—Characteristic “dewdrops on a rose petal” that develop in childhood. Uniformly distributed, pruritic, with known contacts likely. Now less common because of immunization (see Chapter 108, Chickenpox).
- Herpes simplex infection—Grouped, painful vesicles on an erythematous base. May occur as gingivostomatitis in young children but rarely seen in the distribution of the pustular diseases of childhood. More likely to be vesicular rather than pustular (see Chapter 114, Herpes Simplex).
- Hand, foot, and mouth disease—This illness is caused by the coxsackievirus and other enteroviruses and produces papules and macules of the hands and feet that progress to flat vesicles before ulceration and eventual resolution. They typically affect the dorsum of the hands and feet and are also accompanied by painful oral lesions (see Chapter 113, Hand, Foot, and Mouth Disease).[3]
- Psoriasis, pustular—This severe form of psoriasis is rare in children and is characterized by the acute appearance of diffuse, painful, pinpoint pustules with high fever, fatigue, and anorexia (see Chapter 136, Psoriasis).[1]

MANAGEMENT

Acropustulosis:

- Corticosteroids (topical and oral) generally are not effective,[1] and not necessary in management.[5] SOR Ⓒ
- Oral antihistamines may be helpful in controlling pruritus.[1] SOR Ⓒ
- Pramoxine, lotion or cream, may be used topically for control of itching as it works by a different mechanism than antihistamines.[5] SOR Ⓒ
- Dapsone (1 to 2 mg/kg per day, maximum dose of 100 mg/day)[5] has been used with good results. However, the risks of complications are generally considered to outweigh the benefits, unless the pruritus is debilitating.[1] SOR Ⓒ

Transient neonatal pustular melanosis:

- No treatment is necessary. The parents should be reassured that the condition is benign and will resolve spontaneously with eventual normalization of any hyperpigmented macules.[6] SOR Ⓑ

PROGNOSIS

- Acropustulosis resolves spontaneously by 6 to 36 months of age.
- TNPM resolves spontaneously by 3 months of age.

FOLLOW-UP

Acropustulosis may require initial follow-up for control of symptoms and assurance of a stable disease course. With symptoms controlled, follow-up may be unnecessary as the child ages and the disease decreases in severity and frequency. If dapsone is prescribed, proper monitoring is indicated.

TNPM needs no specific follow-up other than normal well-child care.

PATIENT EDUCATION

Once other conditions have been ruled out, reassurance that these diseases are self-limited is the most important piece of information to communicate to the family.

95 DIAPER RASH AND PERIANAL DERMATITIS

Bridget Malit, MD
Julie Scott Taylor, MD, MSc
Richard P. Usatine, MD

PATIENT STORY

A 2-month-old baby girl was brought to the office with a severe diaper rash that was not getting better with Desitin. Upon examination, the physician noted a white coating on the tongue and buccal mucosa. The diaper area was red with skin erosions and satellite lesions (**Figure 95-1**). The whole picture is consistent with candidiasis of the mouth (thrush) and the diaper region. The child was treated with oral nystatin suspension and topical clotrimazole cream in the diaper area with good results.

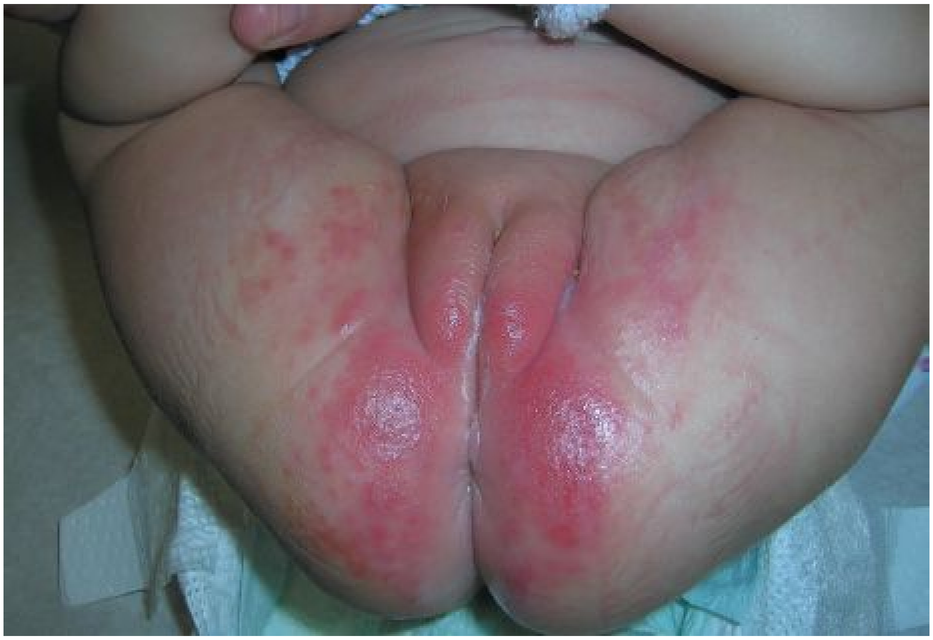

FIGURE 95-1 *Candida* diaper dermatitis in an infant who has oral thrush. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Diaper rash is a general term used to describe any type of red or inflammatory skin rash that is located in the diaper area.

SYNONYMS

Diaper dermatitis, napkin dermatitis.

EPIDEMIOLOGY

- Diaper dermatitis is the most common dermatitis of infancy.
- Variability in prevalence of 4 to 35 percent among children in their first 2 years of life in different studies.[1]
- Diaper rash is thought to be present in 25 percent of children presenting for outpatient visits.[2]
- No differences in prevalence between genders or among ethnic groups.
- One study showed an incidence of 19.4 percent in children ages 3 to 6 months.[1]
- Higher incidence among formula-fed compared with breastfed infants.[1]
- Condition typically begins around age 3 weeks, peaks at age 9 to 12 months, and then decreases with age until it resolves completely with toilet training.

- Individual episodes last from 1 day to 2 weeks.
- Aggravating factors include poor skin care, diarrhea, recent antibiotic use, and urinary tract abnormalities.
- Perianal streptococcal dermatitis occurs in children between 6 months and 10 years of age (**Figures 95-2** and **95-3**).

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary diaper dermatitis—An acute skin inflammation in the diaper area with a multifactorial etiology.[3] The main cause is irritation of thin skin as a result of prolonged contact with moisture including feces and urine. The multiple factors involved are:
  - Occlusion/lack of exposure to air.

  - Friction and mechanical trauma.
  - Local irritants—Fecal proteases and lipases.
  - Increased pH.
  - Maceration of the stratum corneum with loss of the protective barrier function of skin.
- Irritant diaper dermatitis (IDD) is a combination of intertrigo (wet skin damaged from chafing) and miliaria (heat rash) when eccrine glands become obstructed from excessive hydration. It is a noninfectious, nonallergic, often asymptomatic contact dermatitis that typically lasts for less than 3 days after a change in diaper practices.
- Candidal diaper dermatitis—Within 3 days, 45 to 75 percent of diaper rashes are colonized with *Candida albicans* of fecal origin.
- Bacterial diaper dermatitis may be a secondary infection caused by *Staphylococcus aureus* or *Streptococcus pyogenes*. Other common bacterial isolates include *Escherichia coli*, *Peptostreptococcus*, and *Bacteroides*. Usually occurs during the warm summer months.
- Perianal streptococcal dermatitis is caused by group A β-hemolytic streptococci (**Figures 95-2** and **95-3**).

RISK FACTORS

- Diarrhea.
- Formula-fed infants.
- Recent antibiotic use.
- Urinary tract abnormalities.
- Poor skin care.

DIAGNOSIS

CLINICAL FEATURES

- IDD begins with shiny erythema with or without scale and poorly demarcated margins on the convex skin surfaces in areas covered by diapers. Moderate cases can have papules, plaques, vesicles, and small superficial erosions that can progress to well-demarcated ulcerated nodules typically with sparing of skin folds (**Figure 95-4**).

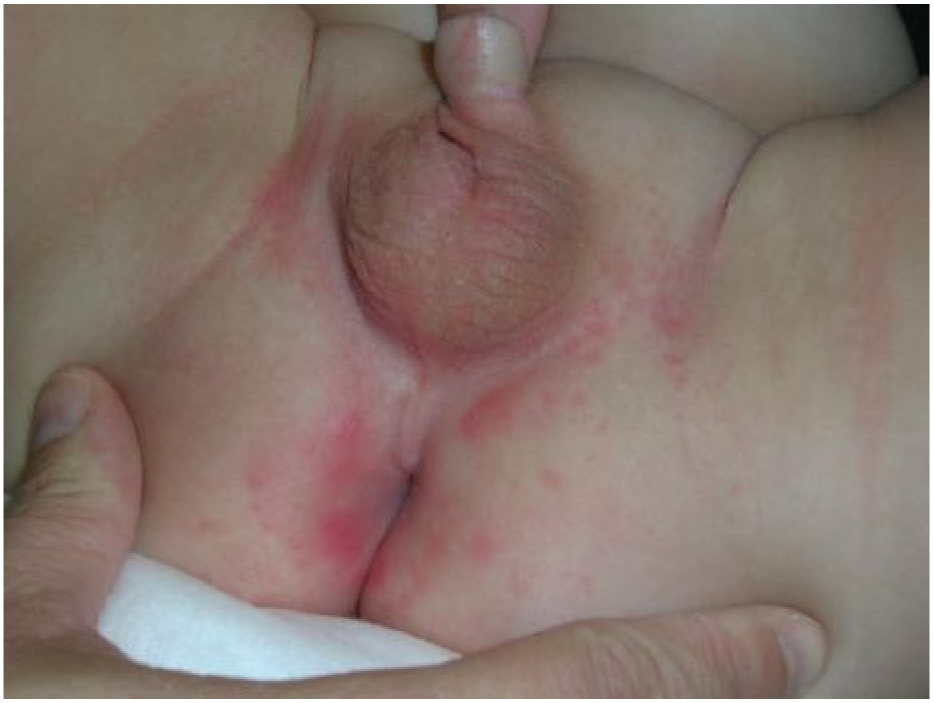

FIGURE 95-4 Irritant diaper dermatitis precipitated by diarrhea secondary to amoxicillin-clavulanate prescribed to treat otitis media. Note the absence of satellite lesions and how it spares the deep folds. (*Used with permission from Richard P. Usatine, MD.*)

- Pustules or papules beyond the rash border (called “satellite lesions”), involvement of the skin folds, and white scaling all indicate a fungal infection with *Candida* (**Figure 95-5**).

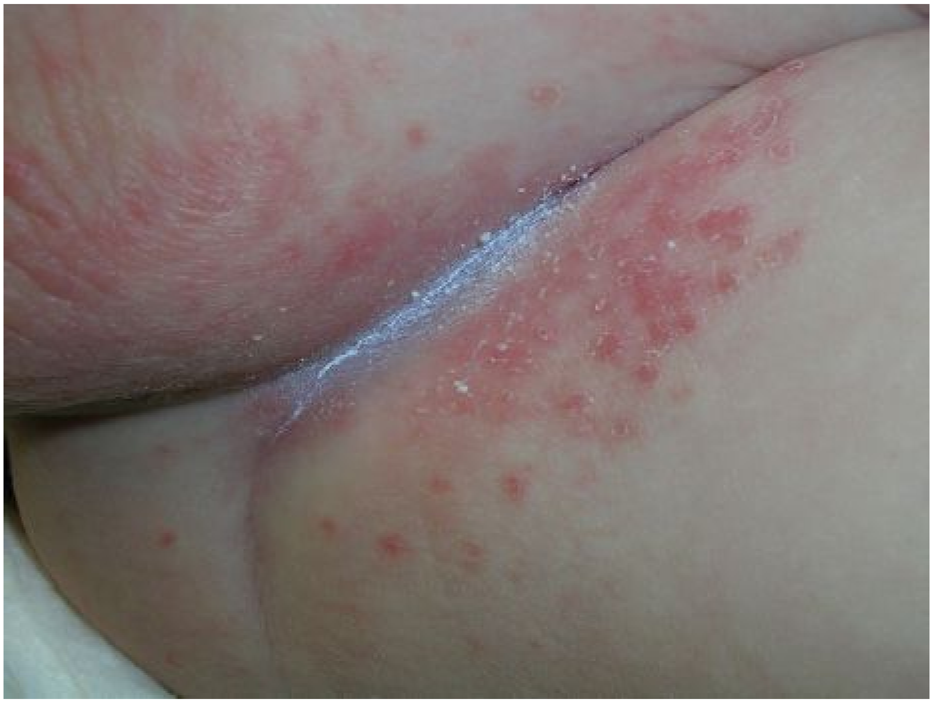

FIGURE 95-5 Close-up of a *Candida* diaper dermatitis in a 5-month-old infant. Note the superficial scaling around the satellite lesions. (*Used with permission from Richard P. Usatine, MD.*)

- Secondary bacterial infections can have redness, honey-colored crusting, swelling, red streaking, and/or purulent discharge. With impetigo in the diaper area, bullae are not usually intact but instead present as superficial erosions.
- Perianal streptococcal dermatitis is a bright red, sharply demarcated rash sometimes associated with blood-streaked stools (**Figure 95-2**).

TYPICAL DISTRIBUTION

Diaper dermatitis is primarily found on the buttocks, the genitalia, the mons pubis and lower abdomen, and the medial thighs. Be sure to evaluate for rashes outside of the diaper area as well. If *Candida* is suspected, the oropharynx should be inspected for signs of thrush, such as adherent white plaques on the mucosa. If seborrheic dermatitis is suspected, look at the scalp and face.

LABORATORY STUDIES

Clinical diagnosis is based primarily on the physical examination. Rarely indicated tests that are occasionally used in more complicated cases include potassium hydroxide preparation for fungal elements, mineral oil preparation for scabies, complete blood count with differential, zinc level, or skin biopsy (**Figure 95-6**). A rapid strep test can be used to diagnose perianal streptococcal dermatitis (**Figures 95-2** and **95-3**).

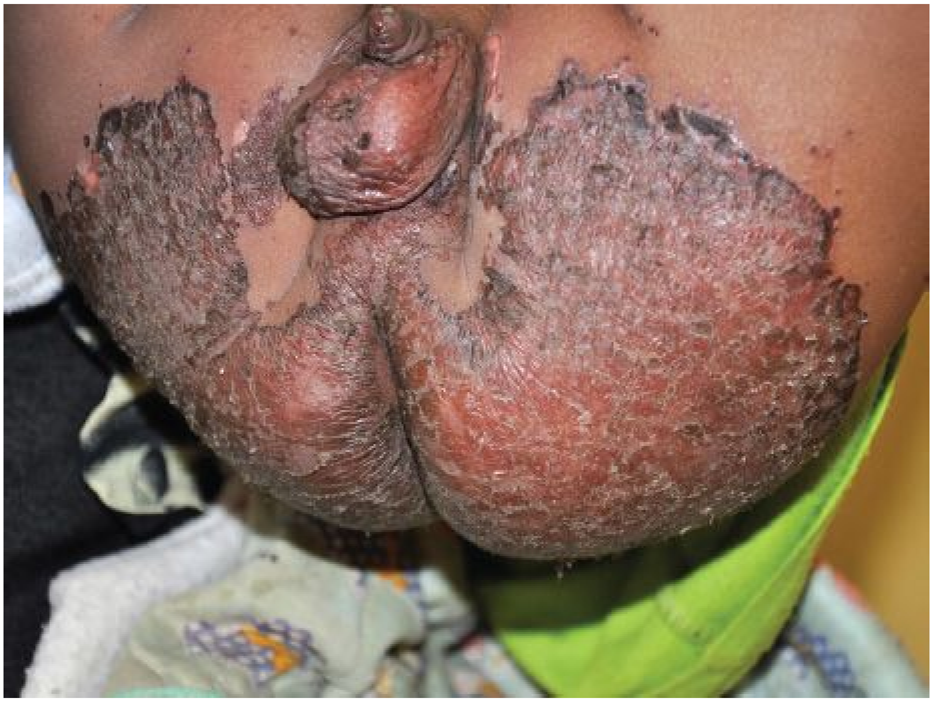

FIGURE 95-6 Acrodermatitis enteropathica caused by zinc deficiency. The child also had perioral dermatitis that appeared similar to the diaper dermatitis. (*Used with permission from Richard P. Usatine, MD.*)

DIFFERENTIAL DIAGNOSIS

There are three distinctive severe variants of irritant diaper dermatitis:

1. Erosive diaper dermatitis (dermatitis of Jacquet) is a severe, slow-healing diaper dermatitis in children with persistent diarrhea.[4] The

erosions that can lead to nodular lesions with heaped-up borders (**Figures 95-7** and **95-8**).

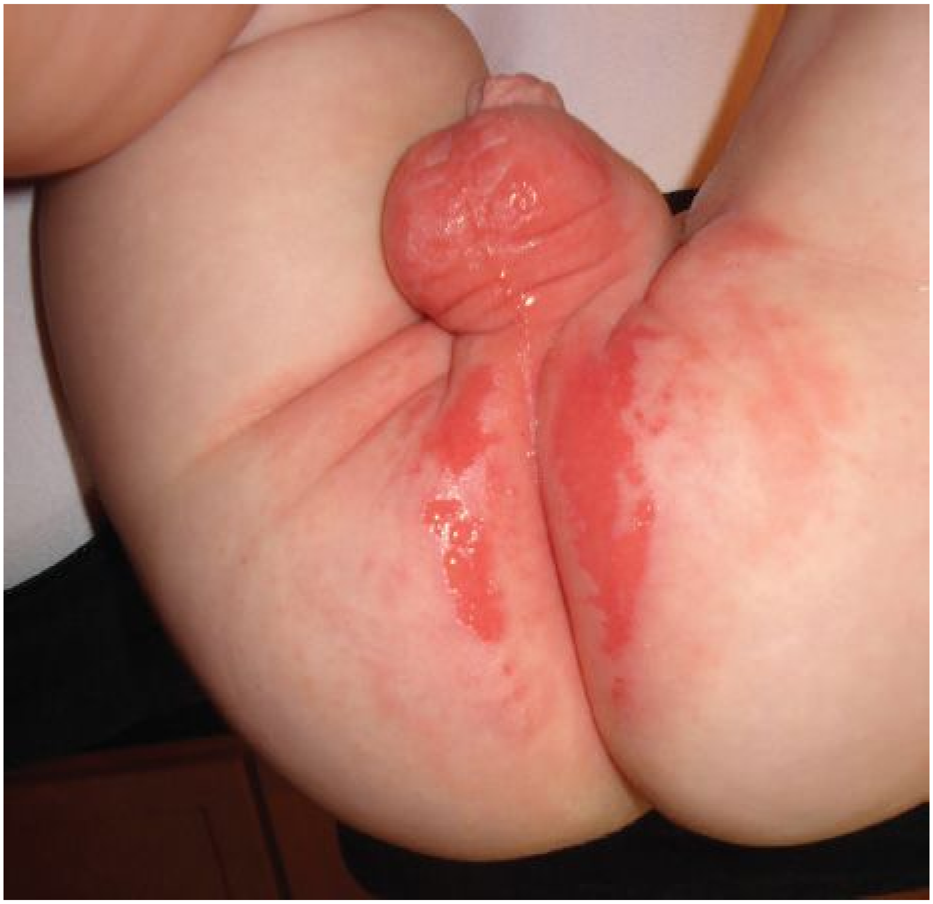

FIGURE 95-7 Erosive diaper dermatitis of Jacquet in an infant with prolonged diarrhea. Note the red erosions and the elevated nodules. (*Used with permission from Richard P. Usatine, MD.*)

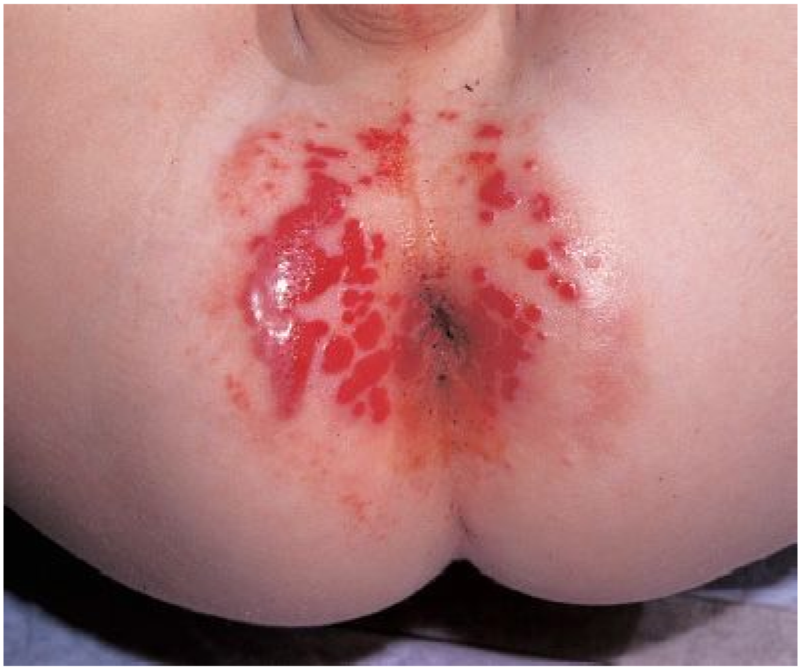

FIGURE 95-8 Erosive diaper dermatitis of Jacquet with bright red erythema, punched-out ulcers and elevated nodules with rolled borders. (*Used with permission from Weinberg SW, Prose NS, Kristal L, Color Atlas of Pediatric Dermatology, 4th edition, Figure 8-42, New York, NY: McGraw-Hill, 2008*.)

2. Granuloma gluteale infantum is a rare primary diaper dermatitis that presents with granulomatous nodules that can be large and raised with rolled margins (**Figure 95-9**). Contributing factors are inflammation, candida superinfection and high potency topical steroids. This can resolve over the course of a few months with good diaper care and removal of offending agents. It may leave residual scarring and hyperpigmentation.[5]
